PREFACE TO THE SEVENTH EDITION

This Manual of Pharmacology again aims to furnish a rather comprehensive outline of current knowledge and conceptions of drug actions, especially from the point of view of their practical importance in therapeutics and toxicology. The last few years have brought extensive developments in this field, partly foreshadowed in the preceding period, but greatly accelerated, intensified and focused by the demands of war. These have led to some profound changes in emphasis and attitude. The most impressive discoveries perhaps are in the field of the highly potent anti-infective agents which check the multiplication of parasites within the body by interfering with essential features of their nutritional metabolism. This has a vast practical importance as a new concept of "chemotherapy," because it utilizes actions specifically harmful to the invader, but not to the host; and it also promises a better insight into the nature of pharmacological actions, or at least into the metabolic phases of these, which have long baffled inquiry.

The entirely new "antibiotic" agents are not the only ones that have profited by intensified research activity. There have also been important advances in other selective anti-infective agents, the sulfonamides, the antimalarial drugs, the antimonial drugs, the insecticides and rodenticides, the auxins and weed killers. Vitamins and hormones have become more important as information has increased. The antithyroid drugs, anticonvulsants, antihistamine agents, anticholine-acetylases, folic acid, standardized curare, reliable digitoxin, "nitrogen mustards," and BAL have opened new fields of knowledge and use.

Drug therapy seems to stand in the doorway of a new era, or rather has already entered, and is perhaps tempted to close the door upon the old. However, the importance of many of the older drugs has not diminished. Anesthesia, systemic and local, is as vital as ever; so are analgetics and digitalis, and many others. But their use has been modified: Medication has become more "heroic." The prime essential of therapy has gradually changed from the aim of "do no harm" to that of "do some good" even if this involves a risk, provided that the probable benefit is materially greater than the probable injury. It is justified only if the risk is fully understood. This requires a thorough knowledge of the actions of these drugs, with all the light that pharmacology can throw upon them. It requires also a broad background of the actions of drugs in general. However, a number of the older drugs have declined in importance, some to the point of insignificance. Others are again on trial, and the information about them should be available without too much difficulty.

The revision of this book has aimed to strike a reasonable balance by subordinating what appears of questionable value, and eliminating what no longer has real importance or interest; stressing critical observations and subordinating speculations that lack factual foundation. The statements are supplemented by references to the authors where more information may be found if desired. The citations are primarily for this purpose rather than for assigning credit. The bibliography in the back of the volume has again been restricted to the last twenty years, or, rather, from January 1st, 1926; earlier authors may be generally located through the later papers, or through the Index of the Surgeon General's Library, or in the earlier editions of this book.

As in the former editions, the text in ordinary type presents the material that *all* students should aim to know; small type contains the data that would be consulted only as special occasion arises. The new arrangement in two columns should facilitate the search for information.

I would again thank the W. B. Saunders Company for careful composition and production of the book.

TORALD SOLLMANN

Cleveland, Ohio

CONTENTS

PHARMACOGNOSY 1

IMPORTANT PLANT CONSTITUENTS 1

PHARMACEUTIC STANDARDS 4

PHARMACEUTIC METHODS 5

Preparatory Processes, 5—Processes of Separation, 5—Pharmaceutic Assaying, 7.

CLASSES OF PHARMACEUTIC PREPARATIONS 7

Watery Solutions, 7—Alcoholic Solutions, 8—Preparations Made by Extraction, 8—Mixtures, 9—Semisolid Preparations, 10—Solid Preparations, 12—Dosage Forms, 12.

PRESCRIPTION WRITING 14

Prescription Latin, 16.

METROLOGY 17

COLORING AND FLAVORING 20

Coloring, 20—Flavoring, 20—Sweetening Agents, 21—Saccharin, 22—Aromatic Waters, Spirits, Oils and Tinctures, 22.

SOLUBILITIES 23

General Solubility of Commonly Used Salts in Water, 23.

INCOMPATIBILITY 24

ADMINISTRATION OF DRUGS 25

For Systemic Effects, 25—For Local Effects, 29—Conditions Influencing Absorption, 32—Excretion of Drugs, 35—Dosage (Posology), 35—Influence of Conditions on Drug Actions, 37—Manifestations of Pharmacologic Actions, 41—Classification of Drugs According to Selective Action, 43—The Chemical and Physical Basis of Pharmacology, 45.

OBJECTIVES OF TREATMENT 46

GENERAL TOXICOLOGY 48

Treatment of Poisoning, 49.

MEDICINAL FOODS 52

DIGESTIVE FERMENTS 53

PROTEIN FOODS AND AMINO ACIDS 54

CARBOHYDRATE FOODS 57

INSULIN 59

PHLORHIZIN 67

FATTY FOODS 68

CHOLESTEROL 69

LECITHINS 71

VITAMINS 72

Ascorbic Acid (Cevitamic Acid), 74—Vitamin A: The Antixerophthalmic Vitamin and Carotene, 79—Cod Liver Oil and Other Fish Liver Oils, 85—Vitamin B Complex, 86—Thiamine, 87—Nicotinic Acid, 93—Riboflavin, 94—Yeast, 97—Nucleotides, 98—Antisterility Vitamin E (Tocopherol), 98.

CHAULMOOGRA OIL 99

EMOLLIENTS, DEMULCENTS AND PROTECTIVES 101

Olive Oil and Other Bland Fatty Oils, 102—Soft Animal Fats, 103—Wool Fat: Lanolin, 103—Compound Ointment Bases, 103—Waxes and Waxlike Fats, 104—Petrolatum and Other Petroleum Products, 104—Glycerin, 106—Glyceryl Acetates, 107—Glycols, 107.

DEMULCENTS OR MUCILAGINOUS SUBSTANCES 108

Poultice Masses, 109—Indifferent Dusting Powders, Adsorbents, 110—Mechanical Protective Agents, 111.

LOCAL IRRITANTS, CORROSIVES AND ASTRINGENTS .. 113

General Toxicity of Irritants, 119—Fixed Alkalis, 121—Ammonia, 122—Soaps, 122—Sodium Morrhuate and Other Sclerosing Solutions, 124—Alkaline Sulfides and Polysulfides, 125—Hydrogen Sulfide, 125—Sulfur, 126—Sodium Thiosulfate, 128—Sodium Sulfite, 128—Sulfur Dioxide (Sulfurous Acid), 129—Sulfonated Petroleum Distillates, 129—Thiocresol and Thioglyceral, 130— Glutathione, 130—Caustic Acids, 130—The Local Actions of Metallic Salts, 132—Tannins and Vegetable Astringents, 134—Nonvolatile Organic Irritants: Cantharidin, 136—Poison Ivy, 138—Chrysarobin, 139—Pyrethrum Flowers ("Insect Powder"), 140—Miscellaneous Insecticides, 141—

Chlorinated Diphenyl Ether ("DDT"), 141—Irritant Volatile Oils, 142—Olfactory Stimulants, 143—Hysteric Sedatives or Antispasmodics, 143—Mustard Oil Group, 144—Onion and Garlic, 145—Oil of Turpentine, 145—Eucalyptol, 146—Rubefacient Volatile Oils, 146—Balsams and Aromatic Resins, 147—Diuretic Volatile Oils, 147—Volatile Oils and Oleoresins in Urethritis and Cystitis, 147—Ecbolic and Toxic Volatile Oils, 148.

Gaseous Irritants and "War Gases" 149

Chlorine Gas, 155—Chlorine Antiseptics, 155—Phosgene; Carbonyl Chloride; $COCl_2$, 157—Nitric Vapors, 158—Chlorarsines, 160—Dichlordiethylsulfide (Dichlorethylsulfide), Chloroethylamines, "Nitrogen Mustards," 160.

Photodynamic Actions 166

Stomachics 166

Carminatives, 166—Bitter Stomachics, 167—Astringent Bitters, 168—Aromatic Bitters, 169.

Cathartics 169

Irritant Cathartics, 173—Emodin or Anthraquinone Cathartics, 174—Cascara Sagrada, 175—Senna, 175—Rhubarb, 176—Aloe, 176—Phenolthalein, 177—Castor Oil, 177—Ricin, 178—Abrin, 179—Croton Oil, 179—Cathartic Resins, 179—Resin of Podophyllum, 180—Jalap, Scammonium, Ipomea, 180—Colocynth, Elaterin and Bryonia, 180.

Cholagogues and Choleretics 181

Bile, 182.

Anthelmintics 184

Carbon Tetrachloride, 186—Chenopodium Oil, 188—Thymol, 189—Aspidium or Male Fern, 191—Pelletierine, 191—Santonin, 192—Local Vermicides for Threadworms (Oxyuris), 193.

Convulsant Poisons 193

Strychnine and Nux Vomica, 193—Picrotoxin, 203—Synthetic Medullary Stimulants and Convulsants, 206—Camphor, 208—Menthol, 211—Bulbocapnine, 212.

Caffeine, Theobromine, Theophylline and other Methylxanthines 213

Adenyl Compounds 227

Opium, Morphine and Related Alkaloids 228

Opiate Addiction, 246—Demerol, 254—Papaverine and Perparine, 255—Protopine Group, 256.

Hydrastis 257

Cotarnine 258

Benzyl Benzoate and Other Benzyl Esters 258

Cannabis 259

Peyote (Mescal) 261

Harmaline Alkaloids 261

Local Anesthetics 262

Drugs Acting Peripherally on the Autonomic System 279

Autonomic Reactions of the Gastro-Intestinal Tract, 291—Of the Musculature of the Genito-Urinary Organs, 295—Of the Eye, 298—Of Bronchial Muscle, 300—Of the Heart, 302—Of the Blood Vessels, 303—Autonomic Poisons and Skeletal Muscle, 306—The Response of Secretions to Autonomic Poisons, 308.

Atropine 309

Hyoscyamine 321

Agaric Acid 321

Scopolamine (Hyoscine) 321

Pilocarpine 324

Physostigmine and Neostigmine (Prostigmine) 328

Di-Isopropyl Fluorophosphate, "DFP" 332

Choline and Choline Esters 333

Muscarine 339

Mushroom Poisoning, 340.

Quaternary Ammonium Bases 340

Nicotine 341

Tobacco as a Habit-Drug, 346.

Lobelia and Lobeline 352

Conium 353

Lathyrism 353

Gelsemium 353

Sparteine 353

GUANIDINE AND METHYLGUANIDINES............ 354

Synthalin, 356.

CURARE.. 356

EPINEPHRINE................................... 361

EPHEDRINE..................................... 379

AMPHETAMINE (BENZEDRINE).................... 383

NEO-SYNEPHRINE................................ 386

OXYTOCIC AGENTS............................... 389

Posterior Pituitary Gland, 390—Ergot and Its Alkaloids, 397—Oxytocics of Minor Importance, 405.

UTERINE SEDATIVES AND HEMOSTATICS........... 405

Viburnums, 406.

HISTAMINE...................................... 406

PARAPHENYLENEDIAMINE......................... 411

REACTIONS RESEMBLING THOSE OF HISTAMINE.... 413

Secretin, 413—Proteases ("Peptone"), 413—Tissue Extracts with Histamine-like Actions, 415.

ALLERGIC PHENOMENA............................ 415

True Anaphylaxis, 416—Anaphylactoid Hypersensitivity, 419—Drug Idiosyncrasies, 419—"Reactions" to Intravenous Injections, 420—Normal Serum, 420—Serum Reactions, 421.

SPECIFIC SERUMS, VACCINES AND ALLERGIC PREPARATIONS................................ 422

HISTAMINE ANTAGONISTS........................ 422

BLOOD COAGULATION............................ 423

Agents Promoting Blood Coagulation, 424—Agents that Impede Blood Coagulation, 425.

A Manual of
PHARMACOLOGY

PHARMACOGNOSY

Pharmacognosy (the knowledge of drugs) deals with the origin, anatomical structure and chemical composition of crude drugs. The obsolescent title "Materia Medica" includes also the actions and uses, now generally called "Pharmacology."

Drugs are derived from the three natural kingdoms, the animal, vegetable and mineral and from the "fourth estate" of synthetic chemistry. Natural plants furnish the greatest variety of chemical substances and, therefore, the greatest number of drugs.

Vegetable Drugs.—The active principles are often diffused throughout the plant, but they are generally more abundant in the part which is used as medicine. The following are technical names of the more important parts, with some characteristic examples:

Root (*Radix*): The underground part of the plant, which is generally devoid of chlorophyl (green coloring matter) and does not produce leaves (Dandelion, Belladonna, Ipecac, Rhubarb). **Tuberous Roots:** Roots swollen with accumulation of reserve food material (Sweet Potato, Aconite, Jalap). They are often called *tubers*; but true tubers (Potato) are similar formations on rhizomes. **Corm:** A thickened underground stem (Colchicum). **Bulb:** Very fleshy, closely crowded leaves, enfolding the underground base of the stem (Onion, Squill). **Rhizome:** Underground stems which bear leaves (Podophyllum, Hydrastis, Ginger, Aspidium). **Wood** (*Lignum*): The wood of trees, in fragments, chips or coarse powder (Quassia, Hematoxylon, Sandalwood). **Bark** (*Cortex*): The outer layer of the stem (Cinchona, Cascara, Wild Cherry) or of the root (Sassafras, Cotton-root). Sometimes only the inner bark is collected (Ceylon Cinnamon, Elm). **Leaves** (*Folia*): Digitalis, Uva Ursi, Belladonna, Senna. **Herb** (*Herba or Species*): The smaller leafy and flowering or fruiting stems (Peppermint, Cannabis Indica, Savin). **Flowers** (*Flores*): Chamomile, Arnica. Unexpanded flowers are: Cloves, Santonica. **Fruit** (*Fructus*): The ripened ovary, with any persistent parts of the flower, containing the seeds (Pepper, Hops, Colocynth, Anise). **Seed** (*Semen*): The essential part of the fruit (Nux Vomica, Strophanthus, Physostigma, Mustard, Linseed).

The **microscopic structure of plants** differs from the animal cells, especially by the thick cell walls, and by the frequent presence of protoplasmic enclosures, starch, fats, calcium oxalate, protein crystals, etc. The cell walls are chiefly responsible for the shape and physical properties of the cell. They consist primarily of cellulose, variously modified by certain allied substances (lignin in wood, suberin in cork). These are insoluble in ordinary solvents and in the alimentary canal of man. The processes of pharmacy consist largely in separating the active constituents from this inactive material.

IMPORTANT PLANT CONSTITUENTS

These belong to the chemical groups of proteins, fats, carbohydrates, tannins, resins, alkaloids, glucosides, acids, terpenes and inorganic salts. Plants of the same family generally produce substances with similar chemical structure and actions (Jussieu), but there are many exceptions, and indeed a single plant may form substances of various actions.

Cellulose is found in the cell walls. It exists in almost pure form in cotton. It is an isomer of starch. It is insoluble in all ordinary solvents, and is not affected by boiling water. It dissolves without change in Schweitzer's reagent (ammoniated solution of copper sulphate). In older cells it is often modified by the introduction of allied molecules: *wood* (lignin) or *cork* (suberin). Cork is very resistant to reagents and impermeable to water, and hence protects the plant against evaporation and chemic injury. Cellulose may undergo a retrograde metamorphosis into gum or pectin.

Starch $(C_6H_{10}O_5)_n$ is produced as one of the first stages in the assimilation of CO_2. The starch molecule probably consists of a long chain of monosaccharide molecules linked by primary bonds (Staudinger and Hausmann; W. Z. Hassid, 1943). It has two chemically distinct carbohydrate components, amylose and amylopectin (W. Z. Hassid, 1945). It occurs in the form of granules, usually showing a laminated structure around a center (hilum). The character of this lamination, as well as the average shape and size of the granules, is important in distinguishing between different plants.

Starch can be recognized by the blue color which it gives with iodine. It is insoluble in all ordinary solvents, but swells with boiling water and forms a peculiar colloidal solution (paste), which is precipitated by alcohol. It is hydrolyzed by acids and by diastases, yielding dextrin (which colors red-brown with iodine) and then glucose.

Gums are colloidal carbohydrates, swelling or dissolving in water to viscous adhesive fluids (mucilages or pastes). They are precipitated by alcohol. They are formed in the plant by the transformation of cellulose and cell contents, especially as the result of pathologic processes. They yield glucose when hydrolyzed by acids. *Hemicellulose,* which occurs in seaweed (agar), lichens and fungi, is more difficult to hydrolyze. *Pectins* are related substances, occurring in fruits and causing the boiled fruits to set into jelly. Gums and pectins do not color with iodine; they reduce copper only after inversion.

Sugars are carbohydrates, of more or less sweet taste, generally freely soluble in water, sparingly soluble in alcohol, insoluble in fat solvents. Some reduce copper directly, others only after hydrolysis. They contain an asymmetric carbon, and therefore rotate polarized light. The more important types are: *Glucose* (*Dextrose*) and *Levulose,* $C_6H_{12}O_6$; *Maltose* and *Saccharose,* $C_{12}H_{22}O_{11}$; and *Mannite,* $C_6H_{14}O_6$.

Glycosides are ester-like combinations of sugars with various other substances (genins), frequently with phenols. Acids or appropriate enzymes hydrolyze them into sugar and the other substances. Many do not contain nitrogen. Most glycosides are neutral or weakly acid; a few are alkaloidal. They are widely distributed in plants, and include the digitalis constituents, saponins, tannins, etc. Their pharmacologic actions are generally inherent in the genin, the sugars modifying the penetration, persistence and reactivity.

Saponins are also widely distributed. They are so called because they foam like soap, emulsify oils and lake red blood corpuscles. They are neutral, non-nitrogenous substances related to bile acids in structure and action. Some are glucosides. Those which are markedly toxic are called *sapotoxins,* but they are generally not very poisonous by mouth, because they are poorly absorbed.

Tannins are a group of phenol derivatives, distinguished by giving a bluish or greenish color with ferric salts. The greater number also form insoluble compounds with other metallic salts, with alkaloids, proteins, etc. This precipitation leads to astringent action. Tannins occur in many plants, especially in the leaves and bark, and in pathologic formations (nutgalls). They are non-nitrogenous; some are glucosides. They are soluble in water and in alcohol; but since they form insoluble compounds with many substances, they often occur in plants in granular form.

Tannins are easily decomposed into resin-like substances called *phlobaphenes.* These exist naturally in plants, but are usually formed as decomposition products in extractions. They are dark-colored, soluble in alcohol and in alkaline liquids, insoluble in water. Tannins and phlobaphenes, as well as most other plant constituents, are easily converted into a group of substances called *humins.* These do not exist in living tissues, and arise on the death of the cells, by the action of air and moisture. They cause the brown color which plants assume on drying; they are also present in the brown bark. Tannins, phlobaphenes and humins form a series without sharp demarcation. They are rather resistant to the action of bacteria and in this way protect plants against putrefaction.

Alkaloids comprise many of the most active and important plant constituents. They may be defined as natural nitrogenous organic bases (generally tertiary amines); *i. e.,* they are organic substances, containing nitrogen, of basic character, combining with acids without the elimination of hydrogen, forming well-defined and usually crystalline salts. The salts with halogens are called hydrochlorides, hydrobromides, etc. (not chlorides, etc.). The names of alkaloids are spelled with a final *e,* to distinguish them from neutral principles (thus morph*ine,* an alkaloid; sali*cin,* a glucoside).

The *discovery of the alkaloids* is an achievement of the 19th century (morphine, by Sertuerner, 1805 to 1817; strychnine, 1818; quinine and caffeine, 1820; nicotine, 1829; atropine, 1833). Alkaloids are of common *occurrence* in the higher plants, the same plant usually containing several alkaloids, which are often formed from one another. They may be found in all parts of the plants, but sometimes they are strictly localized in certain portions. They are probably metabolic waste products (F. A. Henry, 1927). The alkaloidal content varies according to the climate, culture and other conditions. Individual plants also show considerable variations. They can be improved by selected breeding (Sievers, 1913, 1916). Alkaloids are also formed by bacteria ("ptomaines") and molds. The active amines of animals, such as epinephrine, may be considered as alkaloids.

Properties of Alkaloids.—Most alkaloids have a bitter taste, alkalinity to litmus, nitrogen reaction; generally profound physiologic action, without postmortem lesions; some alkaloids contain oxygen; others do not. Those containing oxygen are solid and comparatively nonvolatile; those free from oxygen (nicotine and coniine) are liquid and volatile. Free alkaloids are *soluble* in ether, chloroform, and oils, much less soluble in alcohol, and comparatively insoluble in water. Alkaloidal salts have the opposite solubility: They are soluble in water and alcohol, insoluble in chloroform and ether. This reversal of solubility is used to isolate alkaloids from crude drugs and mixtures. Alkaloidal salts are *precipitated* by iodine, mercuric-potassic iodide (Mayer's reagent); phospho-molybdic acid; picric acid; gold chloride, platinic chloride, etc.; some precipitate mercuric chloride, potassium bichromate, tannin, etc. Many alkaloids give characteristic *colors* with concentrated acids, with or without the addition of oxidizing or reducing agents. The chemical *structure* of many alkaloids is well understood; others are still obscure. The greater number are fairly complex derivatives of *pyridine* (coniine, nicotine); *pyrrolidine* (cocaine, atropine); *quinoline* (quinine, cinchonine); *isoquinoline* (hydrastine, narcotine, cotarnine, berberine); *morpholine* or *phenanthrene* (morphine, codeine, thebaine).

Neutral or bitter principles are a heterogeneous group of substances which have not been assigned to other classes. They usually have a bitter or sharp taste, and are generally crystalline and non-nitrogenous. A number are *lactones*.

Resins are also a heterogeneous group, including solid, nonvolatile, amorphous substances of obscure composition, commonly non-nitrogenous. Their distinguishing character is insolubility in water and solubility in alcohol, most fat solvents (except petroleum ether) and strong alkalis. The resins are often contained in special vessels, from which they exude after incising the plant. When the resins occur mixed with essential oils, they are *natural oleoresins;* when mixed with gums, *gum-resins.* If they contain aromatic acids (cinnamomic, benzoic, etc.) or essential oils, they are called *balsams. Resinoids* are artificially isolated principles soluble in alcohol and insoluble in water. They are generally mixtures, often containing true resins.

Volatile oils (essential oils) are odorous principles, of the physical characters of fatty oils, except that they are volatile and soluble in alcohol. Chemically, they are mixtures of esters, aldehydes, alcohols, ketones and especially terpenes (Kremers, 1898). The constituents may separate on cooling, the liquid part being called *eleoptene,* the solid *stearoptene. Camphors* are analogous substances, but solid at ordinary temperature. *Rubber* (caoutchouc and gutta-percha) is related to the terpenes. Plants also contain many other alcohols, aldehydes, organic acids, aromatic derivatives, etc.

Fats and fixed oils (esters of fatty acids and glycerin) are abundant, especially in seeds, occurring within the cells as drops or crystals. The fats are greasy liquids or soft solids; when heated, they undergo decomposition, denoted by acrid acroleine vapors. They are insoluble in water or glycerin, sparingly soluble in alcohol, and freely soluble in ether, chloroform, benzine (petroleum ether), carbon disulfide, turpentine, etc. (*fat solvents*).

Waxes are more solid substances with the solubility characters of fats. They are esters of fatty acids with alcohols other than glycerin.

Proteins are represented in all vegetable cells, but are especially abundant in seeds, sometimes as crystals (aleuron). Several classes of the proteins are peculiar to plants.

Chlorophyl, the green pigment of plants, is insoluble in water, soluble in alcohol and fat solvents. It is allied to blood pigment, but contains magnesium instead of iron. It is readily changed and discolored by reagents.

The chlorophyl occurs in the cells as granules (chloroplasts), made up of a colorless, spongy, protein groundwork, containing in its meshes the chlorophyl pigment, which consists of a mixture of green and yellow colors (chlorophyl and xanthophyl). Chlorophyl is found mainly in the higher plants, and serves in the presence of light to assimilate CO_2 and to form starch. During drying, especially if this occurs slowly, the pigment is acted on by acids, etc., developed under these conditions, and undergoes various changes, usually becoming brown.

Other Pigments.—Plants are rich in colors belonging to various chemic groups, often unidentified. Many alter with changes of reaction. The brown coloring matter of barks, etc., is allied to the tannins and phlobaphenes.

Enzymes of many kinds occur in different plants, a few being used in medicine.

Extractive matter is a term applied to the mixture of unidentified organic constituents which remains as a smeary mass after evaporating extracts from which the important constituents have been removed.

Mineral salts are fairly abundant in plants, constituting the ash which remains on incineration. Ca and K are especially important.

◆

PHARMACEUTIC STANDARDS

Pharmacy deals with the preparation and compounding of drugs for the purpose of administration. It has for its *objects* the separation of the active principles of drugs, their combination, and their presentation in acceptable form.

Official Drugs.—Civilized countries have standards established by law, to which drugs and preparations in the shops must conform. The book in which these standards are published is usually called the *Pharmacopeia.* Preparations listed in these official books are termed "official." A pharmacopeia, therefore, is an official book of standards for official drugs. The "*United States Pharmacopoeia*" and the "*National Formulary*" are now revised every five years. The current editions are designated as "*U.S.P. XIII*" and as "*N.F. VIII.*" The standards of the U.S.P. apply solely to articles intended for medicinal use.

International Uniformity.—The first effective step in this direction was taken by the Brussels Conference of 1906, the "International Conference for the Unification of the Formulas for Potent Medicines." This conference drew up a list of the potent drugs for which uniformity was most important, and established standards of strength for them and their preparations. These have been adopted essentially by most of the civilized nations. The standards of the Brussels Conference of 1925 are designated as "P.I." (Protocol International) by the U.S.P.

Scope of the Pharmacopeias.—These usually aim to include only "standard drugs," *i. e.,* those of established value. There is a healthy tendency to restrict the admission of complex mixtures.

Galenic Preparations.—"Galenicals" are, strictly speaking, medicines prepared after the formulas of Galen. The term is now used to designate preparations containing one or several organic ingredients, as contrasted with pure chemic substances.

Proprietary Drugs are protected by monopoly, generally by patent or trademark, or by secrecy. Those concerning which information is freely available are generally official in the U.S.P. if their value has been sufficiently established, or in "N.N.R." (see below) provided that they are marketed under proper conditions.

"**Patent medicines**" is a term applied to proprietary drugs that are advertised, directly or indirectly, to the laity. They are not usually patented, as the name would imply; most manufacturers prefer to rely upon secrecy to impose on the public. The medical profession is generally opposed to patent medicines as a class, and to lay advertising in particular. "The impossibility of controlling the irresponsible claims which are usually made in advertisements to the public, the well-known dangers of suggesting by descriptions of symptoms to the minds of the people that they are suffering from the many diseases described, the dangers of the unconscious and innocent formation of a drug habit, and the evils of harmful self-medication, including the dangers of the spread of many infectious and contagious diseases when hidden from the physician, and similar well-known considerations, are the reasons for discouraging, in the interest, and for the safety, of the public, this reprehensible form of exploitation" (N.N.R.).

The Federal Food and Drug Act, which went into full effect in 1940, greatly improved the situation by giving to the Food and Drug Administration broad powers to enforce the pure food and drug laws, and to establish standards for drugs not in the U.S.P. or N.F. No new drug may be introduced until its safety has been demonstrated to the satisfaction of the Administration; and if it is not sufficiently safe it may not be sold directly to the laity. Labels must bear adequate directions for use and warnings against abuse. The active ingredients must be so designated. The Food and Drug Act, however, does not pass on the value of drugs except that they must not be "*misbranded*" by making false claims on the package. Other advertising is under the jurisdiction of the Interstate Commerce Commission.

"The United States Pharmacopoeia" was first published in 1820. It is revised at five year intervals by a Pharmacopoeial Revision Committee, appointed by the United States Pharmacopoeial Convention, which consists of delegates from pharmaceutical and medical organizations. The current committee of revision consists of fifty members, headed by an executive committee. The "U.S.P. Vitamin Advisory Board," organized at the time of the eleventh revision, establishes standards for vitamin preparations, while a similar board, the "U.S.P. Anti-Anemia Preparations Advisory Board," organized at the same time, establishes standards for anti-anemia preparations. The standards of the Permanent Commission on Biological Standardization of the League of Nations Health Organization and the National Institute for Medical Research, of London, England, for vitamins and for digitalis have been the standards of comparison for similar "U.S.P. Reference Standards" now distributed in the United States by the U.S.P. Board of Trustees. Other "U.S.P. Reference Standards" are a "Reference Pepsin" and a "Reference Ergotoxine Ethanesulfonate." The Pharmacopoeial Board also distributes other International Biological Standards as a representative of the League of Nations Committee. **"The British Pharmacopoeia,"** the B.P., published by the General Medical Council, resembles the U.S.P. in scope and arrangement.

"New and Nonofficial Remedies" (N.N.R.) contains descriptions of the characters, actions and uses of those proprietary drugs that are marketed in a proper manner. It is issued by the American Medical Association and revised annually by its Council on Pharmacy and Chemistry. **"National Formulary"** (N.F.) is a collection of formulas for less important preparations, issued by the American Pharmaceutical Association. It is also a legal standard. **"Dispensatories"** are commentaries which enlarge and explain the official texts, and generally also describe unofficial preparations. The U.S. Dispensatory is principally used in the United States. The British Pharmaceutical Codex (B.P.C.) is a similar work. **"Useful Drugs"** is a small manual issued by the American Medical Association which contains only the most useful drugs with such information as is of especial interest to physicians. **"Physicians' Epitome of U.S.P. and N.F.,"** another A.M.A. publication, gives brief abstracts of all U.S.P. and N.F. preparations.

PHARMACEUTIC METHODS

These are adapted to the physical and chemic nature of the crude drug and to the character of the desired product. They may be roughly classified into *general methods* used in the making of many different preparations, and *special methods* used in a limited number. The methods may be discussed in the order in which they are usually applied to the drug.

PREPARATORY PROCESSES

Desiccation or drying is usually the first operation to which the crude drugs are subjected after their collection. It reduces the bulk, assists preservation and facilitates comminution.

Drying was formerly effected by spreading or hanging the drugs in airy lofts. At present they are usually placed on perforated trays in special drying closets and heated artificially (steam, etc.). They are often cut into smaller pieces before this drying. The degree of heat must not be so high as to injure the sometimes unstable ingredients. The U.S.P. designates 32° to 39° C. as "gentle heat."

Comminution, or reducing of the substance to smaller pieces, is usually done by machinery.

Crude vegetable drugs are first sliced or chopped, often before drying. They are then bruised by pounding in a mortar and finally ground, the finer grades of powders often several times, the grinding surfaces being brought closer together each time. The mills for this purpose employ the same general principles as flouring mills. On the small scale, drug mills, constructed more or less on the principle of the coffee mill, are used for fibrous, and mortar and pestle for friable, drugs. Mortars are made of iron, wedgewood, porcelain, and glass.

Pulverization is comminution to a powder. *Trituration* is a process of rubbing (not pounding) a substance to a powder in a mortar.

Fineness of Powder.—It is often essential to use a powder of a certain degree of fineness, especially for percolation. The powders are therefore sifted, and are classified according to the size of the meshes of the sieve through which they pass, thus: No. 80 = 80 meshes to linear inch, very fine. No. 60 = 60 meshes to linear inch, fine. No. 40 = moderately coarse. No. 20 = coarse. Since the different structures in a crude drug do not powder with equal readiness, it is necessary that the whole of the drug to be powdered should be passed through the sieve.

Levigation is employed to obtain very fine powders of insoluble substances by making them into a thick paste with water, and rubbing this between polished slabs. *Elutriation* is used to separate fine insoluble powders by suspending them in water and decanting.

PROCESSES OF SEPARATION

Three methods are available for the separation of the desired ingredients from inert material: Volatile constituents may be separated by the *application of heat*—distillation and sublimation. If they are not volatile, the separation is usually affected by exposing the drug to the *action of a solvent* in which the desired principles are soluble, and the undesired constituents are insoluble. In some cases mechanical means are sufficient, as in the separation of fixed oils from seeds, etc., by *pressure.*

Desiccation (drying), **torrefaction** (roasting), **carbonization, ignition** drive off some volatile constituent from a solid, the fixed residue being the portion desired.

Evaporation consists in vaporizing the solvent from a solution, the object being the concentration of the dissolved substance.

Sublimation separates a volatile from a nonvolatile solid by heat.

Distillation separates a volatile liquid from a less volatile liquid or solid.

Solution incorporates a solid into a liquid in a state of "molecular subdivision." Applied to crude drugs, it separates the active ingredients from the insoluble inert materials.

Maceration, the simpler process, consists in leaving the solvent in contact with the drug under suitable conditions for a sufficient length of time.

When maceration alone is employed, a given quantity of the drug is put in a suitable vessel with a definite proportion of the solvent (called *menstruum*) and left a certain time, usually a week or two. The liquid is then strained off, the residue (*marc*) is expressed and the mixed extract filtered. Maceration offers the advantages of simplicity and constant results. Its main disadvantages are the required time and the loss of the extract retained in the insoluble residue.

Percolation consists in passing a solvent through a thick layer of the powder to be exhausted. This exposes a large surface of the latter; the nearly saturated solvent flows off and fresh unsaturated portions continuously replace it, insuring very rapid solution. The powder is packed into a tall vessel, with an opening at the bottom, and the solvent trickles through it. The process is usually preceded by a short maceration.

The powder (the fineness of which depends upon the nature of the drug and is directed for each case by the Pharmacopoeia) is moistened in a jar with some of the menstruum. This moistening is for the purpose of swelling the drug, for if this took place in the percolator, the drug would become so firmly impacted that the menstruum could not penetrate through it. The moistened powder is then passed through a coarse sieve and transferred to the prepared percolator, which it should fill about two-thirds. The firmness of the packing is important; if it is not firm enough, the menstruum runs through too rapidly and the percolate will consequently be weak. If too firm, it can not run at all. Drugs in coarse powder should be packed more firmly than fine powders. An alcoholic menstruum requires firmer packing than a watery one. The packing being completed, the menstruum is poured on until it stands an inch or two above the drug; the percolator is then covered and set aside for maceration for a specified time, the tube being raised so that no liquid flows out. When the time of maceration is completed, the tube is lowered, and fixed at such a level that the outflow occurs at the rate of 2 to 15 drops per minute. New menstruum is poured on as the old flows out. A layer of liquid must be maintained above the powder, else cracks may appear and necessitate repacking. *The choice of a menstruum* may be determined by the nature of the constituents, so as to extract all the active ingredients and the minimum of inactive. Alkaloids and resins require strong alcohol; gums, weak alcohol; licorice, alkaline alcohol; sanguinaria and ergot, acidified alcohol; gentian and quassia, water plus alcohol enough to keep.

Pharmaceutic Solvents.—The most useful are the following:

Water or glycerin dissolves salts (including those of alkaloids), sugar, gums, tannin, acids, alkalis, etc. *Dilute acetic acid,* especially for alkaloids. *Alcohol* dissolves alkaloidal salts, neutral principles, resins, volatile oils; precipitates gums and most inorganic salts. Ether, chloroform, acetone dissolve free alkaloids, neutral principles, resins, volatile and fixed oils, and fats. *Petroleum benzene* has the solvent properties of the preceding, except resins. *Aromatic spirits of ammonia* dissolves resins and organic acids.

Expression separates a liquid from a solid by pressure. Its principal employment in pharmacy is for the recovery of tinctures from the "marc," *i. e.,* the liquid retained by the drug residue after maceration and percolation. It is also a process of separating fixed oils. The drug is put in a coarse strong cloth and subjected to pressure in a press.

Straining or **colation** separates coarse solid particles from a liquid by pouring it through a cloth or strainer.

Filtration separates solid particles (fine or coarse) from a liquid by pouring it through a finely porous material, such as filter paper.

Dialysis may be used to separate crystalloids (alkaloids, salts, etc.) from colloids (extractives).

Decolorization may sometimes be accomplished by choosing appropriate solvents; or the solution is filtered through activated charcoal. This may retain some of the active constituents as well as the coloring matter.

Clarification removes suspended solids: when filtration does not suffice, it is accomplished by agitating the mixture with insoluble powders (talcum, phosphate of lime, aluminum hydrate) or by adding egg albumen and boiling; or by centrifugation.

Sterilization, the destruction of bacteria and their spores, employs the various customary methods.

Solutions that are not readily decomposed by heat may be boiled in a current of steam for one-half or, better, one hour. *Solutions that are readily decomposed* by heat are either prepared aseptically or filtered through porcelain. *Emulsions in glycerin or oil* are prepared aseptically, the solvent being first sterilized by heat.

PHARMACEUTIC ASSAYING

Different samples of vegetable drugs may vary widely in active constituents. These variations are especially undesirable when they occur in potent, so-called *"heroic" drugs.* Definite chemic compounds are not subject to this variation, but the removal of the last traces of innocuous impurities may greatly increase their cost without adding to their therapeutic usefulness. The Pharmacopoeia has therefore aimed to furnish quantitative methods of estimation, assays, wherever possible, and to establish practical standards to which medicinal substances must conform. With inorganic drugs, it states the largest permissible quantity of innocuous impurities (usually less than 2 per cent). With crude vegetable drugs, it states the permissible limit of foreign matter and insoluble ash, etc.; and the lowest permissible percentage of active ingredient, wherever practical methods for their determination are available. Assayed galenic preparations are adjusted to contain a definite proportion of active constituents.

The *assay of inorganic drugs* involves the methods of ordinary quantitative analysis, volumetric processes being preferred. Special tests are furnished for determining the permissible limits of accidental *impurities,* and the presence of harmful substances, such as metals. A series of volatile oils are assayed for their *most important ingredient.* Fats and fixed oils are tested for their "iodine absorption" and "saponification values"; resins for the "acid number"; some vegetable products for their ash. These tests serve mainly for identification and the exclusion of wilful adulterations.

Drugs containing aklaloidal principles are assayed by utilizing the method of immiscible solvents. In principle, alkaloids are extracted by chloroform or ether, or a mixture of both, in alkaline reaction. This solution is then shaken in a separator with acidulated water, which converts the alkaloids into salts and dissolves them, leaving the impurities behind. For futher purification, the watery solution is again rendered alkaline and extracted with chloroform or ether. On evaporation, this leaves the fairly pure alkaloid which may be weighed; or titrated, by dissolving it in a known amount of acid, and titrating back with alkali. This estimates the sums of all the alkaloids present in the drug, and suffices when the important one predominates largely over the others. Otherwise the assay must be confined to the particular alkaloid desired. For Opium, advantage is taken of the comparative insolubility of the morphine in ether. In Nux Vomica, the brucine is removed by oxidizing it with nitric acid.

Bio-Assays.—Drugs which depend for their activity on neutral principles are often unsuited to chemic assay, there being no reliable chemic method for estimating the constituents of such important drugs as digitalis, ergot, pituitary extract, etc. These are adjusted by **physiologic standardization,** estimating the strength of a preparation by comparing its effects on animals with those of the *"reference standard"* product, issued by the U.S.P. Revision Committee and approximately identical with the International Standards of the League of Nations Commission. The potency is generally expressed in *"units'* which are similarly identical (except for Tetanus Antitoxin). The more important methods are described in the U.S.P. Bio-assays are more difficult and more variable than the best chemical assays, partly because of the natural variability of living objects, and partly because they are often used for complex drugs. The criteria must be selected so that they reflect the therapeutically important ingredient, although not necessarily the therapeutic action. The variability must be discounted by using a sufficient number of animals and by suitable statistical methods (Burns, 1930). The fundamentals of biological assaying are reviewed by C. I. Bliss and Cattell, 1943. The cost of the animals makes bio-assays relatively expensive.

◆

CLASSES OF PHARMACEUTIC PREPARATIONS

The Latin titles in the following are given in the singular.

WATERY SOLUTIONS

These include the Waters, Liquors, Mucilages and Syrups. Their advantage is that water is a cheap solvent of wide applicability, itself devoid of any therapeutic property. The greatest drawback lies in the fact that watery solutions of organic substances tend to spoil rapidly by the development of micro-organisms. Solutions of chemic substances are less subject to this change.

Waters, Aquae (singular, Aqua; abbreviated, Aq.), are clear aqueous solutions of volatile substances. Two dissimilar classes of preparations come under this heading:

Aromatic Waters, *U.S.P.* (*Flavored Waters*) are generally saturated solutions of volatile oils. They are prepared by distilling the plant or oil with water, or simply by shaking the oil with distilled water. The quantity of active substance gives them a pleasant flavor without imparting noticeable therapeutic properties. The absence of alcohol makes them good solvents for salts. Their main use is as a pleasant vehicle for the conveyance of active substances. The *dose* of flavoring waters is practically unlimited (1.5 cc., 4 drachms U.S.P.). The U.S.P. includes waters of Anise, Camphor, Cinnamon, Peppermint, Spearmint, Rose and some others.

The second class of Waters (included under Liquores by the B.P.) are fairly strong *solutions of gases* (ammonia, etc.) prepared by passing the gas into water. Their doses are relatively small.

Solutions (*Liquor; Liq.*) are aqueous solutions of solid chemic salts or hydrates, made either by dissolving the pure salt directly in water by trituration or heat; or, more often, by chemic decomposition (simple and chemic solution). (The British Pharmacopoeia includes solutions of gases under this heading.) When used for special purposes, solutions receive special names. Injections (Injectio), Eye Waters (Collyrium), Washes (Lotio), Gargles (Gargarisma). *Collyria* should be isotonic with 1.4 per cent NaCl, and be neutral or buffered (Kopet, 1943). *Injections* are solutions or suspensions of drugs in water, saline solutions, oil, etc., for parenteral administration. The water must be "water for injection," U.S.P., *i. e.*, sterilized distilled water free from pyrogen, as determined by intravenous injection on rabbits. They should be preserved and dispensed in single containers, "*ampuls*" (ampulla), except for special circumstances. The pharmacopoeia lists *sizes* in which these and other dosage forms are "usually available."

For the *preservation of solutions* of organic substances intended for parenteral administration the U.S.P. permits the addition of not more than 0.5 per cent of chlorbutanol, cresol, phenol, sulfurous acid, sodium bisulfite or other suitable preservative. Not more than 0.85 per cent of sodium chloride may be present. The air in the container may be replaced by carbon dioxide or nitrogen. The presence and amount of any preservative in a solution intended for parenteral administration must be stated on the label of the container. The U.S.P. gives specific directions for *light-resistant containers* when these are necessary.

Mucilages (*Mucilago; Mucil.*) are aqueous solutions of gummy substances used as vehicles and demulcents. Since gums are insoluble in alcohol, mucilages are incompatible with this substance. They should be recently prepared because they are apt to mold.

Syrups (*Syrupus; Syr.*) are dense saccharine solutions of medicinal substances. The syrup serves as vehicle and preservative. Simple syrup is a nearly saturated solution of cane sugar, containing 85 Gm. in 100 cc., U.S.P.

Honey is sometimes used instead of cane sugar, makink a class of preparations called *mellita*, or *oxymellita* if acetig acid is added. *Confections* (*Confectio*; *Conf.*) are thicc medicated jams. They were formerly popular, but have now been almost abandoned. *Electuaries* were similar but somewhat thinner preparations.

Elixirs (*Elixir; Elix.*) are sweetened aromatic alcoholic liqueurs used, like the syrups, as flavoring vehicles. Their content in alcohol (about 25 per cent) is apt to lead to abuses, which must be kept in mind. The official Aromatic Elixir is flavored with orange peel, lemon, coriander and anise. *Iso-Alcoholic Elixir* (*Iso-Elixir*), N.F., is made by mixing a "low-alcoholic elixir" (about 10 per cent of alcohol) with a "high-alcoholic elixir" (about 75 per cent of alcohol) in such proportion as best dissolves the other ingredients of the prescription; the adjustment is left to the pharmacist.

Glycerites (*Glyceritum, U.S.P.; Glycerinum, B.P.; Glyc.*) are solutions in glycerin. Glycerin is a good solvent for many substances. It keeps well, and is especially useful for external application. It is less irritant than alcohol and is devoid of the pharmacologic action of this agent.

ALCOHOLIC SOLUTIONS

Alcohol is an outstanding solvent of volatile oils, alkaloids and resins. In prescribing, these should not be mixed with an aqueous solution. Alcohol is also a good preservative; it has therapeutic qualities which may or may not be desired.

Spirits (*Spiritus*, genitive *Spiritus; Sp.*) are alcoholic solutions of volatile drugs. They are all fairly potent. Flavoring spirits contain 10 per cent of the volatile oil. Their dosage is 1 to 2 cc., 15 to 30 minims. Spirits other than flavoring vary in strength and dose.

PREPARATIONS MADE BY EXTRACTION

In these, only a part of the crude drug is dissolved. They comprise the aqueous Infusions and Decoctions, and the alcoholic Tinctures and Fluid and Solid Extracts.

Infusions (*Infusum; Inf.*) are aqueous solutions of the soluble principles of vegetable drugs, obtained by pouring water on the moistened drug, letting it stand for half an hour and straining. They must be freshly made, and correspond to 5 per cent of the drug unless otherwise specified by the physician. **Decoctions** (*Decoctum; Dec.*) are made by boiling the drug with twenty parts of water for fifteen minutes, straining, and adjusting to correspond to 5 per cent of the drug. They spoil easily and must therefore be recently prepared. It is not practical to standardize them. They are virtually obsolete.

Tinctures (*Tinctura; Tr.*) are alcoholic or partly alcoholic solutions of the useful constituents of such drugs as are not wholly soluble in the menstruum; except *tincture of iodine, tincture of ferric chloride* and *tincture of tolu,* in which the solution is complete. Tinctures of potent drugs represent 10 per cent of the drug of minimium U.S.P. strength. Nonpotent drugs generally represent 20 per cent. Tinctures have the advantage that the dose is relatively large (about 2 to 4 cc. for the nontoxic); the quantity of solvent is sufficient to keep the principles in solution; the use of heat in the preparation is avoided. The greater number of tinctures are *prepared* by percolation; a few by maceration. The menstruum is alcohol or alcohol and water; acetic acid or glycerin is added in a few cases.

Aromatic spirit of ammonia is used in the *ammoniated tinctures. Detannated tinctures* are tinctures from which the tannin has been removed (as by powdered skin). They do not precipitate with iron salts. *Ethereal tinctures* are made with ethereal spirit, a mixture of 7 parts of ether and 3 parts of alcohol. Since some drugs are supposed to lose part of their activity by drying and keeping, a class of *Green Tinctures* made from the freshly collected green drugs has been introduced under the name of Tincturae Herbarum Recentium. *Wines* (*Vinum, Vin.*) are tinctures in which wines have been substituted for alcohol. They have inferior keeping qualities and are little used. *Aceta (Acet.)* are medicated vinegars, prepared by maceration with dilute acetic acid.

Fluidextracts, U.S.P.(Liquid Extracts, B.P.) (*Fluidextractum; Fldext.—Extractum Liquidum; Ext. Liq.*), are liquid alcoholic extracts, 100 cc. representing approximately 100 Gm. of the drug. The menstruum is sometimes modified by the addition of glycerin, acetic acid, etc. They are the most concentrated fluid preparations, but many are of doubtful value. Fluidextracts are usually prepared by percolation, the first four-fifths of the percolate being set aside, the remainder evaporated to the consistency of a soft extract, dissolved in the reserved portion, and menstruum added to make the required volume.

The simple ratio of drug strength has no special advantage in therapeutics, and has led to abuses such as preparing tinctures, infusions, etc., by the dilution of the fluidextracts. These dilutions often differ materially from the orthodox preparations. Concentration may sometimes be desirable to reduce the bulk of the dose, but is often secured at the cost of efficiency. The heat which must necessarily be used in their preparation may be detrimental. Precipitates are apt to form on standing, and may contain active principles. They are also much more subject to precipitation on mixture with other liquids, and the dose is usually so small that they require some such admixture.

Solid Extracts U.S.P. (*Extractum; Ext., Extractum Siccum; Ext. Sicc., B.P.*) are solid or semi-solid preparations obtained by evaporation of solutions of the medicinal principles of drugs. Some are dry, others of a "pilular" consistency, *i. e.*, like a pill mass. They are convenient for administration in solid form, *e. g.*, in pills, ointments, plasters, etc. Nearly all the potent, and most of the other, extracts are adjusted by the addition of glucose, etc., to four times the strength of the fluidextracts. "*Powdered extracts*" are dried, and mixed with sufficient diluent (lactose or starch) to give them the same strength as the solid extracts.

Most extracts are prepared by percolating and subsequent evaporation; the last and weaker portions of the percolate being evaporated first, to avoid the deleterious actions of prolonged heat on the main portion. Some of the extracts are obtained by evaporating the fluidextract. The menstruum is sometimes water or alcohol, or a mixture of both; acetic acid is added in some cases. The finished product is assayed, if possible, and adjusted to a definite standard by the addition of a diluent powder.

Artificial resins are precipitates obtained by mixing alcoholic solutions with water. Where they constitute the active principle, this is a convenient method of isolating it in a concentrated although somewhat impure form. Their strength is fairly constant. They are practically identical with the eclectic "resinoids." *Oleoresins* (*Oleoresina, Oleores.*) are extracts containing the resinous and oily constituents of the drug, and are obtained by evaporating ethereal, acetone or alcoholic percolates.

MIXTURES

Mixtures, in the wider meaning of the word, are fluids resulting from the mixture of fluids with other fluids or with solids. They comprise: Liniments, Mixtures and Emulsions.

Liniments (*Linimentum; Lin.*) are solutions of irritant drugs in oily, soapy or alcoholic vehicles, intended to be rubbed on the skin as counterirritants.

Mixtures (*Mistura; Mist.*), in the narrow meaning of the term, are generally suspensions of a solid in a liquid, sometimes by the use of a gummy substance; for heavy powders can not be evenly distributed in a light liquid without this aid. The B.P. also includes some emulsions under this title.

The *stabilizing, suspending or "deflocculating"* agents are protective colloids which raise the viscosity of the liquid and provide internal friction. *Acacia* is the suspending agent usually prescribed, employing up to 10 or 15 per cent of the powder, or 25 to 50 per cent of the Mucilage of Acacia. Acacia has the objection that it sours readily and tends to agglutinate bismuth subnitrate. Tragacanth, 5 to 10 per cent of the 6 per cent mucilage, is more efficient. Fantus advocated the (unofficial) *Karaya gum,* 1 per cent of the powder.

Emulsions (*Emulsio; Emul.*) are mixtures of a milky or creamy appearance, made by suspending fine droplets of a liquid in another liquid in which it is insoluble. The droplets constitute the internal or disperse phase. The fluid in which they float is the external or continuous phase. The dispersion or emulsification of the inner phase is effected and stabilized by the addition of emulsifiers, especially viscid colloids such as gums and protein substances, or agents that lower surface and interfacial tension, such as the bile salts, soap and saponin. These condense on the interphase of the liquids and form a pellicle around the droplets which prevents them from coalescing. The emulsion-state has considerable biological importance. Most pharmaceutical emulsions are of the oil-in-water type; "cold cream" is an example of water-in-oil emulsion. The object of *oil-in-water emulsification* is to break up the insoluble oil into fine particles and envelop each of these in a coating of the emulsifying agent. This allows dilution and the admixture of other substances, and facilitates absorption. Emulsification also improves the taste of undiluted oils, as cream is more pleasant than undiluted butter. Milk is a natural emulsion in which the butter fat is kept suspended by the casein. It may be taken as a type to which artificial emulsions should conform. The globules must be uniform and of about the same size as those in milk. A variety of substances may be used as emulsifier, especially gum acacia, tragacanth, karaya, agar, gelatin, yolk of egg, Irish moss, extract of malt, soap-bark and soap. The substance most commonly employed is gum acacia. This emulsifier is incompatible with more than 15 per cent of alcohol. Gum emulsions tend to ferment in a few days unless they are preserved by 10 per cent of alcohol or 1 per cent of benzoic acid. They should be kept in a refrigerator. Gelatin is wetted by both phases, the phase in large excess being external (R. M. Woodman, 1926).

In making the acacia emulsion, the oil is subdivided by trituration in the presence of the gum and enough water to make a thick mucilage. The friction against this viscid "nucleus" tends to tear the oil droplets apart; and as the smaller globules form, they are at once coated with the acacia film. The trituration must be brisk; for after the acacia films have formed it is much more difficult to break up the droplets further; nor must too much water be added until the emulsification of the nucleus is completed, for this would reduce the viscosity and the film formation. When the nucleus has been made, the films are adsorbed so firmly that they are not disturbed by contact with any quantity of water and may therefore be freely diluted. Two methods of emulsification are in common use: the Continental method, in which a nucleus is first formed from gum, oil, and water, and to which the remainder of the water may then be added; and the English method, in which a mucilage is first made, to which the oil and water are added in alternate small portions.

The *Continental method* deserves preference. To form a nucleus there should be used for each part of oil ¼ to ½ part of acacia and 1 part of water. Stir the oil with the acacia in granular powder, then add the water at once. The mixture of the oil and the gum must not be allowed to stand too long before adding the water, otherwise it will cake. In the *English method* the acacia, the amount of which should be half that of the oil, is rubbed up with an equal volume of water, and then small portions of oil and water are added alternately. If this addition should be done too rapidly, there is danger that the emulsion will separate or "crack." In *yolk emulsion,* the yolk of egg is triturated in a mortar and the oil and water are added alternately in small portions. One yolk suffices for from 1 to 2 ounces of oil. The yolk emulsions are incompatible with the same substances as gum emulsions and do not keep nearly as well. *Soap bark* has saponin for its emulsifying agent. It is not incompatible with any of the above-named substances, but has decided therapeutic properties which preclude its use in many cases. It is used in the proportion of 1 part of the tincture to 8 parts of the oil. Crude saponin (0.3:100 of oil) can also be employed. *Extract of malt* emulsifies its own weight of oil. It is used as the nucleus in the Continental method. *Solutions of alkalis* may be used for emulsification, since they form soaps, but they are usually not desirable. *Natural emulsions,* ready formed in nature, are milk, the yolk of egg, and some plant juices. *Gum resin and seed emulsions* are emulsions made from substances that contain their own emulsifier. Examples of such gum resins are ammoniac, asafetida and myrrh. The drugs are reduced to a coarse powder and water is added gradually. Seeds which yield such emulsions are poppy, hemp and almond.

SEMISOLID PREPARATIONS

Ointments (*Unguentum; Ung.*) are soft fatty masses for external application. They consist of the active ingredient and the base. The latter may be lard, petrolatum, wool fat (lanolin) or various mixtures. *Petrolatum* is a distillate of petroleum, either of amber color (flavum) or decolorized (album). *Wool Fat* (*Adeps Lanae*) is a mixture of cholesterol-like substances obtained from sheep's wool. It mixes with its own weight of water as a water-in-oil emulsion. This is of advantage for water-soluble salts, since these can be incorporated in the form of solution. It is also official as *Hydrous Wool Fat* (*Adeps Lanae Hydrosus, Lanolin*), in which about 27 per cent of water has been incorporated. This is rather stiff. A mixture of one part of anhydrous wool fat with three parts of petrolatum is miscible with twice its weight of water (Fantus). A mixture of equal parts of petrolatum and hydrous wool fat is a generally useful ointment base, as is also the U.S.P. *Unguentum*, consisting of white petrolatum and about 5 per cent each of wool fat and white wax. *Lard* rapidly becomes rancid. This tendency can be diminished by the incorporation of antiseptic substances. Benzoinated Lard is an attempt in this direction; but the dispensing of ointments in tin tubes is the most efficient protection against rancidity as well as against dirt. It should not be used if the ingredients of the ointment attack the metal.

The physical characters of the ointment bases, their melting point and their viscosity and adhesiveness, influence their availability for different purposes. When the ointment is to be applied by friction, for instance if it is to be rubbed in the hair follicles, a nonviscid base, such as lard, would be preferred. If a thick layer is to be kept in contact with the skin, the adhesive wool fat would be better. For a protective ointment, a thin layer, for instance of petrolatum, may suffice. The U.S.P. authorizes variations in the proportions of vehicle ingredients to adjust the consistence to climatic conditions. The nature of the base influences the *penetration of the ingredients* of the ointment into the skin. The absorption is high if the solubility of the substance in the epidermis is greater than its solubility in the ointment. Since this varies for each substance, no base is uniformly either favorable or unfavorable to absorption.

Deuterium tracer studies show that the fat, mineral oil and cholesterol of ointments are not at all absorbed (Czettsch-Lindenwald, 1943), and there is no good evidence that the ointment base acts as vehicle to carry substances through the skin (S. Rothman, 1943). The only visible penetration of fats is into the gland ducts (Strakosch, 1943; review, Calvery *et al.*, 1946).

Ointments are *prepared* by fusion, mechanical admixture or chemic reaction. In mixing ointments by fusion, that constituent of the ointment which has the highest melting point is first melted, and the others are then added in the order of their melting points. The active substance is added last, to obviate the prolonged action of heat upon it. Mechanical admixture is usually done on a slab or in a mortar. Powders must be as fine as possible.

Oculenta (*Oculentum*; *Oculent.*) are ointments for the eye. General formula, B.P.: 90 parts by weight of yellow soft paraffin and 10 parts by weight of wool fat plus a drug as stated by the prescriber. **Oleates** (*Oleatum*; *Oleat.*) are solutions of metals or alkaloids in oleic acid. They are used like ointments.

Cerates (*Ceratum*; *Cerat.*) are preparations similar to ointments but made of a firmer consistency by the addition of wax so as to remain semisolid at body temperature.

Plasters (*Emplastrum; Emp.*) are made by spreading on a thin cloth or leather support a mass or base which is hard at an ordinary temperature, but is softened and rendered adhesive at body temperature. They are applied for protection or counterirritation. A rubber composition is the base for most modern plasters.

The typical old-time plaster had for its base diachylon, Burgundy pitch or other resins. Diachylon is a lead soap made by boiling lead monoxide with olive oil and lard. To avoid the irritation resulting from the confinement of the secretions of the skin, plasters are sometimes made porous. Isinglass plaster is made by spreading a thick solution of isinglass on silk.

Chartae are medicated papers, *i. e.*, pieces of paper covered or impregnated with a medicinal substance. Charta Sinapis is used as a plaster, Charta Potassii Nitratis for fumigation.

Collodions (*Collodium; Collod.*) are solutions of pyroxylin (gun cotton) in a mixture of ether and alcohol, or in acetone. On evaporation of the solvent they form a film on the skin, and thus act like plasters. Collodion must not be brought near fire.

Poultices (*Cataplasma; Catapl.*) are used mainly for supplying heat. Linseed poultice may be taken as a type: It is prepared by pouring a cup of linseed meal into 2½ cups of boiling water, stirring constantly. The mush is spread thickly on a piece of flannel, folded so as to form a sack, and applied as hot as can be conveniently borne. Other pasty materials (flour, clay, etc.) are also used.

SOLID PREPARATIONS

Powders (*Pulvis; Pulv.*, Gen., *Pulveris*) are finely powdered drugs intended for external or internal administration. Those for internal use are generally folded in papers (*chartulae; chartul.*). Hygroscopic (deliquescent) substances, such as potassium acetate or citrate, cannot be prescribed in papers, nor substances that become fluid when mixed (such as camphor with chloral). If the dosage is less than 0.5 Gm. the powder should be diluted with sugar to this amount. If the dosage exceeds 1 or 2 Gm. and if it need not be accurate, it is more economical to dispense the powder in bulk, directing "dispense in box" or "dispense in bottle" (for hygroscopic substances), and to let the patient measure the quantity, on the assumption that a level teaspoonful would weigh about 5 Gm. Correction must be made for unusually light powders (quinine) and for heavy powders (bismuth subcarbonate).

In mixing compound powders, one should begin with the smallest ingredient and add the others in the order of their amount, triturating thoroughly after each addition. In dividing the powder, it is not always necessary to weigh out each powder. The object is often accomplished with sufficient accuracy by flattening the powder on a piece of paper, squaring off the edges, and dividing into a number of equal parts with a spatula. For more bulky powders, such as Seidlitz powders, measures are used. *For external use,* as for dusting powders, extreme fineness is the main desideratum. They should be mixed with a spatula and not in a mortar, since the former insures greater smoothness.

Triturations consist of one part of the medicinal substance and nine parts of lactose rubbed together to a fine powder. Their advantage lies in the greater ease in weighing out a comparatively large amount of substance. When no special directions are given, triturations are made of a strength of 10 per cent. *Eleosacchara* are triturations of volatile oils with sugar in the proportion of 1:30. They are used to flavor other powders.

Effervescent salts are dried salts, mixed with sodium bicarbonate and tartaric or citric acid so as to evolve carbonic acid when they are dissolved in water. This aids in disguising the taste. A number of these salts are official in the N.F.

DOSAGE FORMS

Capsules, tablets, lozenges, pills, etc., are used to divide the drug into definite doses, to avoid the inconveniences of dry powders, and to reduce the bulk. Care must be used in prescribing the dosage forms not to make them too large to be swallowed. The administration of drugs in compact solid form delays solution and absorption. This is especially true of old pills, in which the excipient may become so impervious that they pass unchanged into the feces; but it applies also to some tablets. A mere delay in solution may be an advantage if an intestinal action is to be procured; but difficultly soluble substances (salol, bismuth, etc.) should not be administered in these compact forms. Corrosive substances are unsuited for solid administration.

Capsules are small soluble containers, usually of gelatin, intended to be filled with the drug and swallowed. They furnish fairly accurate dosage and disguise the taste. Those used for powders consist of a body and a cap. In filling the capsules, the powder is divided into the requisite number of parts, forced into the body with a spatula, and the caps placed on. There is a range of sizes, but ordinarily not more than 0.25 Gm., 4 grains, should be placed in a capsule. Oils, up to 0.35 cc., eight drops, may be dropped into a capsule at the time of taking. Larger quantities of oils, 2 to 4 cc., can be taken in a "soft" capsule, but it is not convenient to prepare these extemporaneously.

Pill Masses in Capsules.—Capsules can be made to hold larger quantities of powders when these are made into pill masses. *Wafers* are thin sheets formed of a dried flour paste, in which the powder is enveloped. They are immersed in water and swallowed. They possess the advantage that larger quantities of the drug (up to 1 Gm.) may be administered. *Cachets* are wafers, molded into concave circular forms.

Tablets (*Tabellae; Tab.*) are small discs composed of medicated powders. They are convenient to administer, but are not easily made to order, so that the prescriber is confined to those carried in stock by the pharmacist. If this is not definitely known, it is advisable to direct "tablets or capsules."

Tablet triturates are prepared from the powdered drug and milk sugar or sugar, made into a paste with alcohol, pressed into molds, and dried. *Compressed tablets* are formed by strong dry compression. These are used like pills, or they may be chewed, or dissolved in water. Those of bitter taste may be coated with sugar or chocolate. By suitable choice of ingredients, they may be made acceptable to children (*Tabellae Dulces*, "Candy Medication," Fantus, 1912–1914). *Hypodermic tablets* are similar to the tablet triturates, especial care being exercised to facilitate quick solution. **Troches or lozenges** (*Trochiscus; Troch.*) are made by punching or cutting out circular or oblong disks from a mass made up from the active substance, sugar, and mucilage or fruit base. These are then dried in the air. They are usually intended for solution in the mouth, especially for throat medication. *Pastilles* are analogous preparations made with a sweetened gum-glycerin-gelatin base. **Lamellae** (B.P.) (*Lam.*) are thin gelatin discs, softened with glycerin, and impregnated with substances acting on the pupil. They are intended to be placed under the eyelids.

Pills (*Pilulae; Pil., U.S.P.*) consist of powders made into a plastic "mass" with a gummy or syrupy material "excipient" which keeps them more or less plastic. This *mass* (the B.P. "pill") is divided into suitable doses and rolled into small balls, to be swallowed. They can be prepared extemporaneously, and should not be kept too long, as they tend to harden, with decrease of solubility. Not more than 0.35 Gm. (5 grains) should ordinarily be prescribed in a single pill. If the pill is of larger size, it is called a *bolus*. Very small coated pills are spoken of as *granules*. The quantity of drug in the official pills is adjusted so as to make the average dose two pills. The choice of excipient may usually be left to the pharmacist.

Moist excipients are: glycerite of acacia or tragacanth thick flour paste, glycerin, syrup, confections or extracts· *Solid excipients* are: acacia, tragacanth, starch, althea, licorice powder, soap. For chemicals which are destroyed by organic substances the best excipient is formed by a mixture of petrolatum and kaolin. All excipients *delay absorption* somewhat. For iodide pills, Rieben, 1907, found the greatest delay with waxy and oily excipients, the least with vegetable extracts and syrups.

Pill-Coatings.—Pills may be coated with sugar, gelatin, chocolate, etc., to disguise their taste while being swallowed. The coatings tend to interfere somewhat with absorption. The simplest coating is to insert the pill into an ordinary gelatin capsule.

Enteric pills are coated with some substance (keratin, salol, stearic acid, formaldehyde-hardened gelatin, or shellac) which protects them from the gastric juice, but dissolves in the intestines. They would be useful when the drug is to act only after passing the stomach. They often fail to accomplish their purpose, for soluble drugs diffuse through them rapidly (Linossier, 1911) even if the coating is insoluble in the gastric juice, and water may be drawn in by osmosis and break the coating.

Goorley and Lee, 1938, experimented with a variety or enteric coatings and concluded that a mixture of castof oil, shellac and alcohol is the most satisfactory, especially if taken an hour or two before eating. Small pills and capsules pass into the duodenum much more easily than do the larger sizes. Improved directions for the salol coating of pills are given by Peacock, 1915; for stearic acid by Toplis, 1915. The latter claims that the stearic coating apparently fulfills its purpose. *Keratin* (a protein derived from horn, goose quill, etc.) was tried extensively, but it is totally unsuitable, since commercial specimens are largely soluble in artificial gastric juice (Puckner, 1911). *Formaldehydized capsules* are prepared by immersing the filled capsules in water containing 1 per cent of absolute formaldehyde, and drying. The capsules should become insoluble in acid pepsin solution, but remain soluble in 0.5 per cent sodium carbonate. The degree of insolubility s governed by the duration of the immersion (Scoville, 1915).

Suppositories (*Suppositorium: Supp.*) are cone-shaped masses of solid, medicated, usually fatty substances, intended for introduction into the rectum, vagina or urethra. They take the place of ointments for local treatment where these cannot be readily applied. Suppositories are made by incorporating the medicinal substance into a suitable base, and molding into masses of suitable shape and size. The base should be solid at the ordinary temperature and melt by the heat of the body. Such is cacao butter (Oleum Theobromatis), Glycerinated gelatin or a soapy base is also sometimes used, especially with urethral suppositories for which cacao butter would be too brittle. Rectal suppositories are usually made with sufficient base to weigh about 2 Gm. *Vaginal suppositories* are globular or oviform, and weigh about 4 Gm. *Urethral suppositories* are pencil-shaped, pointed at one end, measure 7 or 14 cm. and weigh 2 or 4 Gm. when made with glycerinated gelatin.

The "hot" process of making theobroma suppositories consists in melting cacao butter, adding the active substances, and pouring the mixture into cold molds. In the "cold" process the active substances are triturated with grated cacao butter and sufficient expressed oil of almond or wool fat to make a suitable mass, which is then rolled out and divided as for pills. They may also be formed by pressure. *Glycerin* is made into a suppository by a hard soap formed from stearic acid and sodium carbonate.

Ampuls (*Ampullae, Ampules*) are small, hermetically sealed glass flasks containing sterile solutions or suspensions of medicinal substances for parenteral injection. The glass must not give an alkaline reaction to water. Single dose ampuls, containing the desired dose generally in 1 or 2 cc. of water or normal saline, or larger quantities for intravenous injection, are closed by fusing the glass. "Multiple dose" ampuls, economical for hospital practice, are closed with a rubber diaphragm, which is pierced by the hypodermic needle.

PRESCRIPTION WRITING

A prescription is an order for medicine sent by a physician to a pharmacist. The first essential in such an order is that it be clear and free from errors. The use of Latin in writing prescriptions is an old tradition that should be abandoned; modern physicians and pharmacists are not at home in this language and are therefore more liable to make errors. The use of *abbreviations* is universal, but care needs to be used that they are not ambiguous.

Parts of the Prescription.—In writing a prescription, it is advisable to proceed in a definite order, which may guide the thought and protect against omissions and errors. The prescription is composed of four chief parts:

1. *The Superscription.*—The heading (℞). The ℞ stands for recipe, take thou. The stroke has been considered an ancient invocation to Jupiter; but probably it is simply a sign of abbreviation (McGuigan, 1913).

2. *The Inscription.*—The ingredients and their amounts. In these one should strive for simplicity, and multiply ingredients only if they are really indicated. If several are prescribed, they should be written in the following order, which places the most important first and the least potent last:

Basis: the principal substance.

Adjuvant: the substance which is used to aid the action of the basis.

Corrective: whose purpose is to modify or correct an undesirable action of the basis.

Vehicle: the indifferent substance used to dilute the active ingredients.

3. *Subscription.*—The directions to the dispenser. With liquid mixtures, the directions to the pharmacist may often be confined to M. (misce, mix).

4. *The Signature.*—The directions to the patient (for "signa," sign, label, abbreviated Sig. or S.). This is always written in English except for conventional abbreviations, so that the pharmacist may label the medicine with the words of the prescriber. The directions should be explicit and should include everything which it is necessary for the patient to know about the use of the medicine; unless the directions are unusually complicated, in which case they should be supplemented by written instructions. Verbal instructions are not safe. Medicines intended for external application should be plainly labeled to that effect, and when a medicine contains poison it should be so labeled, except when there is special objection to this.

The custom of having prescriptions "*refilled*" obtains in many localities. If the physician wishes to avoid this, he may write "non repetatur" on the prescription.

When the patient is very poor, the druggist may be invited to charge the lowest terms by writing P. P. (Pauperissimus) under the prescription. It is not just to do this if the physician himself receives a regular fee.

5. The prescription should also bear the signature of the physician, the date, and the name of the patient.

6. *Prescriptions for Habit-Forming Drugs.*—The federal law requires that prescriptions for cocaine or for opium or its alkaloids or derivatives must contain: the signature of the physician in full; his address; his registry number; and the name and address of the patient.

Such prescriptions cannot be "refilled." If their administration is to be continued the physician must write a new prescription.

The following illustrates a complete prescription:

Superscription.........	℞		Gm. or cc.
Inscription:	Basis	Codeine Sulfate	0.18
	Adjuvant	Ammonium Chloride	3.6
	Corrective	Ipecac Syrup	12.0
	Vehicle	Glycyrrhiza Syrup	36.0
Subscription:	Mix		
Signature:	Sig: A teaspoonful every two hours if needed for cough.		
	For Mr. Smith		John Doe, M.D.
January 1, 1947.			Reg. No. 12345

Forms of Administration.—If the medicine is to be used *internally*, it may be prescribed as:

Solution.—If the ingredients are soluble in water, alcohol or glycerin.

Mixtures or emulsions, i. e., suspended by acacia, if insoluble in water.

Powder.—If the substance does not have a very bad taste. These are preferred to the following preparations if the dose is bulky, or if the substance is to be dissolved in water before swallowing.

Pills, Capsules, etc.—If the substances are solid or semisolid, and possess a disagreeable taste; or if they are to act locally on the alimentary canal.

If the medicine is intended for *external use*, it may be prescribed as:

Plaster.—If the action is to be prolonged and superficial.

Ointment.—If the action is to be deeper, or briefer.

Lotions or Injections, Eye Waters, Gargles, etc.—If it is soluble in water.

Liniment.—If it is soluble in oil or alcohol.

The size of prescription is determined primarily by the number of doses. For instance, with the common routine of "three times a day," there would be 21 doses in a week. For liquids with a teaspoonful dosage, each one at 4 to 5 cc., this would come to 84–105 cc. (or ℥ iij in the apothecary system). The number may be rounded off so as approximately to fill the bottles in current use (15, 30, 60, 90, 125, 200, 400 cc.) (½, 1, 2, 3, 4, 6, 8, and 16 ounces). *For drop doses and eye waters*, the usual amount is 15 to 30 cc. (½ to 1 ℥); for teaspoon doses, 60 to 125 cc. (2 to 4 ℥); for *gargles, liniments and injections*, 60 to 150 cc. (2 to 6 ℥); *for lotions*, 120 to 200 cc. (4 to 8 ℥); *for tablespoon doses*, 150 to 400 cc. (6 to 16 ℥). *Pills* are prescribed in numbers of 5 to 25; *powders*, 1 to 24; *ointments*, 10 to 30 Gm. (½ to 1 ℥).

Calculation of Doses.—The prescriber generally starts with the dose to be taken at one time, and either directs the pharmacist to "make six (number) such doses" (fac tales doses numero sex); or else the single dose is multiplied by the number of doses, which is simple enough in the metric system, but more complicated in the apothecaries'. In either case the quantities are generally rounded off to a convenient number; a latitude of 10 per cent of the total falls quite within the ordinary variation of physiological response. Objection is sometimes made to the writing of the single dose and leaving the arithmetic of multiplication to the pharmacist, as a "lazy man's device." In fact, however, it protects the patient; for arithmetic is more safely performed in the quiet atmosphere of the prescription counter than under the stress and diversion of the bedside. In either case, the pharmacist is expected to check the doses of the ingredients, and not to dispense a prescription containing an *unusual dose of a powerful poison* without convincing himself that the physician prescribed this intentionally. While this does not lessen the responsibility of the physician, it is a desirable safeguard. To avoid delay, it is customary to mark large doses in such a way that the pharmacist will have no doubt that they are intentional. Thus: Tr. Digitalis, 15 cc. or 15 cc.! or 15 cc. Q. R. (quantum recte); or better to write out the words in full: 15 (fifteen) cc.

Percentage Solutions.—According to the U.S.P., when the expression "per cent" is used in prescriptions without qualification, it is to be interpreted to mean: for solutions of solids or gases in liquids, weight in volume; for solutions of liquids in liquids, volume in volume. The slight change in volume due to variations in room temperature and the trifling difference between the volume of the cubic centimeter and the milliliter may be disregarded.

The Need of Practice in Prescription Writing.—The construction of a prescription is based on simple principles which are easily memorized; but their application requires some practice.

The student who would master this subject should not rest content with doing the few exercises which can be given him in class. As he studies each drug, or as he reads up the treatment of diseases, he should himself compile such prescriptions as the subject suggests. This will aid him not only in prescription writing, but in pharmacology and therapeutics as well. It is only in this way that he can acquire the necessary self-confidence and skill. In this home practice, method and detail should be cultivated, for in these lies the secret of the art. The following rules may prove helpful:

Routine Construction of Prescriptions.—When writing a prescription for a given condition, set down, first, the name of the best remedy. Ask yourself whether there is any other drug which may be employed to aid or usefully modify the condition. Put this down also.

Then consider in which form the medicine should be administered, whether as liquid, powder, salve, etc. This will usually determine which preparation of the ingredient is to be employed. Put this down.

Then ask yourself what may be added to render the mixture agreeable to the patient. Add the vehicle. When this is written, all the ingredients will be represented.

Now look over this carefully and see that there are no incompatibilities and that the constituents are soluble if the mixture is to be a liquid. Write the directions to the dispenser. Assure yourself that the meaning is clear, the writing legible, and the abbreviations not ambiguous (the U. S. P. and the N. F. give official abbreviations). Decide how many days the mixture is to be taken, and how many doses a day (on the basis of sixteen hours to the day). Decide whether the dose of the total mixture is to be a teaspoonful, tablespoonful, etc. By multiplying the total number of doses with the size of the single dose, ascertain the approximate size of the mixture. Round this off to a convenient figure. If the prescription is to be of the "make X such doses" model, write after each ingredient the quantity of the single dose. If the total quantity is to be calculated, multiply the single dose of each ingredient by the total number of doses (again reducing the quantities to round numbers, unless the constituent is very potent). Check the doses. Write the directions to the patient. Consider whether a *non repetatur* is advisable. Affix your signature, the date, and the name of the patient. This finishes the prescription. Look over the result carefully in the same order. It is very important to use *legible handwriting*. It is astonishing, in view of the dire results that may follow, how often this self-evident rule is disregarded. The same remarks apply to *abbreviations;* it is necessary to make these in such a way that they cannot possibly be misinterpreted. A useful aid in acquiring practice in writing prescriptions is to look over a druggist's prescription file.

Simplicity in Prescription Writing.—Prescriptions were formerly written with many ingredients, with the hope that among these some might fit the patient. As medicine has become more scientific, it has aimed at simplification; prescribing several drugs only when there is evidence that this gives useful results. This makes it more feasible to watch and to control the effects, and incidentally makes it easier to avoid incompatibilities. When it is necessary to prescribe at the same time drugs which differ markedly in quickness of action, absorption or elimination; or habit-producing drugs with others that will presumably be used for longer periods, these should be administered in separate prescriptions. If the prescription includes a number of mixtures, each containing several ingredients, such as the numberless preparations put on the market by many firms, the result is, of course, as much a "shot-gun" prescription as if the prescriber had enumerated all the ingredients.

Non-Prescription Orders.—Pharmacists make a professional service charge on prescriptions above the "over-the-counter" cost. If the physician deems it justifiable to avoid this charge to the patient, for commercial articles, he may write the English name and the quantity ("Absorbent cotton, 1 lb."; "Cod liver oil, x brand, 1 pint"), but he must not sign it with his name or initials, for this would make it into a prescription, *i. e.*, an order from a physician to a pharmacist. Preparations which must be compounded extemporaneously will generally be treated as a prescription, even if they are not signed.

PRESCRIPTION LATIN

The inscription and the subscriptions are still often written in Latin, but this is not compulsory and indeed generally not advisable.

Advantages of Latin.—The use of the Latin names of drugs is generally urged because they are more definite and concise, and less liable to change than common names, and because they serve to keep the patient in ignorance of the nature of the drugs. This is sometimes desirable, *f. i.*, to guard against drug habits. The Latin names of the addiction drugs are, however, so close to the English names that they would generally be recognized; the object is more effectively secured by other means. Similarly, the official English names are equally definite. As a matter of fact, less than 5 per cent of the U.S.P. "Latin" names are really classical Latin (Oldberg, 1910). In the directions to the dispenser, Latin has no advantage, except in the brevity of the customary abbreviations. Indeed, unusual Latin terms are likely to lead to mistakes (Fantus, 1916).

Grammatical Rules for Latin Prescriptions.—The superscription, ℞ (recipe: "take thou"), requires the name of the substance to be in the genitive, if the quantity is given, the quantity itself being in the accusative (though, of course, rarely written out in full). When the quantity is not given, the name of the substance is to be placed in the accusative. Adjectives agree with their nouns in gender, number and case.

The following rules for the formation of the genitive case will be found valuable ("Mann's Manual"):

Nouns ending in a *form the genitive in* ae; as Quinina, Quininae. *Exceptions:* Aspidosperma, Physostigma and Theobroma form the genitive in *atis. Folia* is plural; genitive, *foliorum.*

Nouns ending in us, um, os, on, *form the genitive in* i; as Conium, Conii. *Exceptions:* Rhus, gen. Rhois; Flos, gen. Floris; Fructus, Cornus, Quercus, Spiritus, do not change.

All other nouns of whatever termination make the genitive in s, *or* is, *f. i.,* Elixir, gen. Elixiris.

Some lengthen the termination thus:

as, genitive *atis* (Acetas, Acetatis)
is, genitive *idis* (Anthemis, Anthemidis)
o, genitive *onis* (Persio, Persionis)
x, genitive *icis* (Cortex, Corticis)

Exceptions: Mas, gen. Maris; Phosphis, Sulfis, etc., gen. itis; Mucilago, gen. Mucilaginis; Solidago, gen. Solidaginis; Pulvis, gen. Pulveris, etc. The following words do not change in their genitive: Buchu, Cannabis, Catechu, Condurango, Cusso, Digitalis, Hydrastis, Jaborandi, Kino, Matico, Sassafras, Sago, Sinapis, Gambir, Sumbul.

The accusative is rarely employed. It is formed according to the following rules: *Nouns singular ending in* a *are feminine, and make the accusative singular in* am *and the plural in* as. Example: Drachma, acc. sing. Drachmam, pl. Drachmas. *Those ending in* um *or* us, *make the accusative singular in* um. *The accusative plural of those in* us *is* os, *and of those in* um *is* a. Those in *us* are masculine, those in *um* are neuter: Congius, acc. sing. Congium; acc. pl. Congios. Granum, acc. sing. Granum; acc. pl. Grana. *Those whose genitive ends in* is, *form the accusative in* em, *plural* es.

The student must not forget that adjectives change their endings.

The following *prepositions* are frequently used and command the following cases:

ad	to	accusative
ana[1]	of each	genitive
cum	with	ablative
in	into	accusative

The following **Latin words and phrases** occur frequently in prescriptions:

ad	to, up to
ad libitum	at pleasure
adde	add (thou)
ana (āā)[1]	of each
aqua bulliens	boiling water
aqua destillata	distilled water
aqua fervens	hot water
aqua fontana	spring water
bene	well
bis in die (b.i.d.)	twice daily
cape, capiat	take, let him take
capsula	capsule
charta	a paper (medicated)
chartula	a small paper for a powder
cibus	food
cochleare magnum	a tablespoon
cochleare parvum	a teaspoon
cola, colatus	strain, strained
collyrium	an eye wash
congius (C.)	a gallon
cum	with
dilute, dilutus	dilute (thou), diluted
dimidius	one-half
dividatur in partes aequales	let it be divided into equal parts
divide (Div.)	divide (thou)
dividendus	to be divided
dosis	a dose
fac, fiat, fiant (ft.)	make, let be made, let them be made
fac tales doses	make such doses
filtra	filter (thou)
gargarisma	a gargle
gutta, guttae (gtt.)	a drop, drops
haustus	a draught
hora	an hour
hora decubitus	at bed time
hora somni	just before going to sleep
instar	like (with genitive)
lac	milk
libra (lb.)	a Troy pound
magnus	large
mane primo	very early in the morning
misce (M.)	mix
mitte	place, send
more dictu	as directed
non repetatur	do not repeat
numerus, numero (No.)	a number, in number
octarius (O.)	a pint
ovum	an egg
pars	a part
partes aequales (P. æ.)	equal parts (governs genitive)
parvus	small
pilula (pil.)	a pill
pone	place
pro re nata (p.r.n.)	according to circumstances, occasionally
pulvis (gen. pulveris)	a powder
quantum sufficiat (q.s.)	as much as is necessary
quaque die	every day
quaque hora	every hour
quater in die (q.i.d.)	four times a day
secundum artem	according to the usual practice
semel in die	once a day
(cum) semisse (ss.)	and a half
signa	sign
sine	without
si opus sit (s.o.s.)	if necessary
solutio	a solution
solve, solutus	dissolve, dissolved
statim	immediately
talis	such
ter in die (t.i.d.)	three times a day
tere simul	rub together
tritura	triturate
vitellus	the yolk (of an egg)

◆

METROLOGY

A ready working knowledge of weights and measures is indispensable in prescribing.

---

[1] From the Greek, "at the rate of."

Formerly every country and some cities had their own system of weights and measures, resulting in endless confusion and loss of time. This still exists to some extent. In the United States and Great Britain no less than five different systems are in common use. In the United States, however, there is a strong trend toward the use of the metric system in prescribing. This is stressed by the U.S.P. and N.F. and employed exclusively in the N.N.R. and in the medical services of the Government. The metric system, which originated in France near the close of the eighteenth century, has been adopted in science to the exclusion of all others, and has advantages which should cause all other systems to be discarded. Since, however, the common systems are still used in many hospitals and journals, these must also be mastered, and the conversion of the systems practiced.

The metric system is based on the decimal system and has for its unit the measure of length, the meter (M.).

This was intended to be a natural unit, viz., the ten-millionth part of the distance from the pole to the equator of the earth at a particular meridian. Subsequent measurements have given a slightly different value to this distance. The meter is therefore an arbitrary standard—the length of a platinum bar, the original of which is preserved in Paris.

The meter is divided into 10, 100 and 1000 parts, called, respectively, decimeter (dm.), centimeter (cm.) and millimeter (mm.). The thousandth part of a millimeter is a micron (μ). The contents of a cube whose edges measure a decimeter, or 10 cm., form the unit of capacity, practically equivalent to the liter (L.). The thousandth part of this is a cubic centimeter (c.cm. or, briefly, cc.; also termed a "milliliter" or "*mil.*"). The unit of weight is the weight of a liter of distilled water at 4° C. *in vacuo:* this is the kilogram (Kg.). A thousandth part of this is a gram (Gm.). The tenth part of the units is expressed by prefixing the Latin numeral deci; one-hundredth, centi; one-thousandth, milli.

Thus:

1000 Gm. = Kilogram (Kg.)[1]
1 Gm. = Gram (Gm.)
0.1 Gm. = decigram (dg.)
0.01 Gm. = centigram (cg.)
0.001 Gm. = milligram (mg.)
0.001 mg. = microgram (μg; but not to be abbreviated in prescriptions)

In quantities including several denominations only one unit is used: thus, 1.234 Kg. would be read as 1234 Gm. Fractions below 0.1 Gm. are usually written as milligrams (99 mg. instead of 0.099 Gm.). The quantities are always denoted by Arabic figures placed before the appellation. Fractional parts are always converted into a decimal fraction. In continental Europe liquids are usually weighed.

Common Systems of Weights and Measures.[2]—The denominations are as follows:

APOTHECARIES' OR TROY WEIGHT

(USED IN PRESCRIPTIONS)

Grain (gr.)
[Scruple (℈) = 20 gr.]
Drachm[3] (ʒ) [= 3℈] = 60 gr.
Troy ounce (℥) = 8ʒ = 480 gr.
[Troy pound = 12℥ = 5760 gr.]
(℥j of water under standard conditions[4] measures 504.83 minims.)

AVOIRDUPOIS OR IMPERIAL WEIGHT

(A SYSTEM USED IN COMMERCE)

Grain = same as Troy grain.
Ounce (oz.) = 437½ grains.
Pound (lb.) = 16 oz. = 7000 grains.
Ton = 2000 lb.

UNITED STATES APOTHECARIES' OR WINE MEASURE

(USED IN UNITED STATES FOR BOTH PRESCRIPTION AND COMMERCIAL PURPOSES)

Minim (♏ or min.) (approximately equal to 1 drop or to 1 grain of water—more exactly, 0.95 grain).
Fluidrachm (fl ʒ) = 60 ♏.
Fluidounce (fl ℥) = 8 fl ʒ = 480 ♏ (fl ℥ j of water under standard conditions[4] weighs 456 2/5 grains).
Pint (pt., or Octarius, O) = 16 fl ℥ = 7680 ♏.
Quart (qt.) = 2 pts. = 32 fl ℥.
Gallon (gal., or Congius, C) = 8O = 128 fl ℥ = 61,440 ♏.
A gallon holds 231 cubic inches.

---

[1] Some authors begin all abbreviations with capitals; others use capitals for Gram, Liter, Meter and their multiples; and small letters for fractions.

[2] Those in square brackets are practically obsolete

[3] Also spelled dram.

[4] At 4° C. in vacuum.

Another system of liquid measure is in use in *Great Britain,* and must not be confused with the American system. It is the

IMPERIAL MEASURE

		UNITED STATES SYSTEM
Minims (min.)	=	0.96 ♏
Fluidrachm (fl. dr.)	= 60 min.	= 0.96 fl ʒ
Fluidounce (fl. oz.)	= 8 drachms	= 0.96 fl ℥
Pint (O)	= 20 fluidounces	= 1.2 O
Gallon (C)	= 8 pints	= 1.2 C

In writing the apothecaries' measure in prescriptions, the numbers are written in the Roman system and placed after the appellation. Thus, gr. xx, not 20 gr. The ones are always dotted, and the last one is formed like a j: thus ʒiij, ℥vj. The fl. before the sign is often omitted with liquids. Fractions are written as common fractions: gr. 1/10, not gr. 0.1.

Popular measures are formed of utensils commonly found in the household, and are inexact. They should be displaced by graduated medicine glasses. Spoons are supposed to be filled so that the fluid stands level with the rim.

The usually accepted equivalents of these measures are:

1 drop (gtt.)	= 1 minim[1]	= 0.05 cc.
1 teaspoon	= 1 fl ʒ[2]	= 4 cc.[3]
1 dessertspoon	= 2 fl ʒ	= 8 cc.
1 tablespoon	= 4 fl ʒ (½ ℥)	= 15 cc.
1 wine-glass	= 2 fl ℥	= 50 cc.
1 tea-cup	= 4 fl ℥	= 125 cc.
1 tumbler	= 8 fl ℥	= 200 cc.
1 knifepointful (tableknife)	= 15 to 30 gr.	= 1.0 to 2.0 Gm.

Equivalents of Metric and Common Systems.—Doses and formulas may be transposed on the basis that 1 Gm. equals 15.4 grains; but errors of reckoning may have serious consequences. It is generally safer to use the following approximate equivalents which are sufficiently exact for prescription purposes:

APPROXIMATE EQUIVALENTS

1 Gm. } = 15.5 grains or minims
1 cc. }
1 milligram = 1/64 grain
1 Liter = 1 quart (+)
1 Kilogram = 2.2 lb.

1 grain or minim = 0.065 Gm. or cc.

1 drachm = 4.0 (−) or cc.
1 ounce = 30.0 (−) or cc.
1 pint = 0.5 Liter (−)

EXACT EQUIVALENTS—SPACE

1 meter = 39.370 inches
= 3 ft. 3.370 inches
= 1 yd. 3.370 inches

1 inch = 0.0254 M. = 2.54 cm.
1 ft. = 30.48 cm.
1 yd. = 91.440 cm.

CAPACITY (United States)

1 cc. = 16.23 ♏
1 L. = 33.815 fl ℥
= 2.113 pts.
= 0.2642 gal.

1 ♏ = 0.06161 cc.
1 fl ʒ = 3.7 cc.
1 fl ℥ = 29.574 cc.
1 pt. = 0.4731 L.
1 gal. = 3.7854 L.

CAPACITY (British)

1 L. = 1.760 pints
= 0.2209 gallons

1 pint = 0.5679 L.
1 gallon = 4.5435 L.

WEIGHT

1 mg. = 1/65 gr.
1 Gm. = 15.432 gr.
= 0.03527 oz. Av.
= 0.03110 ℥ Troy.
1 Kg. = 2.2046 lb. Av.

1 gr. = 64.8 mg. = 0.0648 Gm.
1 ʒ = 3.888 Gm.
1 oz. Av. = 28.3495 Gm.
1 ℥ Troy = 31.1035 Gm.
1 lb. = 0.4536 Kg.

---

[1] The size of a drop varies according to the nature of the fluid and of the container; there may be from 50 to 150 to a fluidrachm. The U.S.P. specifies a standard dropper "adjusted to deliver 20 drops of distilled water weighing 1 Gm. at a temperature of 15° C." This would deliver about three times as many drops of alcohol, and about five times as many of ether or chloroform, per cc. Drops are indefinite and inaccurate with a standard dropper.

[2] Really from ½ to 2 fl ʒ.

[3] As a matter of fact, the actual capacity of teaspoons averages 5 cc. when filled level (Wilbert, 1905).

COLORING AND FLAVORING

These are used to make medicines more agreeable. Children may need to be bribed, but for adults it may suffice to remove the repulsive features so far as feasible, and this can generally be accomplished by relatively simple means. The most important of these is the form of administration. Small doses of powders may be given in capsules or tablets or in a spoonful of jelly. Large doses may be taken with cereal or in thick soup. The taste of water-soluble drugs is often best improved by simple solution, in half a tumbler or a tumblerful of water or mineral water, quickly swallowed and followed by a draught of cold water; or they may be taken in milk, tea or soup.

COLORING

Liquid prescriptions intended for internal administration should be clear if possible. The appearance may sometimes be improved by adding a coloring matter, which may prove useful through its suggestive element. The coloring agent must vary according to the nature, and especially the reaction, of the mixture. The usual colors for internal use are red, brown, and yellow. Aniline dyes should be avoided, except methylene blue and gentian violet for external preparations, and eosin, fluorescein and indigocarmine for identification, for instance, for local anesthetics.

The most useful pharmaceutical coloring agents[1] are:

For Red or Pink: *Solution of Amaranth*, U.S.P., a 1 per cent aqueous solution of amaranth, trisodium naphthol sulfonic acid, a synthetic vivid red dye, not changed by acids, intensified by sodium hydroxide.—*Tinct. Cudbear* (Tr. Persion, N.F.); red in neutral or acid, violet in alkaline solution. Used in proportion of about 1.5 per cent. Prepared from a lichen allied to litmus.—*Tinct. Cardamom Compound* (Tr. Cardam. Co., U.S.P.); colored with Cochineal; 50 per cent alcohol.—*Carmine Solution* (Liq. Carmin., N.F.); pink to deep red in alkaline solution (used in proportion of about 1 per cent), incompatible with acids. *Carmine* is used in powders, etc. (1:500). It is prepared from *Cochineal* (Coccus, U.S.P.), a dried scale-insect.—*Red Saunders* (Santalum Rubrum, U.S.P.), a wood, is used in Comp. Tinct. Lavender.

For Brown: *Fldext. or Elixir of Glycyrrhiza* (Licorice) (U.S.P.); not suitable for acids.—*Caramel* (Carbonized Sugar) (N.F.). Commercial caramel is generally made by heating glucose with a little alkali until the sweet taste is destroyed and a uniform dark mass results. It is probably a complex mixture. Caramel from cane sugar, according to Stolle, 1899, is a single substance, $C_{12}H_{18}O_9$, formed by the elimination of two molecules of water from sucrose. Caramel has been tried in diabetes, being apparently well tolerated (Grafe, 1914; Umber, 1915).

For Yellow: *Tinct. Hydrastis* (Tr. Hydrast., N.F.), or *Tr. Curcuma* (Turmeric); about 1 per cent. Tr. Curcuma precipitates with water, but sufficient remains in solution to impart a yellow color. An infusion of the root of Curcuma longa is used by West African natives to treat jaundice (G. W. Harley, 1941).—*Saffron* (Crocus, N.F.) has been used as abortifacient, but it apparently lacks this action and is practically nontoxic (Cevidalli, 1914). It is but slightly toxic to mice (Zipf and Bernebée-Jay, 1936)

FLAVORING

Suitable flavoring secures more effective cooperation of the patient and may be necessary to obtain the retention of the medicine in the stomach.

Patients may fail to take a disagreeable medicine, and the physician should be on the lookout for such cases. He may approximately control the amount taken by judging as to the quantity left in the container. If the patient carries the deceit further and pours away the appropriate amount of the medicine, and if the physician does not obtain the anticipated results, it may be well to prescribe some test medicine, such as salol (0.3 Gm.) or sodium iodide (0.5 Gm.), which can be detected in the urine.

The taste of liquid medicines may be improved by dilution, sweetening, demulcents, aromatics, alcoholics, acids, bitters and drugs which paralyze the taste endings. Several of these means may be combined. *Cooling of fluids decreases their taste.* The taste threshold is lowest between 34.5° and 37° C., increasing about a third for each 5° below and above this level (Hahn and Günther, 1932).

Simple dilution is often most effective for substances with disagreeable but not very intensive tastes, such as salts, alkalis and most hypnotics. These should be taken in a half-glass or glass of water, milk, tea or carbonated water. Flavoring syrups, which are usually prescribed as one or two teaspoonfuls, are diluted with water "to taste" at the time of taking.

---

[1] The preparations of each class are generally arranged alphabetically under the crude drugs. The important preparations, which the student is expected to study, are marked.* In addition to these, he should glance over the descriptions of the corresponding crude drugs.

"U.S.P." stands for preparations official in the United States Pharmacopoeia; "B.P.," British Pharmacopoeia; "N.N.R.," New and Nonofficial Remedies; "N.F.," National Formulary; "B.P.C.," British Pharmaceutic Codex.

The following abbreviations are used in connection with solubilities. Alc. = alcohol; glyc. = glycerin; eth. = ether; chlorof. = chloroform. The figures refer to the part of the solvent required to dissolve 1 part of drug (*f. i.*, 1:0.5 = 1 part of drug dissolves in 0.5 part of solvent). The solubilities refer to 25° C. (room temperature), unless otherwise stated.

The Most Important Flavors.—The following will be found to be generally sufficient: *To disguise bitter taste:* Aromatics (Tr. Cardamom Co.; Aromatic Elixir; Red Elixir; Orange Syrup; for children, Syr. Glycyrrhiza, Syr. Tolu, Anise Water, Balsam. *To disguise acrid taste:* Aromatics as above; also syrups, acacia, acid flavors (Syr. Orange). *To disguise salty or alkaline taste:* Dilution with simple, carbonated or aromatic water or milk. *To disguise oily taste:* Aromatics (Oil or Spirit of Peppermint, lemon, orange, wintergreen or almond, according to personal preference). *For insipid drugs:* Aromatics and acids (Syr. Orange).

The popularity of flavors changes from time to time. In a survey of students H. N. Wright, 1937, found the order of preference as follows: highest; Syrup Cacao (chocolate) and Syr. Raspberry, N.F.; then, Syrups of orange, cherry, sarsaparilla, citric acid; least, Syrup of wild cherry, aromatic elixir, and glycyrrhiza.

Incompatibles.—Fruit syrups are discolored by alkalis, even by methenamine or sodium citrate.

SWEETENING AGENTS

The property of sweetness, like that of bitterness, is found in a variety of substances. It is a common characteristic of the sugars, which differ, however, in degree. The otherwise rather inert saccharin has most intense sweetening power. Licorice owes its taste to a glucoside, glycyrrhizin, which is sweet in alkaline, but not in acid liquids. Other substances of sweet taste are glycerol and chloroform. Although all these are "sweet," there are qualitative as well as quantitative distinctions in their taste. Attempts to connect sweetness with the chemic structure have not been very successful (C. J. Carr *et al.*, 1936).

The usual agent for sweetening liquids is sucrose, in the form of its saturated watery solution or "syrup." This is improved by the presence of flavors with more distinctive taste, such as glycyrrhiza, tolu, and orange; or a mixture of aromatics and alcohol, as in the Aromatic Elixir. Honey, fruit syrups, jams and jellies are flavors that can be added in the household. Saccharin is used for diabetic patients, and in pill coating. Powders may be sweetened with lactose, which also assists in grinding the powders because of its hardness. Sugars are foods, and dextrose and levulose, lactose and maltose will be described in that connection.

Intensity of Sweetening Power.—If that of sucrose is taken as 1, then levulose is about 1¾; glucose, ¾; maltose and galactose, ⅓; lactose, ⅙ (Beister *et al.*, 1925). The ratios differ somewhat for individuals and alter with the *concentration.* This increases the sweetness of fructose more than of sucrose. Glucose and sucrose together give a sweeter taste than the sum of their separate sweetness (A. T. Cameron, 1943). The sweetness of various substances and their mixtures is reported by Cameron, 1945.

Taste Blindness—Phenylthiocarbamide.—Crystals of this and other thiocarbamides are intensely bitter to some persons; to others they taste sour or peppery or astringent; to others again they are tasteless. The "dual taste reaction" accompanies the grouping: —NH=C=S (C. Y. Hopkins, 1942). A. F. Blakeslee and Salmon, and independently L. H. Synder, found that the nontaste is a recessive Mendelian character. The difference is quantitative, for saturated solutions are bitter also to nontasters. The crystals are less tasted partly because of different solubility in different salivas. There is no close relation to the acuity of the bitter taste of quinine or picric acid (which also show wide variations), nor is there any relation to the appreciation of acid or sweet taste, or odors. The differences illustrate that "different people live in different worlds, therefore, so far as their sensory reactions are concerned" (A. F. Blakeslee, 1931).—Phenylthiocarbamide produces pulmonary edema in rats (Richter and Clisby, 1942; see Index).

PREPARATIONS.—*Syrup of Citric Acid,* U.S.P. (Syr. Acidi Citrici), a 1 per cent solution flavored with Tincture of Lemon, an alcoholic extract of fresh Lemon Peel.

***Aromatic Elixir,** U.S.P. (Elix. Aromaticum; Simple Elixir), a syrup containing about 23 per cent of alcohol and flavored with aromatics (Comp. Spir. Orange).

***Syrup of Orange,** U.S.P. (Syr. Aurantii), flavored with tincture of sweet orange peel and contains *one half per cent of citric acid.*

***Fluidextract of Glycyrrhiza,** U.S.P. (Fldext. Glycyrrhizae; Fluidextract of Licorice Root), a watery extract of *glycyrrhiza* (licorice root), the dried rhizome and roots of varieties of Glycyrrhiza glabra. It is extracted with hot water; a small quantity of ammonia is added to increase the solubility of the sweet principle, *Glycyrrhizin,* which is incompatible with acids. The solution is evaporated and mixed with alcohol to about 22 per cent by volume. Dose, 2 cc., ½ drachm.—*Syrup of Glycyrrhiza,* U.S.P., is a mixture of one part of the fluidextract with three parts of syrup and small amounts of oils of anise and fennel. It is a good vehicle for quinine and other bitter substances.—*Elixir of Glycyrrhiza,* N.F., consists of one part of the fluidextract and seven parts of Aromatic elixir.

***Syrup,** U.S.P. (Syrupus; Sirup, Simple Syrup), is a concentrated aqueous solution of sucrose containing 85 Gm. per 100 cc. of syrup. *Sucrose,* U.S.P. Saccharum, Sugar, from cane or beets or other sources, is very sol. in water (1:0.5) and slightly sol. in alc. (1:170). Used for sweetening powders, for the administration of volatile oils (oleosacchara), for preparation of syrups, elixirs, etc. Simple syrup is miscible with water or alcohol. Official flavoring syrups include syrup of Citric Acid, Glycyrrhiza, Orange, Orange Flowers, Sarsaparilla Compound (used especially for potassium iodide), Tolu Balsam, Wild Cherry (bark).

SACCHARIN

This substance, $C_6H_4{\cdot}SO_2{\cdot}CO{\cdot}NH$, sold also under various trade names, is the anhydride of ortho-sulfamido-benzoic acid (the para-isomer is not sweet). In common with a number of other benzene derivatives, it has an intensely sweet taste, even in very dilute solutions. It passes through the body almost quantitatively unchanged, 75 to 90 per cent being excreted by the urine within twenty-four hours, and the remainder in the feces. Consequently it has a very low toxicity. Its administration in amounts fifty times those ordinarily taken as sugar substitute does not produce any significant effects (Lehmann, 1890). The only objectionable feature is a disagreeable sweet or bitter aftertaste, noticeable generally only with large doses or by especially susceptible individuals (Pavy, 1888). It increases gastric acidity, but not sufficiently to be contraindicated in hyperchlorhydria or duodenal ulcers (H. Staub, 1937).

Small doses, up to 0.3 Gm. per day, continued for months, produce no deleterious effects, so far as ascertainable by available methods of investigation. Large doses, 0.75 to 1.5 Gm. per day, are also practically harmless, except for occasional minor disturbances of digestion (Herter and Folin, 1911). Single doses of 5 Gm. have been given without much effect (Adduco and Mosso, 1887). With 5 to 25 Gm. per day, or 100 Gm. as one dose, there may be anorexia, intestinal irritation and diarrhea, but no more than with equal doses of table salt (review, H. Staub, 1937). Lehmann, 1929, raised three generations of mice on a diet containing saccharin corresponding to about 13 Gm. for man per day.

Uses.—Saccharin is used as a substitute for sugar in diabetes (tablets of 0.003 Gm., ½ grain, replace an ordinary lump of sugar); as flavoring agent and adulterant of sweet foods; and as a mild antiseptic in fermentative dyspepsia (0.2 Gm., 3 grains, several times daily). Saccharin itself is but little soluble in water, but its sodium salt, "*soluble saccharin,*" dissolves readily. It may be prepared by adding ½ part of sodium bicarbonate.

The sweetening power is 300 to 500 times as great as that of cane sugar. It is perceptible in dilutions of 1:100,000; 1:10,000 is agreeably sweet; with 1:1000 it becomes bitter and disagreeable. Even with the more dilute solutions the quality of the taste is somewhat different from that of sugar, and on continued use the persistent aftertaste becomes objectionable.

Effects of Continued Use.—Long-continued and detailed investigations were made for the Referee Board by Herter and Folin, 1911; Herter administered the sodium salt, Folin the free saccharin, in "small" doses to 0.3 Gm. per day, and "large" doses of 0.75 to 1.5 Gm., corresponding in sweetening power to 150 Gm. and to 375 to 750 Gm. of cane sugar respectively. The small doses produced no discoverable effects. The large doses were also negative except that occasionally there were slight hyperacidity and indications of slight increase of intestinal putrefaction. *In vitro*, the efficiency of all the digestive ferments is not altered by the concentrations which might occur in the body (except by the acidity of free saccharin, a factor which had been neglected in some of the earlier investigations). The *antiseptic action* is slight. The older literature contains reports of digestive and other disorders, especially after continued use (v. Jaksch); but these observations were not made with the same degree of accuracy.

The toxicity for animals is very low (Adduco and Mosso, 1887). Matthews and McGuigan observed depression, stupor, convulsions and nephritis. Herter, administering soluble saccharin to rabbits by stomach, found no effects with 4 to 5 Gm. per kilogram; double this dose was fatal in two hours, the autopsy showing violent gastrointestinal irritation. Kusaka, 1926, claimed to have produced gastroenteritis in rabbits; and central paralytic effects and chronic toxic phenomena in rabbits and mice.

Saccharin for Measurement of the Circulation Time.—This may be gaged by the time of the appearance of sweet taste after a solution of soluble saccharin is injected into the cubital vein: Three Gm. are dissolved in 3 cc. of warm water, and 2.5 cc. injected as rapidly as possible The taste is normally noted in 8 to 16 seconds (A. M. Fishberg *et al.*, 1933). Care must be taken that the solution does not escape into the subcutaneous tissue, as its alkalinity produces necrosis (Leinoff, 1935).

Use of Saccharin in Foods.—No serious damage need be apprehended from the quantities of saccharin which would ordinarily be used. The peculiar taste may become repulsive and diminish appetite. For this reason and because saccharin has no food value, its indiscriminate use as a sweetening agent should be condemned, except in cases in which sugar is inadmissible.

PREPARATIONS.—***Saccharin Sodium,** U.S.P. (Saccharinum Solubile; Soluble Gluside, Soluble Benzosulfinide), occurs as colorless prisms or white, crystalline, odorless powder; very sol. in water (1:1.5) and alc. (1:50). *Saccharin* is less sol. in water (1:290), more sol. in alc. (1:31), and easily sol. in alkalis. Dose, 60 mg. have the sweetening power of 30 Gm. of sucrose as sweetening agent in diabetes, etc., 1:10,000 (0.1 Gm. per liter, 1/20 grain per ounce); or 0.03 Gm., ½ grain, in place of an ordinary lump of sugar. *Saccharin Sodium Tablets*, U.S.P., are usually available as 15, 30 and 60 mg. (¼, ½ and 1 grain).

AROMATIC WATERS, SPIRITS, OILS AND TINCTURES

Aromatic Waters are miscible with water or alcohol. Their dose is ad libitum. *Aromatic Spirits* are used in alcoholic and oily liquids, in the proportion of 2 per cent. They are immiscible with water. *Aromatic Oils* may be used for flavoring alcoholic or oily liquids, in the proportion of 0.2 per cent The spirits, however, are generally preferred. *Aromatic Tinctures* are used like the spirits. None of the simple tinctures are especially important.

Preparations.—***Compound Tincture of Cardamom,** U.S.P. (Tr. Cardamomi Composita), is flavored with cardamom, cinnamon and caraway; colored red by cochineal; and contains about 45 per cent alcohol. Dose, 4 cc., 1 drachm.

***Cinnamon Water,** U.S.P. (Aq. Cinnamomi), is a saturated solution of cinnamon oil (water distilled from the bark, B.P.). Dose, 15 cc., 4 drachms.

***Peppermint Water,** U.S.P. (Aq. Menthae Piperitae), is a saturated solution of the oil of peppermint. Dose, 15 cc., 4 drachms.

***Rose Water,** U.S.P. (Aq. Rosae), is a half saturated watery distillate of the fresh flowers of Rosa centifolia; used to perfume lotions, etc.

ERIODICTYON (YERBA SANTA)

Extracts of the leaves of this plant disguise bitter taste (not sweet, salt or acid taste). Fantus *et al.*, 1933, attribute this to the adsorption of basic alkaloids; but it is said to be effective also against neutral principles. One cc. of the fluidextract covers the taste of 0.012 Gm. of quinine sulfate or 1.5 Gm. of quassia. It is incompatible with acids and with excess of alkali. Its tannic acid discolors with iron salts.

Preparations.—*Eriodictyon,* U.S.P. (Yerba Santa) consists of the dried leaves of Eriodictyon californicum. Used as the fluidextract in a dose of 1 cc., 15 minims; precipitated by water.

Other plants which suppress taste are: Gymnema sylvestre; Bulmenia dulcifica, and Phrynium Danieli. They are not practically effective.

Gymnema.—The leaves of this plant contain gymnemic acid, which destroys bitter and sweet taste, not acid or salt. The paralysis of sweet taste lasts for two hours. Gymnema has been used in *diabetes mellitus.* R. N. Chopra, Bose and Chatterjee, 1928, reported that it has no effect on the blood sugar; but Maskar and Caius, 1930, who studied its constituents and activities, claim that it produces hypoglycemia, which they attribute to increased production of insulin by the pancreas.

◆

SOLUBILITIES

The following compilations of the solubility of the substances usually prescribed may be found useful. A knowledge of analytical chemistry and of incompatibilities can be utilized, for a substance appearing as a precipitate is, of course, relatively insoluble.

GENERAL SOLUBILITY OF COMMUNLY USED SALTS IN WATER

I. Arranged by Acids.

Group A: Salts Mostly Soluble.

1. *Acetates and Nitrates:* all soluble (except bismuth subnitrate).
2. *Halogen group* (= iodides, bromides, and chlorides): Soluble except Ag; Hg (ous); Pb; Bi.
3. *Sulfates:* Soluble, except Pb, Sr, Ba; Ca sparingly soluble.
4. *Tartrates and Citrates:* mostly soluble.

Group B: Salts Mostly Insoluble.

1. *Arsenates*
Arsenites
Carbonates
Hydrates
(Ca sparingly soluble)
Oxides
Oxalates
Borates
Phosphates

} Insoluble, except those of alkali metals.

II. Arranged by Base.

The salts considered in this table are: Acetates (Ac), Halogens (H), Oxides (O), Sulfates (SO_4), Phosphates (PO_4), Oxalates (Ox), Carbonates (CO_3), Sulfides (S), Nitrates (NO_3), Citrates (Ci). Hydrates agree with oxides.

Those of the above salts which are *not mentioned* with the respective base are *insoluble.*

1. *Alkali Metals* (= Na, K, NH_4): all soluble.
2. *Lithium:* Soluble, except O and CO_3, sparingly soluble, and PO_4, insoluble.
3. *Mg, Al:* Soluble: NO_3, Ac, H, Ci, SO_4, S.
4. *Ca, Ba, Sr:* Soluble: NO_3, Ac, H, Ci, S; sparingly: O.
5. *Zn, Mn, Ni, Co, Fe, Hg(ic), Cu, Sn:* Soluble: NO_3, H, Ci, SO_4 (mercuric iodide is insoluble).
6. *Ag:* Soluble: NO_3, SO_4.
7. *Pb:* Soluble: NO_3, Ac.
8. *Bi, Sb:* Only soluble in form of double organic salts, *e. g.,* Bismuth and Ammonium Citrate, Antimony and Potassium Tartrate.
9. *Mercurous:* Insoluble.

Strength of Watery Solution.—The following table gives the amount of commonly used drugs which can be *safely prescribed in water enough to make 100 cc.* These should be memorized:

50 per cent, or grams: (= ʒiv in water q.s. ℥j) Tannin; Antipyrine; Acetate, Citrate, Salicylate, Iodide or Bromide of Potassium or Sodium; $AgNO_3$; $ZnSO_4$; Chloral; Cocaine Hydrochloride.

5 per cent, or grams: (= 25 grains in water q.s. ℥j) Alum; Phenol; Borax; $KClO_3$; $NaHCO_3$; $HgCl_2$; Tartar Emetic; Quinine Bisulfate; Citrated Caffeine; the majority of the soluble salts of alkalis, earths and metals.

Smaller quantities: 4 to 0.1 per cent: Boric Acid, 4; Morphine Sulfate, 4.5; Quinine Hydrochloride, 3; Quinine Sulfate, 0.13; Strychnine Sulfate, 2.

(It must be remembered that where several salts are prescribed in the same mixture, the solubility of each of these salts may be lowered.)

Solubility in Different Media.—As a general rule, *inorganic substances* are more soluble in water than in alcohol.

Basic alkaloids are insoluble in water, more soluble in alcohol.

Alkaloidal salts are soluble in either alcohol or water.

Gums are soluble in water, insoluble in alcohol. *Resins* and *essential oils* are the reverse.

(In making mixtures, it must be remembered that spirits, tinctures and fluidextracts all contain alcohol.)

Glycerin stands intermediate between alcohol and water as a solvent.

The following substances are much more soluble in glycerin than in water: Boric acid, alum, phenol, mercuric chloride.

Terms Used in Defining Solubility.—The following terms are employed in the U.S.P. to describe the approximate solubility, which is often sufficient for prescribing. Substances that are soluble in less than 1 part of solvent = very soluble. From 1 to 10 parts of solvent = freely soluble. From 10 to 30 parts of solvent = soluble. From 30 to 100 parts of solvent = sparingly soluble. From 100 to 1000 parts of solvent = slightly soluble. From 1000 to 10,000 parts of solvent = very slightly soluble. More than 10,000 parts of solvent = practically insoluble.

Official Solubilities.—The U.S.P. and B.P. state the solubility of articles as grams of substance to cubic centimeters of solvent; *i. e.*, a solubility of 1:10 means that 1 Gm. of substance requires 10 cc. of solvent for solution, at the standard room temperature, 25° C., 77° F., U.S.P.; 15.5° C., 60° F., B.P. The standards given in this book are those of the U.S.P. In percentage solutions, 10 per cent signifies that 100 cc. of solution contain 10 Gm. or cc. of the substance.— **Specific gravities** in the U.S.P. are taken at 25° C. unless otherwise stated (for instance, alcohol at 15.56° C.).

INCOMPATIBILITY

In the following compilation it has been attempted to arrange the incompatibilities into general groups. In this generalization it is not feasible to take account of individual exceptions. Care has been taken to err on the safe side. It is much more important for the physician to remember that mercuric chloride is generally incompatible with alkaloids than it is to know that it may be prescribed with some. In any case, if one is not certain that two substances will get along well together, it is safer to keep them apart.

Incompatibility is said to exist *when the constituents of a mixture interfere with one another in a way not intended by the prescriber.* If an interference is intentional, it is called an *intentional incompatibility.* If a chemical change occurs, the incompatibility is called *chemical.* When it consists in a precipitation of the substance by a change in the solvent, or when a chemic incompatibility does not interfere with the active substance, but produces an unsightly appearance, the incompatibility is *pharmaceutic.* If the interference is with the solubility, or if liquefaction or deliquescence occurs, the incompatibility is *mechanical* or *physical.* When without causing any chemic changes it interferes with the physiologic action of the ingredients, it is *therapeutic.*

Chemic incompatibility may result in explosion, precipitation, or the production of new substances with undesired properties. This is an application of the ordinary chemic reactions, and when the latter have been mastered, the subject is comparatively easy. *Substances used in testing for each other or that form antidotes are usually incompatible.*

Explosives.—Powerful oxidizing agents are liable to explode when mixed in concentrated form with easily oxidizable substances. *The most important oxidizing agents are:* chromic acid; concentrated nitric acid and nitrates; permanganates; chlorates; peroxides. *The most important oxidizable substances are:* all organic substances; sulfur, sulfides, sulfites and hyposulfites; iodine and iodides; phosphorus, phosphites and hypophosphites; reduced iron. Explosions may also result from mixing iodine with ammonia or turpentine; and chlorine with ammonium chloride. Explosions occur only when the substances are dry or at least concentrated, and when they are heated or percussed. *Dilute solutions* may be mixed without danger if not heated. Glycerin, phenol, and in some cases alcohol, behave like dry solids. Permanganate of potash or chromic acid or nitrate of silver decompose organic substances even in solution, but in this case without explosion.

Pills containing these easily decomposed substances are best made with inorganic excipient, clay and petroleum jelly.

Substances containing loosely combined oxygen may explode on concussion or heating when no reducing substances have been added; this is due to their containing dust or other organic matter. They should therefore be handled with care.

Gradual evolution of gas occurs especially on mixing acids with carbonates or sulfides; also when mixing strong acids with alcohols (= esters) or with chlorate (= Cl); also on mixing strong HCl and HNO_3. Formaldehyde effervesces copiously with oxidizing substances even in solution (hydrogen peroxide).

Incompatibility by Precipitation.—*Alkalis* precipitate earths, metals and alkaloids from their salts. Under alkalis may be included oxides, hydroxides, carbonates, phosphates, borates, arsenates and arsenites. *Chlorides, bromides and iodides* precipitate salts of Ag, Pb and some alkaloids. Iodide also precipitates mercuric salts, redissolving with an excess. *Sulfates* precipitate Pb, Ca and the other earthy metals, except Mg. *Salicylates, phenol and tannic acid* precipitate or color iron salts. Tannic acid also precipitates most other metals, alkaloids, and some glucosides and neutral principles. Salicylates precipitate quinine. *Salts of metals* are precipitated by alkalis, sulfides, tannic acid and proteins. They precipitate some alkaloids and acacia. *Mercuric salts* are often incompatible with other metals. *Silver and lead salts* are precipitated by chlorides, bromides and iodides. *Silver salts* are also incompatible with organic substances. *Iron salts* are colored by tannic acid, salicylate and phenol. *Calcium salts* are precipitated by alkalis, phosphates and sulfates; *magnesium salts* by alkalis and phosphates. *Alkaloid salts* and synthetic bases (antipyrine, etc.) are precipitated by alkalis, tannic acid, iodine, potassium-mercuric iodide, and some by iodides or metallic salts. *Acacia* is precipitated by alcohol, borax, Tr. Ferri Chlor.

Production of Substances with Undesired Qualities.—*Iodides* liberate iodine on the addition of acid and oxidizing agents, including H_2O_2, nitrites, salicylic acid, etc. They oxidize mercurous to the dangerous mercuric salts. *Chlorates* liberate chlorine with concentrated acids. *Chloral* liberates chloroform with alkalis. *Glucosides* (*f. i.* glycyrrhizin) are destroyed by acids.

Pharmaceutic Incompatibilities.—*Alcohol* should not be added to acacia, gelatin, proteins, emulsions, strong salt solutions. *Water* should not be added to alcoholic liquids in general (such as tinctures, spirits, fluidextracts, with some exceptions); or to ethereal liquids (oleoresins) or oils. Phenol should not be mixed with collodion. *Liquefaction* occurs when chloral is rubbed with camphor, menthol, phenol, salol, etc. Any of these, when rubbed together, or with coaltar antipyretics, are likely to liquefy.

Especially Incompatible Drugs.—The following are most likely to give incompatibilities, and combinations should therefore be scrutinized with special care: Acids, alkalis and carbonates; permanganates; iodides; salicylates; mercury, iron, silver and lead salts; tannic acid; alkaloids; methenamine.

◆

THE ADMINISTRATION OF DRUGS

The methods of administering drugs vary according to whether a strictly local action is desired, or whether it is aimed to have a drug distributed through the body, to secure "systemic effects." Local applications may have the object of protecting a surface or producing reflex effects; or they may be used as antiseptics or local stimulants; or for absorption and systemic actions.

METHODS USED CHIEFLY FOR SYSTEMIC EFFECTS

These require that the introduction or absorption of the drug should be sufficiently quantitative to insure definitely controllable effects. This condition may be met by the alimentary tract, and by injection under the skin, into the muscles, or directly into the circulation. Gaseous substances are administered by inhalation. Absorption and systemic effects may occur from other surfaces, mucous membranes, serous cavities, etc., which are utilized primarily mainly for local administration. They may then lead to toxic side actions

Oral administration is the most natural, the most ancient and still the most widely used method of administration. Its chief advantages are its convenience to the patient and its relative freedom of local damages. Irritant drugs do give rise, however, to disturbance of digestion, or even to gastritis, especially if they are taken in concentrated form, as in tablets. It can be minimized by giving them in such a form that they will not be rapidly dissolved in the stomach (pills), or by giving them at a time when the stomach is filled with food. Absorption is, of course, also delayed by these means. *Pills* should not be employed for insoluble powders or for corrosive drugs which require dilution.

Absorption from Alimentary Canal.—The absorbing power of the *stomach* is relatively low, even for water and soluble substances (Hirsch, 1892), so that the main absorption does not occur until the drug has reached the small intestines. The effects are therefore relatively slow and may be too slow for emergencies. The maximal concentration of soluble substances in the blood is generally reached in one-half to one and a half hours after their oral administration. The passage is quickest if the drug is taken when fasting and with water; somewhat slower with milk or soup; slowest after eating, especially when administered dry (Moritz, 1898). The conditions in the *small intestines* are favorable for absorption, which is aided by the long sojourn, the segmental movements, the extensive surface, the folds and villi. The *absorption of alkaloids* from the stomach is impeded by its acid reaction, and hastened as much as a hundred times by alkalinization. In the duodenum, they are well absorbed even with acid reaction, due partly to the presence of bile salts (J. Travell, 1938, 1940). Absorption from the intestines becomes progressively slowed if the solution remains in continuous contact (J. C. Andrews and Cornatzer, 1945).—Intestinal absorption (of galactose) is impaired in deficiency diseases such as pellagra, sprue, riboflavin deficiency and pernicious anemia (A. J. Beams, Free, and Glenn, 1942).

The Time of Administration.—Hypnotics and cathartics are most effective when their action coincides with the natural time of sleep and defecation, and if the external conditions are favorable. Stomachics are best given shortly before meals. If the drug is intended to act locally on the gastric mucosa, or if it is to be absorbed rapidly, it should be administered when the stomach is empty, half an hour or an hour before meals. Hot liquids favor absorption. Irritants are administered just after meals, when the stomach is protected by food. This is also the best time for securing slow and continuous systemic action. For intestinal action, the administration should be timed for the emptying of the stomach, two or three hours after the meal; this is also the best time for substances that cause offensive eructations.

Alterations of Drugs in the Alimentary Canal.—Some drugs (for instance, the antitoxins, insulin, epinephrine and arsphenamine) are destroyed so extensively in their passage through the intestines that oral administration is not sufficiently effective. Glucosides are partly destroyed, so that the oral dose must be larger. Drugs which require the action of the digestive juices for their solution (resins, oils, etc.) are more efficient by mouth than by other channels. The oral route must be used for drugs intended to act locally on the upper parts of the digestive tract. Absorbable drugs are apt to act on the intestine more powerfully when they are administered by vein than when they are taken by mouth (Uhlmann and Zwick, 1920).

Sublingual Absorption.—The under side of the tongue absorbs quite well and avoids destruction by digestion and the liver. "Hypodermic" or other friable tablets may be held under the tongue, swallowing being avoided until the taste of the drug has disappeared. Liquids may be dropped on a pellet of cotton (W. Paulson, 1916). The method is valuable for glyceryl trinitrate. The steroid sex hormones are absorbed materially better than when swallowed. In general, the sublingual absorption parallels the oil:water solubility coefficient; but alkaloidal salts are not absorbed materially better than the free alkaloids (R. P. Walton, 1944). The sublingual route is not sufficiently effective for alkaloids to offset the objectionable taste (Walton and Lacey, 1935).

Rectal Administration.—The stomach and small intestine may be avoided by giving the drugs per rectum, either in the form of enema or suppositories. The rectum and colon absorb many soluble substances; and the effects are often greater or more prompt than with oral administration (for alkaloids, salts, narcotics, etc.; and for sodium salicylate or iodide, chloral, methylene blue, atropine and morphine, Enesco *et al.*, 1939).

Enemas for the absorption of the medicine should be as small as possible, but not so strong as to produce local irritant effects. One or 2 ounces is usually the proper quantity, the rectum being first cleansed with warm water. When enemas are employed for their mechanical effect, the amount must be 1 or 2 pints. These should be raised to the body temperature. Rectal injections, after they have passed the internal sphincter, spread quite rapidly through the whole *colon*, where absorption chiefly occurs. Observations on colostomized patients show absorption of glucose, sucrose, methylene blue, atropine, neoarsphenamine. The colon does not excrete methylene blue, glucose or sucrose (Curry and Bargen, 1935). *Rectal absorption* is materially increased by the injection of ether or alcohol (Albi and Boyd, 1931).

Subcutaneous or Hypodermic Administration.—The injection of solutions through a hollow needle into the loose subcutaneous tissue has the advantage of securing quicker and more certain effects, and more exact dosage. Their absorption occurs chiefly through the capillaries and only slightly by the lymphatics. Hypodermic injections are generally made into the forearm, arm, thigh or nates. For bulky injections, *e. g.*, for antitoxin or for saline solution, the loose areolar tissue of the subscapular or mammary region is chosen. The subcutaneous dose may often be made somewhat smaller than the oral dose. The *rapidity of absorption* from hypodermic injections may be hastened by massage, by distributing the injection over several places, and by dissolving the drug in a *small* amount of fluid. The total concentration in salts should not exceed that of the blood, or the injection will be painful. Normal saline solution is the least irritant solvent for alkaloids. *Alkalinization* promotes the absorption of alkaloids (J. Travell, 1940). The absorption of histamine and other drugs (penicillin) may be greatly slowed by injecting them in a *beeswax and mineral oil* mixture, so that the effects of a single dose may last for days (C. F. Code and Varco, 1940). Subcutaneous injection is inadmissible if *local* effects in other parts of the body are desired (*e. g.*, for stomachics, cathartics, locally acting emetics, etc.). *Edematous areas* absorb poorly. The hypodermic injection of drugs that are not local irritants produces little discomfort and no after-effects, provided that reasonable asepsis is preserved. *Irritant drugs* cause severe pain and may be followed by induration, sloughing and abscess. This holds true also of oils, especially mineral oils (Budai, 1922). Hypodermic injection was probably first practiced by E. Rynd, 1844, but was introduced practically by Alex. W. Wood in 1853. Pravaz invented his syringe in 1853 for the injection of aneurisms (Macht, 1916).

Intramuscular injections are made by thrusting the needle through the skin deep into the substance of the gluteal or lumbar muscles, where the fluid spreads out between the fibers and along the fasciae, giving a large absorbing surface relatively poor in sensory nerves, so that absorption is more rapid and pain less than when injections are made into the subcutaneous areolar tissue. There is also less chance of abscess formation (Claude Bernard, "Les Anésthesiques," p. 70; Meltzer and Auer, 1904). Watery solutions spread rapidly during injection; oily and viscid fluids first form a globule, with local trauma of the muscle, and then spread slowly for five or ten minutes along the fasciae. After this time there is little further spreading (W. F. von Oettingen, Todd and Sollmann, 1927). The spreading is much more extensive for solutions than for viscid suspensions (L. W. Shaffer, 1929). Relatively insoluble powders suspended in oil may be injected intramuscularly to establish a depot for the gradual absorption and continued action of a drug, such as bismuth or mercury salicylate in the treatment of syphilis. If the injected material is irritant, directly or by solution in the lymph, there may be considerable local necrosis. Insoluble material that is not absorbed becomes encapsulated. Mineral oils must not be injected under the skin, as they are not absorbed and give rise to tumors.

Fatty oils when injected intramuscularly into rats become encapsulated in a few days, forming oil cysts which may remain for some months and which often form abscesses, especially with almond oil. With hypodermic injections, the oil globules generally disappear without cyst or abscess formation (Emery and Matthews, 1943).

For *ambulatory* patients, intramuscular injections are usually made into the gluteal muscles, through a 2 to 2½ inch needle inserted near the center of the buttocks, somewhat toward the upper and outer quadrant, to avoid striking the bones or the sciatic nerve. It is important to make certain that the needle is not in a vein. Auer and Meltzer, 1911, advised the sacrospinal muscles in preference to the gluteal, as giving better absorption with less pain and other complications.

Intraperitoneal and intrapleural injections are employed in experimental technic, and resemble subcutaneous injections, the drug being absorbed more rapidly. Intraperitoneal injection was introduced clinically by Schmidt and Meyer (1905). It has a distinct field, especially for the administration of saline or dextrose to infants who offer difficulties for intravenous injection (Aikman, 1920; H. M. Sanford and Heitmeyer, 1928). Irritants should not be used, but neoarsphenamine may be employed. Oil is absorbed slowly (E. W. Schwartze, 1921). The *pleura* absorbs through the parietal and pulmonary surface, but the absorption is less than from the peritoneum (Naegeli, 1913). In both membranes, it occurs by the blood rather than lymph. Gravity plays a part, the absorption being rather better with pelvis-down position (Dandy and Rowntree, 1914). Waddell, 1923, utilized *intrahepatic injections* in place of intravenous injections, for small laboratory animals, *i. e.*, frogs, turtles and rats.

Intravenous Injection.—The injection of aqueous solutions into the blood stream is necessary with a few substances for which other methods are not available; for instance, those that are decomposed in the digestive tract, and those that are not satisfactorily absorbed or that produce irritation from the subcutaneous tissues. Arsphenamine is the most important example. Intravenous administration may also be used in emergencies, to secure immediate action. Aside from such definite indications, intravenous injections should be avoided, for they imply a greater risk to the patient than do the other methods of administration, since injection of a foreign substance into the blood stream alters the equilibrium of its colloids, and this may result in alarming fall of blood pressure and even fatal reactions. These have been called "*speed shock*" (S. Hirschfeld, Hyman and Wanger, 1931), because they are more frequent and more serious if the injection is made rapidly. Slowness of injection reduces the liability of reactions. Substances that are definitely incompatible with blood, such as acids or metallic salts, are especially dangerous; but almost all substances may apparently produce reactions in some individuals, under conditions that are not understood and cannot be foretold (Hanzlik and Karsner, 1920; Hanzlik, de Eds and Tainter, 1925; see index, "Allergic Reactions"). The circulatory congestion arising from rapid injection has been studied in dogs by Yeomans, Porter and Swank, 1943. If the distilled water has been allowed to stand it is likely to become contaminated with pyrogenic spores, causing *febrile reactions*. *Irritant substances* may produce thrombosis, inflammation and fibrosis of the vein; but this results more commonly if irritants escape into the perivascular tissue. Aside from the temporary discomfort, this renders the vein unsuitable for further injections. This may be a serious matter later, should a real occasion for intravenous therapy arise. With many substances accidents are so rare that there should be no hesitation in giving these intravenously, if an emergency demands the immediate effect of the drug, or if the drug can not be given effectively by the less risky channels; but unless special indications such as these do exist, intravenous therapy is not advisable. *Intravenous injections of oil* result in pulmonary embolism, even if the droplets are emulsified so as to be smaller than erythrocytes (Markowitz and Mann, 1930). Injections of air may also be dangerous. Intravenous injections are usually made into the veins of the arm. Varicose veins may be used if others are not available, but are more liable to thrombosis.

Instantaneous action is an important advantage only in emergencies; otherwise it is generally undesirable, especially if continued rather than acute effects are desired. The concentration of the drug during the injection rises materially above the level of the continuous dosage, and may result in brief but stormy reactions that differ in kind as well as in degree from the ordinary actions of the drug. The "primary fall of blood pressure" that is liable to occur with all kinds of intravenous injections has always been an annoying complication to experimenters on animals; it is no less serious in clinical practice. The claim of *exact dosage* is somewhat misleading. Intravenous injection controls the quantity of drug introduced, but exact dosage really means the exact adjustment of the quantity to the desired effect. This may be more difficult with intravenous than with oral administration; for with the latter the physician can begin with a relatively small dose, and add further doses, according to the response of the individual patient. With intravenous injection, such frequent repetitions are usually not practicable, and consequently the dosage is often too large or too small. *Avoidance of gastro-intestinal irritation* is also a rather misleading claim; for the most difficult element of these disturbances is often central, and in that case (for instance, with digitalis) the nausea and emesis are not diminished by intravenous injection. The strictly local irritation can often be avoided by suitable methods of oral administration, for instance, free dilution with water or food, etc. *Intra-arterial injection* is generally less potent than intravenous, as part of the drug is absorbed by the peripheral tissues. The difference is especially marked for epinephrine (Ehrismann, 1928).

Historical.—Intravenous injection was tried rather extensively in the seventeenth century. Claude Bernard (Les Anesthésiques) described it as the ideal method for animals, but considered that it would never become practical and common in clinical medicine. The modern application dates from Landerer, 1881, and F. Mendel, 1908 (history, Epstein, 1915; Macht, 1916; Eggleston, 1917).

Intracardiac injection is used in animals for systemic effects, but clinically exclusively for the resuscitation of the heart by epinephrine (E. Vogt, 1914). The injection is usually made into the ventricle through a 4-inch needle inserted in the 4th intercostal space at the left margin of the sternum. A. S. Hyman, 1930, prefers to inject into the right auricle. The puncture itself probably plays an important part in the stimulation. **Intrapericardial Injections.**—Solutions are quite rapidly absorbed from the pericardial sac into the heart muscle. Gunn and Martin, 1915, suggest that this could be utilized in epinephrine resuscitation. The human *pericardial cavity* permits ready absorption of phenolsulfonephthalein through the subepicardial capillaries: the large molecules of vital red are not absorbed (H. J. Stewart *et al.*, 1938).

Intra-osseous injection by way of the bone marrow, through a needle thrust into the sternum of adults, or the upper third of the tibia or lower third of the femur in children, amounts practically to intravenous injection, reaching the general circulation almost immediately. It can be used when the veins are not accessible (L. M. Tocantins, 1940). Since it may lead to pulmonary embolism (Wile and Schamberg, 1942) it requires experience and is safe only if the technic is good (Tocantins and O'Neill, 1945).

Inhalation is used only for gaseous medicines, such as anesthetics or oxygen. The effects do not depend upon the quantity given, but on the concentration of the gas and the time during which it is administered. The rich capillary area of the alveoli (which in man covers nearly a thousand square feet, 90 square meters; Zuntz) is one of the best absorbing surfaces, so that the action is very rapid. The lungs also absorb fluids and dissolved substances rapidly, if these are introduced through the trachea.

The absorption of fluid from the lungs far surpasses ordinary conceptions: Semmola states that Gobier poured about 30 liters of water into the trachea of a horse. Instead of killing the animal, the water was absorbed. Colin ran a *continuous* stream of warm water into the trachea of a horse, at the rate of six liters per hour: This eventually killed the animal by direct water injury of the lungs and tissues, but no trace of the water was found in the lungs. Dogs received 200 cc., rabbits 30 to 40 cc. of fluid into the trachea without damage. Similar observations are described by Winternitz. One accidental experiment on man was recorded by Bichat. A stomach tube was inadvertently introduced into the trachea, and through it bouillon was poured into the lung and absorbed "without disturbance." If the fluid is injected much more rapidly than it can be absorbed, it will, of course, produce asphyxiation.

Absorption of dissolved substance from the lungs is also rapid. If ferrocyanide in solution is injected into the trachea, it can be demonstrated in the carotid blood in two minutes. Claude Bernard showed that opium alkaloids are much more active by trachea than when injected hypodermically, and suggested clinical utilization of this channel (by piercing the trachea with a hypodermic needle) when the circulation is too low for absorption from other situations.

Absorption of chemotherapeutic substances from inhalation of nebulized sprays was studied by N. Mutch, 1944.

METHODS USED CHIEFLY FOR LOCAL EFFECTS

Practically any method of administration may be utilized either for local or systemic actions, according to circumstances. For instance, subcutaneous injections are used for local anesthesia, and intravenous injections for sclerosing varicose veins.

Intracutaneous (*endermic, intradermal*) *injections*, into the corium (F. W. Taylor, 1938) of the skin (instead of under the skin) are used to provoke local diagnostic skin reactions and for local "infiltration anesthesia." The distance from the blood vessels makes the absorption slower than with hypodermic injections (F. Luithlen, 1926). It is sufficient, however, to produce marked systemic reactions, *e. g.*, to epinephrine. Even solid elements may be gradually absorbed (Kasahara, 1916).

Injections into the Central Nervous System.—*Subarachnoid injections* (subdural, intraspinal, lumbar) are used to secure direct action on the spinal cord or nerve roots, especially for spinal anesthesia, and for colloidal drugs that do not readily penetrate the nervous substance from the blood, such as tetanus antitoxin; and for iodized oil in roentgenography. The technic is that of lumbar puncture, some cerebrospinal fluid being withdrawn before the injection is made. There is often some spinal irritation and the procedure may be dangerous, especially if the poison produces local effects or is conveyed directly to the medulla. The action of drugs on the central nervous system is generally more pronounced if injected into the cerebrospinal fluid, for they penetrate the nervous tissue much more readily from this direction than from the circulation (U. Friedemann, 1942). For instance Lewandowsky, 1900, found that strychnine is ten times as potent when injected intraspinally as when injected intravenously.

The efficiency of the absorption of drugs from subdural injections into the general circulation is in dispute. Becht, 1920, found no systemic effects after subdural injection of epinephrine, nicotine and secretin. He attributes the contrary results of Meltzer and others to direct entrance into veins. The absorption may be modified by inflammation of the meninges (*f. i.*, increased, Carnier, 1916; diminished, Meheteus and West, 1917; unaltered, Stollmann and Swift, 1915). The irritation of arsenicals and mercurials may be somewhat diminished by mixing them with serum. *Subarachnoid irrigation* has been tried experimentally (Weed and Wegeforth, 1919). Normal saline produced toxic effects, but Ringer's solution appeared harmless and prolonged the life of animals with meningeal infection. The spinal cord is especially sensitive to changes of *p*H (Dandy and Blackfan, 1913).

Intracisternal and intracerebral injections have been used experimentally. The injections are at once conveyed to the ventricles and produce local and mechanical effects often different from the systemic action of the drug.

Intraneural injections are used chiefly for direct destruction of the nerve, by alcohol, etc. It has been claimed that solutions injected into peripheral nerve trunks ascend rapidly along their lymph channels into the central nervous system (Hoester and Whitman, 1931); but this has been disputed.

Application to the skin is practiced in the form of ointments and plasters, especially for prolonged contact; liniments, especially for reflex stimulation; watery or alcoholic solutions, watery "washes" or moist dressings, especially for antiseptics; dusting powders; poultices, etc. They are generally intended for local actions, as absorption from the skin is poor and uncertain. It is not negligible, however, and systemic effects sometimes arise when they are not desired. The most important use of the skin for systemic therapy is in mercurial inunction. In this case the ointment is vigorously rubbed into the skin, so as to press the liquid mercury into the hair follicles and gland ducts, where it is gradually changed into absorbable compounds. The lower layers of the skin absorb readily, but the stratum corneum is only slightly permeable to most substances. *Skin absorption* is therefore greater where the epidermis is thin, in the axilla, loins and the inner surface of the arms and thighs. The permeability increases if the epidermis is saturated with water by perspiration, or by occlusive dressings, or alkalis or hydrosulfides. Increased vascularity of the skin favors absorption by carrying away the absorbed drug and thus maintaining a steeper concentration gradient. This would result from active or passive hyperemia, heat, friction, any form of irritation, or massage. Absorption is also increased by keratolytic agents—acetic or salicylic acid, pyrogallol, resorcin—which dissolve the epidermis. It is decreased by astringents, such as tannic acid or formaldehyde (Milbradt, 1933). Oils and ointments delay the absorption of fat-soluble substances, such as phenol, mustard oil or dichlordiethylsulfide, analogous to the partition of a substance between good and poor solvents in a test tube (Sollmann, 1918). The influence of the ointment base differs, therefore, according to the substance (Sauerland, 1912). *The absorbability of different substances* depends on their physico-chemical properties rather than on their chemical constitution. Absorbable substances must be freely soluble in *both* oil and water. Volatility is a favoring factor, by facilitating penetration into the skin glands. Many gases are absorbed quite freely. Low melting point is favorable (Lazarew, 1932). Methods for studying systemic poisoning by absorption through the skin are described by Draize and Lang, 1944. Skin permeability is reviewed by H. O. Calvery *et al.*, 1946.

Baths are used almost exclusively for local and reflex effects. For calculating concentrations, the volume is taken as 200 liters for adults, 50 to 100 liters for children.

Wounds and Ulcers.—Removal of the epidermis facilitates penetration and absorption if the circulation is good, as in recently abraded surfaces, blisters, burns, etc. In older burns and ulcers, the circulation becomes restricted and absorption is poor.

The dental pulp readily absorbs water-soluble and diffusible substances, including alkaloidal salts, but not colloidal solutions, such as snake venoms and insulin; nor epinephrine (Obiglio, 1930).

Applications to Mucous Membranes.—Drugs, especially protectives (demulcents), astringents and antiseptics, may be applied to the mucous membranes for local effects on the surface or for superficial penetration. Radiopaque substances may be applied for Roentgen diagnosis. Mucosae are more or less effective absorbing surfaces (Macht, 1917, 1923) so that systemic actions may develop, and they may be utilized for this purpose. The rapidity of absorption differs considerably; for instance, the urinary bladder absorbs poorly, the urethra very freely. Pathologic changes in the mucous membrane, as by scalding or freezing, impede absorption (Macht, 1933). Mucosae are generally rather sensitive to local irritants, especially the conjunctiva and urethra, so that locally acting drugs are used on these in about a fourth to half the concentration that would be employed on the nasal mucosa; the mouth and vagina are less sensitive and may be treated generally with twice the nasal concentration.

Methods of Application.—Medicines are applied to the mucous membranes by irrigation or by painting; to the respiratory tract by spraying and inhalation.

Irrigation serves chiefly for cleansing and for application of heat, but medicinal agents are often added, especially mild alkalis, sodium bicarbonate or sodium borate for cleansing; or mild astringents and antiseptics, such as boric acid, potassium permanganate, colloidal silver or organic mercury compounds. The time of contact is so short that real antisepsis cannot be expected. This is slight even when some of the solution is left in place, as in the urinary bladder or the nasal sinuses. *Painting* or swabbing permits more prolonged contact with stronger solutions; and this may be further extended by the use of tampons, generally with glycerol, sometimes with mucilaginous media. Iodine and silver nitrate are used in this manner to produce astringency, irritation and cauterization. The antiseptic action of these and of germicidal dyes is confined to the surface and debris, because living cells resist the penetration of effective concentrations.

Vehicles.—Surfaces that do not normally come into contact with water are generally irritated by it through osmosis. This is avoided by isotonic solutions, *f. i.*, 0.85 per cent sodium chloride. Solutions in oil are also used to avoid osmotic irritation. Their immiscibility with the moisture of the mucosae prevents direct contact with the cells, and their action is therefore slower and more prolonged. Ointments make even poorer contact, because viscosity limits their spread.

Conjunctiva.—Solutions are dropped into the conjunctival sac to act on its mucosa, and on the iris and ciliary body. Absorption occurs freely from watery solutions (more slowly from oily solutions) by the mucosa and also by the lachrymal ducts, so that the systemic effects often follow the application of drugs, atropine to the eyes, for instance.

few milligrams of apomorphine applied to the conjunctiva of a dog suffice to produce vomiting (Macht, 1917). The corneal epithelium is permeable to acid dyes, much less so to basic dyes. This channel also avoids the destructive action of the digestive tract and liver. Insulin, *f. i.*, is effective, requiring only 60 per cent more than by hypodermic injection, in rabbits. The commercial solution is not irritant (C. D. Christie and Hanzal, 1931). *Excised cornea and sclera* are not permeable to purely water-soluble or purely fat-soluble substances, but only to those that are soluble in both (D. G. Cogan *et al.*, 1944).

Isotonicity is important for the application of solutions to the conjunctiva. Hypotonic solutions tend to render the cornea turbid. Sufficient approximation is attained with: NaCl, 0.8 per cent (2 level teaspoonfuls to the quart or liter), or boric acid or sodium bicarbonate, 2 per cent (4 teaspoons to the quart), or sodium borate, 2.5 per cent (6 teaspoons to the quart). The pH is also important; 8 is optimal; irritation occurs above 9 and below 6.6.

The *mouth, pharynx and glottis* may be treated by troches, by swabbing, or by mouth washes, gargling or irrigation. It is doubtful whether gargling generally reaches the glottis or indeed the posterior pharynx, unless a careful technic is followed (Swain, 1936). Antiseptics would not be in contact sufficiently long to be effective. They merely wash away living and dead bacteria from the surface, as does water.

Nasal applications may be made by dropping saline or oily solutions into the nostrils, by irrigation or sprays, or by swabbing. The nasal mucosa is sensitive to hypotonic and astringent solutions, less so to hypertonic. Absorption occurs rather easily, so that the effects of pituitary, insulin and allergic agents may be produced. Nasal injections of local anesthetics have often caused serious poisoning. The nasal mucosa is a natural channel for securing immune reactions and has been used to this end.

It was the original Chinese method of inoculating against smallpox, and was introduced into England by Richard Mead ("The Gold-headed Cane"). Injection under the mucous membrane of the nasal septum gives extremely rapid absorption, the efficiency approaching intravenous injection (Pilcher, 1914, 1915). The mucosa of the frontal sinus absorbs rather poorly in animals (J. H. Childrey and Essex, 1931).

Cumulative pulmonary irritation by oil aspirated from nose drops occurs especially in young children, leading to characteristic changes and sometimes to pneumonia (Pierson, 1932).

Sprays and inhalations are used in the respiratory tract, from the nose to the alveoli. The latter, however, are reached directly only by gases. Substances that can be vaporized by heating may be evaporated with boiling water, *f. i.*, volatile oils, inhaling the steam through a funnel or cone; or by the "steam-atomizer"; the steam does not penetrate far into the bronchial branches, but as it cools, it condenses on the mucous membrane of the larger bronchi (Semmola). This establishes surface depots of the substance, which saturate the air stream and thus reach the deeper passages in more dilute form. Roentgenography has shown that the churning of the respiratory movements spreads the fluids extensively, giving wider direct contact and larger surface for evaporation. Incidentally, the heat and moisture furnished by steam are often beneficial, perhaps more so than the drugs which it carries. To reach the lower air passages, the steam should be inhaled deeply with the nostrils closed, the mouth wide open, and the tongue protruded. *Inhalation of smoke* is also sometimes utilized. In this, the substance exists partly in very fine suspension, as a mist, which does not condense on cooling as does steam. *Dust* is not carried farther than the ciliated epithelium extends, unless it is suspended in fluid (Barclay *et al.*, 1938). Particles larger than 12 microns cannot enter the alveoli; this is the maximal size found in miners (Policard). *Sprays* secure coarser suspensions mechanically. These behave like the steams, but are generally not inhaled as deeply, and lack the heat of the steam. They are used mainly for effects on the nose, pharynx, larynx and trachea.

Intratracheal Injections.—Small quantities, 2 or 3 cc., of oily solutions may be injected directly into the trachea, usually through the glottis, after local anesthesia. They are then distributed by respiration, like the sprays and steams (Balvay, 1921; J. A. Thompson, 1897; A. Ochsner, 1932). Iodized oil is thus used in roentgen diagnosis.

The *vagina* absorbs freely, and clinical poisoning by this channel is frequent, especially in connection with the improper use of mercuric chloride douches (Macht, 1918, references; G. D. Robinson, 1927). The *uterine cavity* is also an absorbing surface (iodine, Higuchi, 1908).

The *urethra* in man holds 4 to 15 cc. of fluid when distended, and absorbs readily, so that poisoning has frequently occurred from the excessive application of local anesthetics.

The absorption of local anesthetics from the urethra was studied by Sollmann, 1918. The rapidity of absorption is illustrated by the injection of 1 per cent apomorphine into the urethra of a male dog; vomiting occurs in three to five minutes (Macht, 1918).

The mucosa of the *prepuce* is also a good absorbing surface.

The *urinary bladder* absorbs poorly. Strychnine, apomorphine and morphine are almost harmless when injected into the bladder, if the urethra has been tied (Macht, 1918). The reaction plays a considerable role; the absorption of nicotine is much greater at *p*H 9 than at 5 (J. Travell). Even salts and water are absorbed poorly, but urea is somewhat absorbed.

If the ureters and urethra of anesthetized dogs are ligated and the bladder is filled with water or with isotonic sodium chloride solution, the volume remains practically unchanged for hours. Hypertonic sodium chloride produces injury and bleeding. With 10 to 30 per cent urea, about a tenth is absorbed in two hours, and no more in fourteen hours. Mixed solutions lose in urea and not in sodium chloride (Conradt, 1937).

The *ureter, and renal pelvis* absorb fairly well (Macht, 1918); and there is the additional possibility of injecting into the circulation through the pyelovenous backflow (see under Iodized Oils).

CONDITIONS INFLUENCING ABSORPTION

The time required for absorption into the body and into the cells ranges from a few seconds (*e. g.*, hydrocyanic acid) to several weeks (*e. g.*, lead). The rapidity of absorption depends upon the nature of the drug, the place of administration and other factors. The place of administration has been discussed in the preceding section.

Solubility.—Only soluble drugs can be absorbed (except the small quantities taken up by phagocytosis); but the solubility in the protein-containing fluids of the body is not necessarily the same as the solubility in water. The solubility may also be modified by chemical changes produced by the digestive or tissue juices.

There is considerable uncertainty in the absorption of *solid particles* even when they are soluble. They should therefore be avoided unless a very slow action is desired. They are practically unabsorbable from the alimentary tract, although Koellicker and many others, on feeding rabbits with carbon, found particles in the prevertebral and mesenteric ganglia.

Influence of Colloids.—Oil, gums, extractives, kaolin and colloids generally hinder absorption, partly by adsorption of the drug, partly by impeding its access to the absorbing surface. Food in the alimentary canal has this action. The isolated active constituents (alkaloids, etc.) are preferred if a quick systemic action is desired, while the galenic preparations (extracts, tinctures, pills, etc.) are used for local effect. Oils, especially mineral oil, delay the absorption of oil-soluble principles, such as carotene; bile hastens their absorption by emulsification; so does saponin, unless it causes irritation. Alcohol also favors their absorption.

Even with isolated cells there is usually a layer of undisturbed fluid on the surface of the cell, although the fluid is violently stirred (the "*Noyes-Whitney layer*"), and this is exaggerated by the viscosity of colloids. The frog heart, because of its spongy character, has relatively rapid intercellular penetration so that it responds to drugs in a few seconds.

Fullers' Earth (hydrous aluminum silicate) has a high adsorbing power, especially for alkaloids, varying in degree with different samples (Lloyd, 1916). McGuigan, 1914, found that this renders strychnine insoluble in acid fluids, so that the bitter taste develops quite slowly; and that it delays and diminishes the tetanic action in frogs. Fantus, 1915, showed that the combination is not dissolved in the stomach, but dissociates gradually in the intestines. He found the suitability of the earth as alkaloidal antidote very limited. Clowes and Walters, 1920, claim that the fullers' earth adsorbate is not broken up by sodium bicarbonate, as assumed by the other authors; but that this requires the presence of soap or other unnamed constituents of protoplasm. Sollmann found that bile salts, whose general properties resemble those of soaps, do not liberate demonstrable quantities of emetine. Sabbatani, 1913, found considerable antagonism between strychnine and *colloidal carbon* when mixed *in vitro*. The intravenous injection of the carbon furnished some protection against the oral administration of strychnine; but this was too uncertain for practical application. Von Paulucci, 1915, showed that fatty substances (including petrolatum) diminish the toxicity of strychnine, both hypodermically and with direct application to the nerve centers.

Concentration.—Absorption varies generally in the same direction as the concentration, especially for hypodermic injections; but the relation is not simple. Absorption tends to increase with the *extent of absorbing surface* (*e. g.*, by making multiple hypodermic injections). This seems to be less important in the intestines.

Changes of the Absorbing Cell.—In the alimentary canal, injury to the absorbing cell may either facilitate or hinder absorption; astringents tend to have the latter effect, corrosives and simple irritants the former. Sollmann and Hanzlik, 1911–1913, found that phenol, alcohol, iodide and probably other substances tend to inhibit their own absorption; so that the absorption, at first rapid, is promptly slowed.

Circulation.—The rapidity of absorption is proportional to the rapidity with which the drug is removed (just as a burning lamp-wick absorbs the oil more quickly; Mialhe). It therefore increases with the rapidity of the circulation and of the lymph flow. Active hyperemia (hot air; Klapp, 1901) and hemorrhage hasten absorption; while it is delayed by venous stasis, passive congestion, deficient heart action, vasoconstriction, catarrh, etc. Increase of lymph flow, by moderate *distention* and *massage*, quickens absorption. Excessive distention diminishes absorption by slowing the local lymph flow (Hamburger, 1907).

Severe hemorrhage (15 to 25 cc. per Kg.) increases the susceptibility of cats to physostigmine, chloral, ouabain and strychnine. Normal susceptibility returns in three-quarters to two hours, parallel with the restoration of the blood volume. The mechanism is not clear (H. Gold, 1927).

The absorption of gases from intact intestines is arrested by ligation of the arterial supply, and diminished by lowering the blood pressure and by shock; by tying the portal vein, by raising intra-abdominal pressure, and by applying solutions of tannic acid, alum or acacia to the mucosa (Admiraal, 1943).

Absorption by Blood and Lymph.—Most soluble substances are absorbed from the alimentary canal by the blood, rather than the lymph. This also holds for the serous cavities; methylene blue injected into the peritoneum or pleura, for instance, appears in the urine before it is seen in the thoracic duct (Starling and Tubby). A few drugs, however, take the lymphatic path. Tetanus and diphtheria toxin, and perhaps other toxins, are absorbed from the local injections by the nerve sheaths, and reach the central nervous system along these (Meyer and Ransom, 1903; Meyer, 1915).

Absorption in Absence of Circulation.—Considerable absorption occurs when the circulation has stopped. Thus, strychnine and morphine are absorbed by frogs with ligated hearts, producing interesting modifications in their actions (Meltzer, 1911–1913). Abel, 1912, and Abel and Turner, 1914, believed that the solutions in cardiectomized frogs are circulated by the lymph hearts; but Meltzer, 1914, Joseph, 1914, and Githens and Meltzer, 1915, affirm that general effects from the local injection of strychnine, fuchsin or epinephrine may develop when all the lymph hearts are definitely excluded, the absorption occurring through the lymph spaces. The absorption in frogs is delayed by destruction of the spinal cord (Filippi, 1912). *Considerable absorption occurs also in dead animals* (Sollmann and Hanzlik, 1913), probably by diffusion.

Sojourn in the Blood.—The passage of absorbed or injected substances from the blood into the tissue is a very rapid process for diffusible substances, materially slower for colloids.

Masoin (1903) found the time which elapses before just toxic doses disappear practically completely from the blood, after intravenous injection, to be for arsenic, nine-tenths to thirty seconds; cyanides, two to six minutes; diphtheria toxin, four minutes; antitoxin, several hours. *The sojourn of dyes in blood stream* has been investigated in the development of methods for measuring the blood volume. One group remains in the plasma for long periods; another group is excreted rapidly by the urine; a third group disappears from the plasma, but is not excreted by the kidneys. These groups have no apparent relation to the chemical structure (Dawson *et al.*, 1920). In general the capillaries are *more permeable to electronegative* than to electropositive substances. This explains the greater toxicity of basic drugs, and the rapid action of cobra venom in contrast to the slow action of most toxins, which therefore have a longer "incubation" period (U. Friedemann, 1942).

Distribution of Drugs within the Body.—Drugs are not distributed uniformly, but tend to pass first from the blood into the fluid bathing the tissues, and may accumulate especially in certain cells, according to their permeability and physical and chemical affinities. This influences their action; either by bringing them in contact with reactive tissues, or by storing them in places where they may be inactive. The distribution has been studied in relatively few cases, especially for inorganic poisons. It appears to be altered by disease; *e. g.*, degenerating tissue takes up more iodide, etc. The major quantity of dissolved substances is generally found in the skin, liver and muscle because of their great mass. If insoluble compounds are formed, these are laid down chiefly in the kidneys and liver. If colloids, and especially flocculates, are injected by vein, they are largely sifted out in the capillaries of the lungs, liver and spleen, chiefly by the phagocytic *reticulo-endothelial cells* (review, B. Sacks, 1926).

The chlorides, bromides and related ions accumulate in the extracellular fluid of all organs, but mainly in the skin and blood. The thyroid stores a relatively high percentage of iodine as thyroxin. The bones retain the earthy metals and fluoride. The heavy metals are deposited as loose organic compounds, especially in the kidneys, liver and spleen; mercury as a loose globulin compound; arsenic as a more stable nuclein combination (Vamossy, 1905). Iron deposits serve as a reserve stock of this metal.

The "blood: brain barrier" which controls the diffusion of substances from the blood into the central nervous system differs altogether from the passage between the blood into the cerebrospinal fluid or from this into the brain (U. Friedemann, 1942, review), for intravenous injection of almost all basic aniline dyes stains the brain without staining the cerebrospinal fluid. Acid dyes do not stain the brain (P. Ehrlich, 1887). The brain capillaries are therefore directly permeable to basic dyes and not to acid dyes. They are also permeable to lipid solvents (ethyl urethane, ethyl alcohol, paraldehyde), to alkaloids and sulfonamides; less permeable to iodide, bromide and thiocyanate ions than to chloride ions; impermeable to ferrocyanide, neoarsphenamine, germanin and trypan blue. They are permeable to proteins and antibodies, probably impermeable to viruses. The molecular size is relatively unimportant, and so is lipid solubility for basic dyes. Negative electric charge is probably more important. Epinephrine materially increases the permeability of the cerebral capillaries to the substances for which they are naturally permeable, but does not change it for impermeable substances (Friedemann and Elkeles, 1932).

Chemic Changes in Drugs.—Many poisons are altered in the body, and generally rendered less harmful, by oxidation, reduction, hydration or dehydration, or other decomposition, or by the storage of the poison in certain organs, or by its combination with other substances which render it harmless. Were it not for the power of the body to destroy or remove poisons, and thereby to recover from their action, all therapeutic use of drugs would be impossible. This disintoxication makes it necessary to administer the drugs progressively in order to maintain their effect; it may require the use of continuously increasing doses as the power of disintoxication becomes more developed. On the other hand, the alteration of the drug may result in a more toxic substance, as in the case of the nitriles; or may render it more effective therapeutically as with arsphenamine.

Decomposition by Digestion.—The digestive juices destroy some organic poisons by hydrolytic cleavage, especially the proteins, toxins and antitoxins, and the glucosides. On the other hand, they are necessary to saponify and liberate the active constituents of insoluble esters, *e. g.*, phenyl salicylate. The acidity of the gastric juice is important for the solution of bases. It often splits off acyl groups.

Decomposition in Tissues.—Feeding with *thyroid* diminishes the toxicity of acetonitrile, by preventing its conversion into cyanide (Reid Hunt, 1905). Organic compounds of metals (cacodyl, etc.) only develop the metal action after oxidation. Many organic acids (citric, etc.), alcohol and formaldehyde, are oxidized, and thus disintoxicated. Methenamine is activated by the liberation of formaldehyde in acid urines. The *liver* is especially active in disintoxication, partly by destroying, but particularly by storing poisons, so that the same dose may be less effective when given by the mesenteric than by the jugular vein. This has been demonstrated for curare, strychnine, morphine, cocaine, veratrine, quinine, atropine and the metals. Perfusion of alkaloids, glucosides, toxins, barium, etc., through excised liver decreases their toxicity (Woronzow, 1912). Experiments with Eck's fistula gave rather negative results (Rothberger and Winterberg, 1905). Perfusion through excised *muscle* produced disintoxication, but weaker than the liver, with chloral, atropine, physostigmine, curare and alcohol, not with muscarine and ricin (Woronzow, 1912). The *serum* of atropine-resistant animals destroys atropine.

Disintoxication by Adsorption.—Pilocarpine is detoxicated by digestion with serum, but may be recovered from this in fully active form by extraction with acid alcohol, so that it was not destroyed. The nature of the adsorbing substance is not known. It is abundant in rabbit serum, less in that of cats or oxen, and is absent from dog's blood (v. Leeuwen, 1918, Beutner, 1925).

Disintoxication by Combination.—Phenols and other aromatic compounds are rendered less toxic by conjugation with sulfates; aldehydes, camphor, chloral and ethereal oils by glycuronic acid; many metals by combining with proteins; toxins by antitoxins; acids by alkalis; cyanides by sulfur; benzoic acid by glycocoll, etc. The extent of the disintoxication depends on the activity of the metabolic processes which are concerned, or on the amount of neutralizing substance present in the body.

THE EXCRETION OF DRUGS

This occurs mainly through the urine and feces, and with volatile drugs through the lungs. The sweat and other secretions play a minor part. The relative importance of the different channels varies for each drug, but the urine generally contains considerably more than do the feces. The rapidity is proportional to the circulation and to the functional activity of the excretory organs, and may be increased by the factors which stimulate these.

The urinary excretion varies in general as the plasma concentration (although it is not identical with it). Its rate therefore depends on the speed of absorption. With oral administration, soluble substances generally appear in the urine in five to fifteen minutes, reach their maximal concentration in one-half to one and one-half hours, maintain this to the second or third hour, and then decline gradually. Some 80 per cent of the amount administered is generally excreted in the first twenty-four hours. Traces may be demonstrated for weeks, by remobilization from tissue depots. If absorption is slow, the plateau may be maintained for days. If repeated doses are administered faster than they are excreted, the tissue and urine concentration rise, producing cumulation. Cumulative effects may also result from the summation of injuries or of repair.

Fecal excretion appears to lag behind the urinary excretion, partly because nearly a day elapses before the feces reach the rectum. The fecal excretion is compounded of biliary excretion, which differs for various substances; excretion in the saliva, gastric juice (generally small) and duodenal and pancreatic juice; and cellular excretion by the leukocytes and desquamated intestinal epithelium. *Intestinal excretion* occurs chiefly in the colon.

Excretson by the colon has been confirmed for calcium and phosphate by radio-isotopes (H. W. Florey, Wright and Jennings, 1941). There is also good evidence for the colonic excretion of iron, but no indisputable evidence for mercury, bismuth, neoarsphenamine, mercurochrome or metaphen (I. Leitch, 1936).

Excretion by the saliva is rather limited. It generally begins within twenty minutes and may last over nine hours (Howe, 1912). After intravenous injection, iodide and lithium appear promptly in the saliva; dextrose and ferrocyanide very slowly or not at all (Langley and Fletcher).

The pancreatic juice helps to eliminate some dyes, including acid and basic fuchsin, methylene blue and fluorescein. Crandall *et al.*, 1929, report that it does not excrete thiocyanate, iodide or pyridium.

Sweat excretes a considerable number of drugs, especially chloride, iodide and bromide. The quantities are too small to make them significant for elimination.

Elimination by the lungs through the alveoli is rapid for gases and volatile substances. *Dusts* are actively eliminated from the passages, including the terminal bronchi. This involves ciliary motion, which may propel small particles at 0.25 to 1 cm. per minute in the bronchi, and up to 3 cm. in the trachea (Barclay and Franklin, 1937; Florey, Carlton and Wells, 1932).

Cerebrospinal fluid is secreted or filtered by the choroid plexuses of the brain ventricles. Inorganic substances are excreted into this only in a slight degree; iodides and bromides are generally present. Many organic substances pass into it much more freely. Alcohol, chloroform, acetone and methenamine occur constantly in about the concentration of serum (Hald, 1911).

The passage into the cerebrospinal fluid varies with the *species*. Picric acid penetrates in dogs, cats and guinea pigs, but not in rabbits (L. Stern and Gautier, 1918).

Passage to Fetus.—Soluble substances pass freely across the placental circulation, so that their concentration in the fetal and maternal blood, and indeed in the organs, is practically identical. The more important drugs which have been demonstrated are: ferrocyanide (Mayer, 1871); chloroform, ether, CO, ethyl bromide, atropine, morphine, scopolamine, chloral, salicyl, quinine, benzoic acid, phlorhizin, alcohol, nitrate, urea, methylene blue, As, Hg, KI, KBr (Kehrer, 1907), also bismuth. The placenta acts as an ultrafilter, so that colloidal dyes, and presumably proteins, do not pass into the fetal circulation (Schimidzu, 1923).

DOSAGE (POSOLOGY)

Drugs are administered to produce a desired effect, and the dose must be sufficient for this purpose, and neither too small nor too large. Since the effect is influenced by numerous conditions, it is impossible to state exact doses for any drug; experience is the best guide. The doses vary, however, under ordinary conditions only within rather narrow limits, so that it is feasible to state the *customary* or *average dose*, as is done in the U.S.P. and ia this book; *i. e.*, "the doses which may be expected ordinarily to produce the therapeutic effects for which the preparation is most commonly employed." Unless otherwise stated, these doses apply to adults of average size, and to oral administration. They are not intended to be binding on physicians, but they are convenient approximations for memorizing. The metric and apothecaries' doses in the U.S.P. are not mathematical equivalents, but represent the quantities that would be prescribed under identical conditions by physicians trained respectively in the metric or in the apothecaries' system of weights and measures" (U.S.P.). In this volume the emphasis is on the metric doses, and those of the other system are often omitted if they are not commonly prescribed.

The "*maximum dose*" signifies the largest dose which can be safely used in ordinary cases; the "*minimum dose*" is the smallest dose which produces therapeutic effects; n "*toxic dose*" is one which produces dangerous effects; the "*just fatal dose*" is that which is just sufficient to cause death; the "*physiologic dose*" (a rather indefinite term) is used in physiologic experiments on animals.

Most foreign pharmacopoeias (but not the U.S.P. or B.P.) give tables of "Maximum Doses," not with the purpose of restricting the physician, but as a guide to the pharmacist. He is not permitted to dispense doses larger than these unless the physician indicates specifically that the larger doses are intentional. With some drugs, the fatal and active dose are far apart (atropine); with others, they are close together (strychnine). The distance may vary for different actions of the same drug.

Variations According to Administration.—Different methods of administration, by altering the rapidity of absorption, produce quantitative differences in the effects and therefore in the dosage. Since these vary with each drug, they must be determined by observation. General ratios of oral, rectal and hypodermic doses, supposed to apply more or less to all drugs, are dangerous (Hatcher and Eggleston, 1914). The rectal dose may be larger or smaller than the oral. For parenteral administration, the dosage decreases in the sequence of hypodermic, intramuscular and intravenous. The same dose acts more potently the more rapidly it is introduced, mainly because there is less excretion and destruction before the full dose has entered; also because it reaches the heart and other centers before being distributed through the body.

This must be taken into account in fixing the minimal fatal dose. Extremely rapid intravenous injection may simulate a higher fatal dose if death occurs during the injection, because in this case really more poison may have been administered than was necessary for death (I. Simon, 1905).

Daily Dose.—The single doses are usually calculated on the assumption that sufficient time is allowed to elapse between the doses for the greater part of the drug to be excreted. This constitutes a *periodic medication.* The time varies with the drug, but in most cases the drug is administered three or four times a day; so that the *daily dose* is about three or four times the single dose. If *continuous action* is desired, correspondingly smaller doses are given at shorter intervals.

Single and Divided Doses.—With some drugs a given amount is most potent when administered as a single dose (cyanide, emetine, strychnine), while others (strophanthin, chloral, salicylate, heroin, antipyrine) appear more potent when fractional doses are repeated at close intervals (Uchida, 1926).

Effect of Weight.—Other things being equal, the effect of a given dose is inversely proportional to the weight of the individual (exclusive of the adipose tissue). This may be used for calculating the doses for children. It is generally not necessary to make allowance for the weight of adults (twenty to sixty years).

Body surface is regarded by some as a more accurate although less convenient index of the dose (Moore, 1909; Dreyer and Walker, 1914); but the subject is in dispute (Kisskalt, 1915). It probably applies only to heat production; for other actions are proportional to the concentration of the drug, and this varies with the mass, not with the surface. It is not strictly proportional to the weight, however, since the drugs would not be uniformly distributed through the tissues. The early distribution of soluble drugs is in the *extracellular fluid*, averaging 20 to 30 per cent of the body weight, or about 15 Kg. in an adult. The *maximum percentage concentration of the drug in contact with the cells* would therefore be the dose in grams divided by 150.

Calculation of Doses for Children.—In most cases the adult dose is reduced in simple proportion to the weight of the child—either by direct calculation or by the use of empiric rules based on averages, as described below. The dosage so obtained is generally sufficiently exact. It is inadmissible only with extremely young children, and with drugs the action of which is influenced specifically by age.

Clark's Rule.—Multiply the adult dose by the weight of the child (in pounds) and divide by 150 (the weight of the average adult). This rule gives the best approximation.

Cowling's Rule.—Multiply the adult dose by the age of the child at the next birthday, and divide by the adult age, taken as twenty-four. *For instance,* the dose for a child of three years would be $\frac{4}{24} = \frac{1}{6}$ of the adult dose. This rule gives data agreeing sufficiently well with the average weight curve, more accurately than Young's Rule. The results are rather too low, below four years and above fifteen years, but the error is on the safe side.

Young's Rule: Multiply the adult dose by the age of the child (in years) and divide by the age plus 12. *For instance,* the dose for a child of three years would be $\frac{3}{15} = \frac{1}{5}$. As compared with Cowling's Rule, it gives somewhat higher doses below twelve years, and somewhat lower above this age. *Fried's Rule:* Divide the age in months by 150 and multiply it by the adult dose; *f. i.,* for a baby of five months, the dose would be $\frac{5}{150} = \frac{1}{30}$.

The dose for aged people is generally taken as somewhat less than that for adults. Above sixty years, the adult dose is reduced to four-fifths or two-thirds, and in extreme senility to one-half.

Specific Influence of Age on Drug Action.—These (*i. e.,* apart from the difference due to weight) are known definitely only for a few drugs. *Children* are comparatively tolerant to cathartics, strychnine, iodides, iron, belladonna, calomel, digitalis and sparteine (A. Jacobi, 1907). *Old age* is generally less resistant to drugs; purgatives and emetics are especially debilitating. The existence of atheroma makes it dangerous to use drugs which raise the blood pressure.

Clinical age relations are not substantiated by adequate data. *In animals,* K. K. Chen and Robbins, 1944, found the following: *Histamine* by vein is less toxic to guinea pigs younger than ten days; but this does not hold for hypodermic injection. *Morphine* intravenously is more toxic to fourteen day old than to older rats. *Picrotoxin* is more convulsive to two year old mice than to the younger animals. *Alcohol* hypodermically is more toxic to the older rats. Each substance has its own characteristics.

Influence of Sex.—Women usually require somewhat smaller doses than men (one-half to four-fifths). The greater susceptibility is in large part due to the lesser weight, but in part also to the anatomic and functional peculiarities. The influences of sex are of course most pronounced with drugs which act on the generative organs. **Pregnancy** contraindicates the use of irritant cathartics (because of the danger of inducing abortion) and of irritant diuretics (on account of the tendency to nephritis).

"Minimal lethal dose" (M.L.D.) determinations on animals are important for bioassays and the evaluation of margins of safety, and the efficiency of antagonists. Individual animals may differ considerably from the average, due to differences of absorption and other factors. This results in sigmoid "frequency distribution curves" (Trevan, 1927; Durham, Gaddum and Marchal, 1929; Munch and Garbugh, 1935; C. I. Bliss, 1935), which vary considerably even for related substances (Dawson and Little, 1937). The dosage by which 50 per cent of the animals die (designated "LD_{50}" or "FD_{50}") gives the most consistent data and is now generally adopted.

Tiffeneau, 1931, proposed 75 per cent survival as "tolerated dose" and 25 per cent survival as "fatal dose." It is also necessary to set a time limit for fatality, varying for different drugs. The use of logarithmic paper for simplifying probability calculations is described by Prigge and Schäfer, 1939.

INFLUENCE OF CONDITIONS ON DRUG ACTIONS

Pharmacologic reactions vary with the concentration of the drug and with the excitability of the tissues. The latter is influenced by physiologic and pathologic conditions; and among the latter, by the simultaneous action of other drugs.

Quantitative Relation of Concentration and Action.—The pharmacologic response tends to increase with the concentration of the drug; but not generally in simple proportion. There is usually a "minimal threshold," all concentrations below this being apparently ineffective. At the other extreme, once the "maximal response" has been reached, further increase of concentration can produce no further effect. Between these points, every increase of concentration increases the action, generally as a logarithmic function; *i. e.,* the increment being the greater the lower the original concentration, in accordance with the Weber-Fechner law of stimulation.

For instance, when the concentration of ouabain was doubled from 0.00125 to 0.0025, the action was increased 4.6 times; when the concentration was doubled from 0.005 to 0.01, the action increased only 1.28 times (Sollmann, Mendenhall and Stingel, 1915; the paper also discusses the reasons for the phenomenon.) Data on the concentration relations of other pharmacologic phenomena are given by Shakell, 1924.

In some cases it appears as if the drug acts only while passing through the cell membrane, a phenomenon that has been termed "*exodic gradient*" (Straub, 1907; Trendelenburg, 1912; Kuyer and Wijsenbeek, 1913; H. Gremels). This may be due to phase-boundary electric potentials, such as are produced by acetylcholine solutions in contact with cholesterol (Beutner and Barnes, 1945). Sometimes the phenomenon is an artifact. Sigmoid curves are often due to errors of recording apparatus.

Qualitative (Directional) Changes with Concentration.—Pharmacologic stimulation may pass gradually into depression when high concentrations are employed—somewhat analogous to colloidal solutions which flocculate and precipitate when their reaction is neutralized to the iso-electric point, but which dissolve when this point is passed by further addition of the neutralizing agent. Such *diphasic actions*, constituting the "Arndt-Schulz Rule," are fairly common, although far from universal. They have been invoked by Hahnemann and other homeopathic writers in support of the "doctrine of similes," that infinitesimally small doses of drugs should combat symptoms analogous to those produced by larger doses; an assumption which led to some fantastic corollaries.

Multiple Independent Actions.—The relation to the concentration becomes complicated if the drug produces several effects with different optima. This gives rise to *polyphasic variations*, which are often difficult to disentangle. For instance, relatively low concentrations of chloroform depress muscle by liposolvent surface action; high concentrations precipitate the protein within the muscle cells, producing rigor.

The Combined Action of Drugs.—The effects of drugs are influenced by the unusual conditions induced by the simultaneous administration or presence of other drugs. A quantitative change may occur either in the sense of increasing the efficiency (*synergism*) or of diminishing it (*antagonism*). There may also be qualitative changes. New actions may be developed by the reaction of the drugs on each other, with the production of new compounds: acids render the basic salts of bismuth soluble and toxic; oxidizing substances may liberate iodine from iodides; the iodides also decompose calomel and render it irritant. Antagonism of action is employed in the treatment of poisoning, or sometimes to remove undesired side effects. When it interferes with desired effects, it constitutes "*therapeutic incompatibility.*"

Combination Therapy.—Synergism is utilized to secure the summation of the desirable effects of several drugs, while the side actions are not increased in proportion, or may even be neutralized. The potency may be increased, especially when the drugs attack a given cell or function simultaneously by several different mechanisms. Combinations of drugs were formerly popular on the empiric principle of the shot-gun mixture—that of many ingredients, some at least might fit the disease. It is better to employ the fewest possible drugs, until it has actually been shown that combinations give superior results in the particular condition. In giving several drugs of similar actions, the dosage of each must be correspondingly reduced.

Variations of Combined Action.—When several drugs are administered together, each may act independently, as if it were present alone. The result would then be a *simple algebraic summation* of the effects, either synergistic or antagonistic. In many cases, however, the combined action is greater or smaller than would be calculated (*potentiated* and *deficient summation*). If the action of two agents is really identical, their mixture would be equivalent to increasing the concentration of either, and would therefore follow the Weber-Fechner law of diminishing returns and appear deficient. This *complemental synergism* is a means of confirming identity of action. *Potentiation or supplemental synergism* occurs only if the two agents have different points of attack in the cell. W. F. Buergi (1910, 1926) formulated this as "*Buergi's law,*" but Fuehner, 1912, Issekutz, 1913, Zorn, 1913, and others have pointed out numerous important exceptions. It is certainly not universally applicable.

The simple lipolytic narcotics (alcohol, ether, chloroform, etc.) show practically only simple summation; but the addition of the alkaloidal narcotics (morphine and scopolamine) gives considerable potentiation (Knell, 1907; Fuehner, 1911; Kochmann and pupils, 1913). Bromides give simple summation with lipolytic and alkaloidal narcotics (Klammer, 1913). The different opium alkaloids potentiate each other in interesting ways (Straub, 1913; Macht). The organic local anesthetics do not usually potentiate (Schmid, 1913). Fuehner, 1912, worked out the summation of hemolytic agents.

Modified Synergisms.—The relations may vary at different dose levels: Stimulants are antagonistic to depressants only in small doses. Large doses often become synergistic, the depression being greater than if the depressant were used alone. Instances of this are atropine and pilocarpine on embryonal growth (Sollmann, 1904); caffeine and alcohol toxicity (Pilcher, 1912); atropine and physostigmine toxicity (Fraser). The effects of autonomic drugs are generally enhanced by previous exposure of the excised organs to *colloids* or colloidal precipitants (Thienes, 1926).

Cumulative action exists when continuation of a given dose of a drug produces greater effects than the first doses. It may be due to an actual accumulation of the drug, absorption being greater than the capacity for excretion; or it may result from summation of effects, when the changes brought about by the first doses persist; the drug may use up some substance required for its disintoxication (phenol); or there may be general decrease of resistance, sometimes by actual injury.

Inconstant absorption is a frequent cause of apparent cumulative action. Successive doses of the drug may lie unabsorbed in the alimentary canal, to be finally taken into the system *in toto* when the conditions are favorable to absorption. This explains the greatest individual variability to toxic doses for those drugs which are absorbed with the greatest difficulty.

Irregularities of excretion (nephritis, etc.) are favorable to the development of cumulative effects.

"*Education*,"—Effects are sometimes more easily reproduced after they have once been induced. This is seen particularly in the central nervous system. The susceptibility to strychnine, for instance, is said to increase with its administration.

Tolerance may be due to nonabsorption, to rapid elimination, to neutralization or destruction of the poison, or to anatomic peculiarities. Many cases appear to be functional (the "histogenetic" immunity of Behring). The tolerance is rarely absolute, so that it is incorrect to speak of "immunity." Tolerance may be congenital or may be developed by the repeated administration of the poison. This *habituation* may be by functional adaptation (alcohol, caffeine, nicotine); or it may be due to diminished absorption (arsenic) or increased elimination (atropine in cats); or to increased destruction of the poison (atropine); or to the production of antibodies (toxins). The tolerance is usually limited, not absolute. Tolerance to habit-producing drugs is largely psychic: The nervous centers learn to modify their reactions so as to adapt them to the drug environment. When this environment is abruptly altered by the withdrawal of the drug, there is generally extreme discomfort, resulting in craving and great nervousness, constituting "*abstinence symptoms.*" Functional habituation, acquired for a particular drug, may hold also for other drugs having a similar action. A habitual drunkard, *e. g.*, is resistant to the general anesthetics; morphinists are said to be more tolerant to cocaine (Chouppe, 1889). Tolerance is not acquired to convulsive poisons (W. Biehler 1935).

Antitoxin formation is a conspicuous instance of acquired tolerance. It is chiefly confined to proteins, and does not occur with alkaloids or any of the simpler poisons.

Acquired immunity in protozoa has a practical as well as theoretic bearing on chemotherapy, and has been investigated by Ehrlich, 1909, and Neuhaus, 1910. These organisms acquire immunity for several groups of poisons—metals and dyes—the tolerance induced by one drug applying to other chemically related drugs, but not to the other groups. The immunity, when once induced, is transmitted unlimited from generation to generation. The adaptation may consist merely in the selective propagation of the naturally more resistant individuals (mutants), *i. e.*, in the "survival of the fittest." With alkaloids, Prowazek, 1910, found that different individuals, even in the progeny of a single parent, show varying resistance to the same alkaloid. Single cell cultures of various *bacteria* adapt themselves to concentrations of NaCl, $HgCl_2$ and $CuSO_4$ considerably higher than are tolerated by nonadapted strains. This specific resistance is retained by the descendants (Severens and Tanner, 1945).

Idiosyncrasy.—This term (from ἴδιος, one's own, and σύνκρασις, a blending) is applied to exceptional reactions to the effects of drugs. They may consist in quantitative hypersusceptibility to the ordinary actions of the drug. Such hypersusceptibility is especially conspicuous if it emphasizes a side action that is ordinarily negligible. Neurotic individuals are subject to psychic exaggeration or modification of drug effects through fright, excitement or suggestion. *Allergic hypersusceptibility* is a special type of idiosyncrasy in which the patient reacts to special substances, foods or drugs by irritative edema and spasm of smooth muscle, urticaria, bronchial asthma and collapse. It is generally hereditary, but not congenital; *i. e.*, it may not manifest itself till later in life. It usually resides in the tissues, so that it cannot be transferred by the blood serum. Allergic hypersusceptibility may be induced in excised tissues by treatment with colloidal precipitants (Thienes, 1926).

Sensitization or induced drug allergy, more or less analogous to protein anaphylaxis, may develop some five to twenty days after the administration of certain simple chemical compounds, such as iodide and bromide ions. Regular daily administration is less likely to produce sensitization than intermission of seven to ten days between doses. Landsteiner and van der Scheer, 1933, explain sensitization by the assumption that non-protein chemicals of many types combine with body protein to produce substances with antigenic properties.

When this has occurred, the chemical itself reacts directly with the antibody (also *in vitro*) to produce an immunological response which constitutes the hypersusceptibility. Willstätter and Rhodewald, 1934, postulate "*symplex compounds*" formed by the combination of a prosthetic group with compounds of high molecular weight. The potency of the prosthetic group depends on some special configuration rather than on a special element. The activity may be lost by the destruction (or denaturation) of either the prosthetic group or the colloidal carrier.

Quantitative racial differences exist in the skin and iris, and are probably related to the structure and pigment. Dark races are less susceptible to cutaneous irritation, especially by radiation and by chemicals ("mustard gas," petroleum products). Their iris is less responsive to mydriatics.

Impurities of Drugs.—Abnormal reactions may sometimes be due to impurities, but this is rather exceptional. Minimal amounts of foreign substances are not very objectionable unless they are poisonous. The pharmacopoeias permit the presence of small amounts of such innocuous impurities which it would be difficult and costly to remove.

Individual Idiosyncrasy in Animals.—In animals, as well as in man, peculiarities exist in different individuals of the same species. *Qualitative differences* are seen particularly in the action of narcotics on higher mammals. Instances of *quantitative differences* are numerous: In any large series of experiments there is a fair degree of uniformity in the proportion of animals which die with a given dose. The variation for three deaths in five animals ranges from 0.5 per cent (strychnine) to 25 per cent (ergot), but is usually comprised within 5 to 10 per cent. The susceptibility of any one animal is subject to greater possible variations; *e. g.*, with a given preparation of digitalis, 0.6 mg. per gram always kills three guinea pigs out of five; but in a large series, a number of animals die with 0.4 mg., while others die only when 0.9 mg. is reached.

Racial Idiosyncrasy in Animals.—Different kinds of animals may differ in their reaction. This can usually be explained by *differences in the physiologic functions.* Cerebral actions are usually the more pronounced, the more highly the central nervous system is developed; spinal actions predominate in the lower vertebrates; rodents are incapable of vomiting. Atropine quickens the heart action of the dog, but not that of the rabbit, because it acts by paralyzing the vagus, which is not tonically active in the rabbit. The dogfish, which is more or less resistant to nephrotoxic poisons, normally excretes urea and probably other metabolic products mainly by the intestines and bile (Denis, 1913). Natural resistance is often due to the destruction of the poison, *f. i.*, that of atropine by the serum of rabbits, etc. Differences of absorption and excretion also come into play.

Differences which cannot yet be explained on a physiologic basis may be referred to ignorance of the physiologic differences which are involved. The *hedgehog* has a high unexplained resistance to many poisons: morphine, atropine, nicotine, cyanide, cantharides, arsenite, diphtheria and tetanus toxins; not for strychnine (Strubell, 1909; Willberg, 1913). *Birds* react to most poisons qualitatively like mammals, although there are quantitative differences in both directions. Cocaine, however, lowers their temperature (Forchheimer, 1931). Even the same *organs* in different classes of animals may show unexplained differences. Thus, Gunn, 1909, claims that apocodeine, quinine, and yohimbine, which cause vasodilatation in mammals, constrict the blood vessels in frogs—both peripherally.

Influence of Pathologic States.—The effects of drugs in disease may differ from those on healthy animals. The pathologic conditions may diminish absorption (diarrhea) or increase it (corrosion); they may hasten the destruction of the poison (alcohol produces less intoxication in fever); or they may alter the effects entirely. Some of these modifications are explained by the functional or anatomic changes of disease; others are obscure. In judging the effects of drugs on disease, it must not be overlooked that abnormal conditions naturally tend to return toward the more stable equilibrium of the normal, so that comparisons must be controlled by the untreated disease, and not merely by the effects on normal individuals (F. T. Jung, 1938).

Antipyretics reduce the temperature in hyperpyrexia, but do not affect it when it is normal; digitalis is an efficient diuretic in cardiac disease, but not in health; the antiseptics and antitoxins are active only in infections, etc. Numerous other instances may be found in the papers of Salant, 1911, and Wallace, 1912.

Pathologic conditions which modify *absorption and excretion* are of particular practical importance; suppression of urine, as by nephritis, may lead to toxic symptoms from drugs or doses which are ordinarily harmless. The general reduction of vitality, the "*lowered resisting power*," which is common in many diseases is similarly important.

Lusini and Sebastiani, 1906, found the absorptions of poisons hastened immediately after *hemorrhage* but not later. The toxic symptoms were not modified. The resistance was found lowered to a varying degree for different poisons: most for strychnine, less for veratrine, and not at all for physostigmine. Wiggers, 1910, found that severe hemorrhage paralyzes the vagus center and thus alters the response of the heart rate to epinephrine, digitalis and nitrite.

Inflamed vessels react abnormally. Eskin, 1914, found constrictor drugs generally less and dilator drugs more effective. Epinephrine often produced dilatation, while caffeine, which normally dilates, constricted the inflamed vessels of rabbit's ear.

The distribution of the drugs in the body may differ in disease and health. *Inflammation* increases capillary permeability; but the coagulation of the inflammatory exudate soon walls off the area (Menkin, 1931–1933). Iodide and many dyes tend to accumulate in the necrotic areas of tuberculosis and tumors (Cecil and Weil, 1917).

Seasonal variations exist in the susceptibility of animals to a number of poisons. With cold-blooded animals, this would be referred partly to differences of temperature; but considerable variations exist also in mammals. Guinea pigs are more resistant to ouabain, and less resistant to acetonitrile and diphtheria toxin during November to January than in the spring and summer months (Haskell, 1912). Seasonal changes in internal secretions, connected with the sexual activity, probably play a prominent part. Seasonal diet is also an important factor.

Diet has a marked effect on the resistance of animals to many poisons (Hunt, 1910; Opie and Alford, 1914). The people of the undernourished war countries were said to show greater susceptibility to the toxic manifestations of mercury and arsphenamine, to the narcotic action of morphine and to cutaneous reactions for various drugs (Zernick, 1919; Rumpel, 1919). The calcium content is important in influencing cutaneous irritation (Luithlen, 1911, 1912). Barium is better absorbed from a Ca-poor diet (Alsberg and Black, 1912), as is also lead. The acid-base content of the food is an important factor in relation to renal irritations (Salant and Bengis, 1917; MacNider).

Ion Ratios.—The responses of excised or perfused tissues, especially to the autonomic poisons, are modified by the hydrogen ion concentration and the ratio of calcium, potassium and magnesium ions (Salant, 1924). They are of minor importance in the living body, which does not readily change its normal ion ratios.

Temperature influences pharmacologic effects, especially in cold-blooded animals and in excised organs, since heat speeds up chemical and especially enzyme reactions. In warm-blooded animals it affects the responses of the temperature centers, so that dinitrophenol tends to raise the temperature in a warm room, and to lower it in the cold. Warm temperature also increases the action of drugs on and through the skin, by maceration of the epidermis with sweat. This is conspicuous in industrial poisoning.

The influence of body temperature on drug action is reviewed by F. A. Fuhrman, 1946. In cold-blooded animals, colchicine, picrotoxin, strychnine, tetanus toxin, digitalis, veratrine, nicotine, chloral, atoxyl, and alcohol are rendered more active, morphine and curare less active, by raising the temperature; physostigmine, epinephrine and many others are not affected (Fuehner and Breipohl, 1933). The *temperature quotient* of strychnine was investigated by Schlomovitz and Chase, 1916. The temperature coefficient of most pharmacologic actions is $Q_{10} = 2$ to 4. As the reactions of cells are of the nature of chain processes, the limit is set by the slowest link, and the quotient gives no information as to the nature of the process as a whole (A. J. Clark, 1937).

Colchicine is four hundred times more potent for frogs at 30° C. than at 19° C. (Fuehner, 1910). Mice are also four hundred times more sensitive to colchicine than are frogs at room temperature so that the heated frogs react as warm-blooded animals (Fuehner and Wagner, 1932). With *muscles*, the activity of drugs increases in a mathematical ratio with the temperature within certain limits (Veley and Waller, 1910). The temperature relations of digitaloids are discussed by Sollmann, Mendenhall and Stingel, 1915. In mammals, cooling generally increases toxicity by adding its direct depressant action. *The effect of temperature on spinal reflexes* was studied by van Leeuwen and van der Made, 1916, in mammals and frogs.

THE MANIFESTATIONS OF PHARMACOLOGIC ACTIONS

Pharmacologic agents rarely if ever create new functions in a cell or tissue; they only modify existing functions or make evident functions which have previously been latent. The functions of a cell may be increased or diminished, resulting in *stimulation* or *depression*. Since there are also structures the stimulation of which would lead to an inhibition of other structures, an actual increase of function is sometimes distinguished as *augmentation*. A violent stimulation passes usually into injury; such injurious stimulation is called *irritation*. Moderate but prolonged stimulation may pass into depression, either by the disappearance of food substances (*exhaustion*) or by actual injury to the structure (*fatigue*). If the depression is so great that the given function has disappeared, the condition is called *paralysis:* if all the functions are abolished, there is *death*. The greater number of pharmacologic agents produce at first a stimulation, which is followed in large doses by depression. In this respect the differences between the different poisons are again mainly quantitative. The so-called "stimulants" produce strong and prolonged stimulation, the depression being noted only with relatively large doses. The "depressants" cause only slight stimulation, which passes readily into depression. With some depressants, no stimulation whatever exists. It is rare that a depression precedes a stimulation; when this occurs, the action is presumably on different structures.

Selective Action.—The actions of drugs are generally much greater on some tissues than on others; *i. e.*, they are selective. The difference may be almost or quite *absolute*, so that the drug acts specifically on one class of cells. This "monotrope" action is important in parasiticides, and was Ehrlich's ideal of "*chemo-therapy*," the treatment of infections by chemic agents. Antibodies also illustrate a strickly monotropic selective action. With many drugs the differences are merely quantitative or *relative*, a number of structures being affected with various degrees of predilection, which may sometimes shift with changing conditions. The actions on the central and peripheral nervous systems generally belong to this relative type. *The mechanisms of selective actions* may consist in differences of penetration; of the chemic affinities of the cell; or of sensitiveness of the functions. The details are known only in a few cases.

Surface and Interior Actions.—A drug may act upon a cell without actually penetrating into it; for instance, by exciting the nerves supplying the cell or, more directly, by withdrawing water from the protoplasm; but as a general rule the poison must be absorbed into the cell or cell membrane before it can produce any action. In order that this absorption may take place, the drug must be soluble in the cell contents, and particularly in the cell envelope. The solubility of a substance in protoplasm is not necessarily the same as in water; it varies for each kind of cell, and consequently the penetrability of different cells for a given substance may vary greatly.

The quantity of a substance that enters a cell may be considerable and come within the compass of ordinary chemical reactions, even if the effects are produced by high dilutions. This holds especially if the substance undergoes selective concentration, sometimes to a thousandfold the concentration of the solution, particularly if the drug acts on the cell surface. The action in that case has no relation to the amount taken into the cell. In other cases the amount may be too small to cover the cell surface even with a monomolecular layer. It may then be assumed to act selectively on some constituent. When a drug acts on enzymes it may start a chain of events that may be far-reaching (A. J. Clark, 1937).

Ouabain is fixed by the heart of frogs and cats in the ratio of $2:10^6$, which has been calculated to cover less than 3 per cent of the heart cells with a monomolecular layer (Clark, 1933). Similar relations exist for acetylcholine and epinephrine.

The action of *inorganic catalysts* may be inhibited by poisons in amounts too small to cover their surface, so that the action must be limited to foci or "patches" on which the poison condenses. Rapid adsorption on the surface, followed by slow diffusion into the interior, is frequent in inorganic systems, for instance the adsorption of oxygen by charcoal, and illustrates what commonly happens with cells.

Intracellular administration by direct micro-injection may be quite ineffective compared with surface application, indicating that in these cases the drug acts on the cell surface. Instances are cyanide and hydrogen sulfide on Amoeba proteus (F. J. Brinley, 1928) and methylene blue on frog ventricle (R. P. Cook, 1926). Phenol, on the other hand, penetrates into the cells and disorganizes their protein structure.

Selective Absorption.—Absorption into cells is generally much better for nonionized compounds, for instance for free alkaloids (Overton, 1897); CO_2 and H_2S (Osterhout, 1925); and arsenious acid (Hoskins, 1932). All cell membranes, however, are somewhat permeable to ions (U. Friedemann, 1942).

While renal cells are very permeable for sulfates, intestinal cells are but slightly permeable. This peculiarity enables cells to preserve their own composition, notwithstanding considerable changes in the fluids in which they are bathed. It also explains why a given substance acts much more strongly upon one cell than upon another. It is illustrated by the distribution of *dyes* in living and dead tissues; or, indeed, in unorganized materials. Lipid solvents generally penetrate better than other agents, because of their affinity for the lipid constituents of the cell membrane. Other agents probably form "solid solutions" with some of the cell constituents; others are attracted by chemic differences—*e. g.*, the basic stains by the acid character of the nuclear chromatin. Adsorption and surface forces probably play an important part.

Selective Absorption into Pathologic Tissues.—The distribution may be modified by reaction, oxygen, the presence of a second substance, etc. Important differences arise also in diseased conditions, *e. g.*, iodides are taken up in higher concentration by degenerating tissues. Tuberculous caseous tissue has this property of condensing iodides and dyes, especially those of the safranine and acridine groups (A. Lewis, 1917). Other inflamed tissues and inflammatory products also tend to take up dyes (Cecil and Weil, 1917). Trypan red appears in the aqueous humor much more readily when the eye is inflamed or when physostigmine is applied (P. A. Lewis, 1916). The feeding of *madder dye* stains bone and pathological calcareous tissue *in vivo*, probably by forming calcium alizarate (Macklin, 1917).

Functional differences may simulate selective action, *the more delicate functions being damaged more readily.* Hence a poison which acts indifferently on all tissues produces the most conspicuous effect on the central nervous system.

CLASSIFICATION OF DRUGS ACCORDING TO SELECTIVE ACTION

Poisons which produce effects at the place where they are applied are termed "*locally-acting*" drugs. They may produce similar chemic changes in dead tissues. These usually cause inflammation when applied to living structures, and are then called *irritants* (including simple irritants, corrosives and astringents). Others lessen inflammation mechanically (emollients and demulcents). Others act chemically on all living structures, without changing dead tissues; these are termed "*protoplasmic poisons*." Poisons which act selectively on a few structures are called "*muscle-nerve poisons*." They may affect end-organs (sensory endings, gland cells, or striped, smooth or cardiac muscle); or the nerve endings; or ganglia; or any part of the central nervous system. *Nerve trunks* are so protected by their sheaths and by their limited blood supply that they are only affected when the poison is applied to them directly.

Systems of classifying drugs with systemic actions are unsatisfactory, because most drugs produce several effects which, by their interaction, complicate the subject so that no simple system will apply. With some drugs, one pharmacologic, chemic or physical feature predominates so greatly that they can be separated as fairly distinct groups.

The selective action of drugs is rarely absolute. When some one action is so predominant that it may be considered as the characteristic of the drug, there are generally other actions, especially when conditions are altered: even strychnine, a highly selective convulsant poison, acts as a general protoplasmic poison when it is directly applied in sufficient concentration. This accounts for the great variability which is often seen in the action of the same drug under different conditions. Atropine stimulates the vagus center, but paralyzes the endings; it may therefore cause either a quickening or a slowing of the pulse. Another frequent cause of variable actions lies in indirect actions: A drug which causes convulsions thereby tends to stimulate the vasomotor center, although its direct action of this center may be depressant. These variable actions and interactions make the effects of many poisons appear complicated, although they may prove quite simple on analysis. This analysis is important for a proper understanding of the action, but it is still more important to remember the complex effects which result, for it is with these that the practicing physician has to deal.

The pharmacologic action in this sense is often not the therapeutic action. An important pharmacologic action of morphine is stimulation of the spinal cord; but it is not used therapeutically for this purpose, since this action is overshadowed by its other effects. For this reason it would not be advisable to classify drugs strictly according to their pharmacologic actions. On the other hand, a *therapeutic classification* is not favorable to a study of the underlying actions of the drugs, and tends to empiricism Buchheim (the founder of modern pharmacology, by the establishment of the first pharmacologic laboratory at Dorpat in 1856) compromised by grouping drugs according to their principal pharmacologic characters, taking account of all the important actions, as well as of the chemic properties, and in many cases also of the therapeutic uses of the drugs. This is the general objective in this volume.

Definitions of Pharmacologic Terms.—Some rather loosely used pharmacologic terms may be defined in this place, in the sense in which they are generally employed in this volume:

Local actions: produced at the place where the drug is applied. *Remote actions:* occurring in distant parts of the body; they may be either systemic or reflex. *Systemic effects* (sometimes called general action): produced after the absorption of the drug into the circulation. *Direct effects* (sometimes called primary): produced by the direct action of the drug on the tissue concerned. *Indirect effects* (sometimes called secondary), are not produced by the action of the drug on the tissue concerned, but by the intervention of some other structures on which the drug acts (*e. g.*, asphyxial convulsions are an indirect effect of asphyxiant poisons). *Reflex effects* are indirect actions arising from local irritation. *Immediate effects* (also sometimes called primary) are the effects resulting at once. *Late effects* are those occurring later; if they are preceded by other (immediate) actions, they may be called *secondary actions. Side actions* are actions which are not desired in the therapeutic use of the drug, producing untoward effects.

Localization of action involves the methods of experimental physiology:

The Study of Isolated Structures.—To eliminate the complications which arise from simultaneous actions on several structures or from indirect actions, the tissues to be studied are generally isolated. The most certain method is the actual anatomic isolation of the structure. Drugs of known antagonistic actions may also be utilized, but they are likely to lead to erroneous conclusions. The method that gives reliable results with *the least difficulty of technic* is preferred. Complete isolation is in many cases superfluous. If the question is, whether an observed *stimulation* is of a central or of a peripheral structure, it suffices to divide the nerve: on an efferent chain, this abolishes the effects of a central stimulation, while those of a peripheral stimulation persist. With an afferent chain the conditions would be reversed.

A few examples may illustrate this general method:

1. *Strychnine* produces a tetanus. This implies motor stimulation somewhere. The sciatic nerve is cut; it is found that the convulsions disappear in the leg but persist in the rest of the body. The action must therefore be central. The cerebrum and medulla are successively excised; the convulsions persist, and must, by exclusion, be located in the cord. This is confirmed by destroying the cord, which causes the complete disappearance of the tetanus.

2. *Curare* produces complete muscular paralysis. Stimulation of the sciatic elicits no response. The paralysis must therefore be peripheral. Direct stimulation of the muscle is effective. This excludes all the possible structures except the nerve trunk and endings. The nerve of another preparation is laid into the curare solution, and after a time is stimulated; a contraction results, so that the nerve trunk is not paralyzed. The action must therefore be on the endings.

If a peripheral structure is stimulated or paralyzed, it is impossible to decide by this method whether there is not also a central action, for the peripheral effects would obscure the central. Stimulation of the cord, for instance, could cause no effect if the drug had paralyzed the motor endings. In these instances, it is necessary to confine the action of the drugs to the centers.

The Study of the Effects of Drugs on Intact Normal Animals.—A complete conception of the actions of a drug can be obtained only by integrating the study of its effects on isolated structures with careful observation and analysis of the symptoms which it produces in intact mammals. The effects on metabolism, and the histologic lesions, etc., can only be studied in this manner. These experiments are generally undertaken before the more difficult investigations on isolated structures, for they furnish valuable hints of the direction which the latter should take. When circumstances permit, it is advisable to proceed from the lower to the higher classes of animals, and finally to man. Opportunities of observing the *effects of drugs on man* occur in cases of poisoning, but intentional experiments with drugs on man are to be undertaken only with the greatest caution, with doses which do not exceed the therapeutic maxima; and, as a rule, only after the effects have been thoroughly studied on animals. The lower aquatic animals may be used for a preliminary survey if their differences are kept in mind (Daphnia; T. Sollmann and Webb, 1941).

The Effects of Drugs in Disease.—The action of drugs is not always the same in disease as in health. The differences are as a rule quantitative rather than qualitative.

Animal experiments are of limited value in this connection. Observations on patients must be made accurately, psychic factors excluded and the existing pathological condition correctly known. These requirements are not fulfilled in many cases, which accounts in part for the differences which are occasionally noted between clinical and experimental data. Clinical tests of the older drugs have been made so abundantly that further observations might seem superfluous; but accurate observations in the light of advancing knowledge, and employing the improved methods of diagnosis and observation, are always needed. It is highly desirable that every physician should obtain his knowledge of the therapeutic action of drugs at first hand. He should utilize every case under his care for this purpose, and conduct his treatment as if it were a critical experiment, the interests of the patient being, of course, paramount. The conclusions will be greatly simplified if but one drug is used at a time.

Transfer of Results of Animal Experimentation to Man.—The utilitarian aim of pharmacology is to supply medicine with a scientific basis for the practice of therapeutics and for the study of toxicology. This can be attained only by experimentation on lower animals. This brings up the fundamental question: *To what extent can results observed on animals be transferred to man?* The same question applies to all other fields of experimental medical research, and has been abundantly answered by their results. *A similar physiology implies a similar pathology and pharmacology.* In the majority of cases, similar structures are affected in the same way by a given drug, no matter in what animal they are studied. Where differences exist, they can usually be explained by differences of physiologic function. They are now generally recognized so that suitable species can be chosen for experimentation. They can be eliminated further by using the drug on several species: *If a given poison affects all species alike, it may be concluded that its action on man is also the same.* If it produces different effects, which can be explained by differences in physiology, the effects on man will be similar to those produced on the species the physiology of which resembles most closely that of man.

Value and Limitations of Experimental Pharmacology.—Care must be used in applying the results of experimental pharmacology to man. The neglect of this precaution, the drawing of far-reaching conclusions from limited experiments is seen all too frequently. Pharmacology can not be held responsible for misapplication of its data. Its scope is limited primarily to its own results and not to their application, although it may legitimately suggest the latter. It should not be made to replace therapeutics, but should aim to place well-studied tools in the hands of the latter. If this limitation is realized; if the therapeutist will carefully study the results of pharmacology and will utilize and interpret them in the light of bedside experience, then pharmacology will be of great value to medicine. An important service is rendered by pharmacology through the examination of new remedies. The development of synthetic chemistry has resulted in the discovery of a large number of new substances of some therapeutic value. The number is so large that all could not be given a thorough trial on patients. Most of these substances possess some value, but many differ from each other by insignificant details. In this case, pharmacology can select the most promising and, by their thorough study, indicate those which are worthy of trial by the clinician. *The laboratory and clinical appraisal of new drugs* is outlined by W. Van Winkle *et al.*, 1944.

THE CHEMICAL AND PHYSICAL BASIS OF PHARMACOLOGY

Scope of Pharmacology.—The term *Pharmacology* in a general sense covers all scientific knowledge pertaining to drugs, *i. e.*, to substances which may be used in the treatment of disease. *Materia Medica, Pharmacognosy* and *Pharmacographia* have the same meaning when they are used in a general sense. Commonly, however, the term "pharmacology" is used in a more *restricted sense,* as a synonym for *pharmacodynamics.* It concerns itself with the actions of drugs on living structures, or with the reactions occurring between drugs and living structures. It is therefore a branch of physiology on the one hand, of chemistry on the other; and is essentially a division of biology. It has important practical relations with *toxicology* (the science of poisons), and with *therapeutics* (the treatment of disease). A. J. Clark defines "*general pharmacology*" as dealing with the mode of action of drugs.

The Nature of Pharmacologic Action.—The processes of life are conditioned by chemical and physical changes in the constituents of the cells. Foreign chemic substances may enter into these reactions and thus modify them more or less profoundly, with corresponding changes of function. These are termed *drugs* or *poisons,* according to whether they are useful or harmful in a given case. Some of the reactions are comparatively simple, analogous to those produced on isolated proteins. Others involve enzymes; others occur only in living substances. Some compete for substances needed in normal metabolism (review, L. Young, 1939).

Physicochemical Conditions of Life.—The chemic decompositions and syntheses, reductions and oxidations, which are constantly going on in living cells lead to transformations of energy which find their final expression in the phenomena of life. The vital manifestations of the cell are, therefore, inseparably connected with physicochemic transformations, which require for their occurrence the existence of certain chemic and physical conditions.

Changes in the Cell Membrane.—Since most cells are in contact with surrounding fluids, they must be protected against changes of composition by a limited permeability of their surface layer, the cell wall or plasma membrane. This contains lipoid and protein constituents, and may be altered by fat solvents or by agents which either precipitate or liquefy proteins. This explains, at least partly, the effects of *lipolytic narcotics;* hemolysis by these, by *alkalis* and *saponins*; the actions of various *ions*; especially Ca, etc.

Osmotic Changes.—Cells are generally much more permeable to water than to dissolved substances. This leads to osmotic phenomena—the withdrawal or absorption of water—when the cells come into contact with solutions of higher or lower salt concentration. This explains the actions of many otherwise nearly indifferent salts, *e. g.*, *saline catharsis* and *diuresis.*

Surface Forces.—The physical structure of protoplasm is such as to present large surfaces and give peculiar opportunity for the development of surface forces, which are important for various vital functions. These are greatly modified by a variety of substances, including the *lipoid solvents, salts,* etc.

Colloid Phenomena.—Many chemical and physical conditions depend on the colloid character of protoplasm. The aggregation of colloids and their reactions are easily modified, especially by salts, acting by their chemic properties and electric charges. This is an important element in *salt action.*

Dependence of the Pharmacologic Action on the Chemic Constitution.—Drugs of different constitution may have apparently identical actions, as strychnine and tetanus toxin; arsenic and cholera infection; digitalis and barium; but the resemblance may be superficial. In general, however, drugs having a similar constitution possess similar actions; and definite changes in the molecule—as in homologous series, or the introduction of new groups—often produce definite modifications in the pharmacologic effects. This should be expected, since the physical as well as chemical properties change with the constitution. This relation has a wide general application; but its application to details has been rather disappointing, because sufficient knowledge is lacking to take account of the numerous variables. The data which we possess were gathered empirically.

The Importance of the Chemic Radicals or "Side Chains."—A substance, to produce chemical pharmacologic actions, must be capable of combining with protoplasm and then of altering its properties. These two functions—combination and action (analogous to amboceptor and complement, P. Ehrlich)—may be united in the same group; but they may be distinct ("haptophore" and "toxophore" groups), so that one may be modified without the other. Often several groups are present which may enter different combinations under different conditions. It is evident that these may introduce great variations in the actions. Side chains generally do not themselves produce pharmacologic actions, but act indirectly, by altering the chemical and physical properties of the molecule, for instance, its solubility, penetration, lipoid partition, surface affinity, oxidation and reduction. A few configurations, however, are important in themselves; for instance, the curare-action conferred by quaternary structure.

Crum-Brown and Fraser, 1869, showed that a number of alkaloids (strychnine, atropine, morphine and its esters) on conversion into *quaternary salts* by methyl iodide lose more or less of their original actions and acquire curare actions; this is also possessed by quite simple quaternary iodides—for instance, tetramethyl ammonium iodide; and other elements, such as sulfur or antimony, may be substituted for the nitrogen.

◆

OBJECTIVES OF TREATMENT

Physiologic functions tend to run their normal course, that being their most stable equilibrium; or to return to it when they have been disturbed by disease, either by "homeostasis" or by special reactions, as in inflammation. This constitutes the "*vis medicatrix naturae*," the healing power of nature. Adverse conditions may impede the tendency to normal, and the purpose of therapeutics is essentially to remove adverse and to establish favorable conditions for normal functioning.

Preventive or prophylactic treatment aims to protect the body from disease. It comprises individual and community hygiene.

Etiologic, Causal or Curative Treatment.—The cure of disease is scarcely possible while the original cause persists. If the cause can be discerned and removed, the conditions will generally return to the healthy normal unless anatomic lesions have already occurred. The chances for complete recovery are therefore the better, the earlier effective treatment is instituted. Even considerable anatomic deficiencies, however, can be compensated by the fact that the organism has large "factors of safety" (Meltzer).

Symptomatic, Functional or Alleviative Treatment.—When the cause of the diseased condition can not be attacked, it is often possible to remove its functional manifestations or symptoms. This may be useful in some cases, objectionable in others.

The symptoms in themselves may be so objectionable or lead to such secondary results as to make their removal desirable. Pain, cough and fever are symptoms, but they may require relief even though the root of the disorder may not be removed. The derangement of function may be immediately dangerous, as cardiac dilatation; or it may add to the tax on the diseased organs, as the edemas of valvular disease. Faulty functionation may also be relieved by increasing other compensating functions, such as diaphoresis in renal disease. On the other hand, the symptoms may be deceptive—a febrile chill may not require external heat; a referred pain may not be relieved by application of a local anesthetic to the place where it is felt. Removal of the symptoms may remove the index to the treatment of the underlying disorder. In many cases the symptom may itself be salutary, as cough when there is hypersecretion of mucus; or pain when rest is indicated in fracture.

Restorative or Roborant (Strengthening or Tonic) Treatment.—Disease generally impairs the vitality and resistance of the organs directly involved, and of the body at large. This is corrected by rest and efficient nutrition of the diseased organs and of the entire patient; and by correcting any other abnormal conditions (digestive disturbances, suppurations, etc.) which may be present, and which are drains on the vitality of the patient.

Expectant treatment is the absence of treatment beyond hygiene, rest, diet and other similar general measures, with the object of leaving the powers of nature free play. It should be employed in all cases where no better treatment is known. Expectant treatment must be used when it is desired to let the disease progress to a certain point for diagnosis.

Empiric and Rational Therapeutics.—The treatment of disease has developed by two different methods or, perhaps more accurately, attitudes of mind. The *empiric* method follows the dictates of apparent experience, without concerning itself about the reasons of these. It is typified by the charlatan slogan, "It has cured others and will cure you." The objection to the empiric method is not that it rests upon experience, for this is the basis and final arbiter of all science, but that it does not endeavor sufficiently to distinguish whether the experience is real or deceptive, whether the analogy is superficial or genuine. It is an equally grave error to base treatment on theories and deductions inadequately supported by observation. *Rational or scientific therapeutics* should employ observation, experiment and scientific reasoning, checking each against the others.

Pharmacal and Nonpharmacal Therapeutics.—A distinction is sometimes made between "drugs" and "physiological agents," including under the latter physical measures, such as heat or cold, bathing or climate, rest, exercise and massage, diet, etc. The distinction is convenient, but not fundamental. The use of drugs is no more "unphysiological" than the use of abnormal heat or cold, or of special diets. The mechanisms of their action are not essentially dissimilar. Each is intended to produce definite changes of functions. One or the other may be better adapted to secure this end. The body normally produces a variety of pharmacologically active substances, as direct or by-products of its metabolism, and uses them as aids in regulating its own activity. The CO_2 control of the respiration and the various hormones and internal secretions are familiar examples in mammalian physiology (Starling, 1908).

The historical evolution of the treatment of disease explains many errors which still adhere to the subject. Primitive man attributed disease to malevolent spirits which could be appeased by prayers and incantations. This formed the principal "medicine" of prehistoric ages, as it does of the modern savage. It survives in a modified form in "Christian Science." Chance and the observation of animals revealed that certain material products are also efficient. When this was limited to actual observation, the results were usually good; but the fantastic, half logical incongruity of the untutored mind led to bizarre relations.

The Middle Ages tried to combine the spiritual and the material treatment. It was reasoned that the Deity alone could cure disease, but that He had given man material remedies, and had put a seal upon them by which man might know them. Thus arose the doctrine of "signatures," that the use of a remedy was suggested by a fanciful resemblance in shape or color to some organ; *e. g.*, the liverwort, the lungwort, bloodroot, etc. Even a name was sufficient. Silver was used in lunacy because it was dedicated to Luna. In the meantime, alchemists had arisen with their search for the philosopher's stone, which was to convert all metals into gold, and cure all diseases. They gave their nostrums extensive trial on sick and well. The school of spagyrists was founded toward the end of the fourteenth century and reached its zenith with Paracelsus. They insisted upon the mystical virtues of antimony, arsenic, silver and chemicals in general, and stood opposed to the Galenists, who used only organic drugs. Notwithstanding their mysticism, which savors of quackery, they discovered some valuable medicines. A mass of materials, rubbish and otherwise, was added to the various simples, etc. Having a well stocked armory, the physician of that day felt that he was not doing his duty unless he gave his patient the benefit of it all, and the "shot-gun" prescription flourished.

The Homeopathic Doctrine.—A reaction against excessive drugging set in, and had as one of its results the establishment of homeopathy by Hahnemann at the end of the eighteenth century. He believed that disease depends upon a perversion of the spiritual vital powers and is immaterial in its nature. Logically, a thing spiritual could not be combated by material remedies, and Hahnemann turned to a spiritual power which he believed to be bound up in plants and liberated by dilution. The activity would therefore increase with the dilution, and be the greater, the smaller the dose (*doctrine of potency*). He thought that this liberation of the principles exactly turned their action around, so that the action of his dilutions was, he stated, exactly the opposite of that of the concentrated drug, and could be used for the relief of such symptoms as the latter produced: *Similia similibus curantur*. This was the first tenet of Hahnemann. The second was that, the nature of the disease being unseizable, it was not subject to treatment, and only its symptoms could be treated. Hence homeopathy in its pure form had no place for the medical sciences, such as physiology, anatomy, pathology or chemistry. The claims of homeopathy as a rational system hinge on the proof of the *similia similibus* theory and of the doctrine of potentiation by dilution. Its adherents appear to be considerably divided on these questions (Boyd: "The Simile in Medicine," Boericke and Tafel, Philadelphia, 1936). Some seem to deny the relevance of scientific evidence, and to base themselves purely on the slippery ground of superficial experience. Others, while they neglect the bulk of scientific experience, avail themselves of such experimental facts as can be turned into a specious support. Hahnemann seems to have started from the observations that large doses of drugs produce the opposite effects from moderate doses. This holds true for some cases, but it does not warrant the assumption that infinitesimal doses must again cause increasing effects opposite to those of moderate doses! The discovery of the effect of dilution on ionization has been used as illustrating homeopathy, disregarding the fact that the majority of the substances employed in homeopathy are not electrolytes. Hahnemann accomplished considerable for medical science by calling attention to the importance of diet and hygiene, when these were too much neglected; but perhaps the principal use of homeopathy has been to emphasize that disease tends to recover even without medical interference.

Therapeutic Nihilism.—One of the passing fads of medicine was an almost total emancipation from all drugs. This dates from the establishment of the Vienna School by van Swieten in 1745. The strongest advocate of nihilism was Skoda (1805–1881). Such nihilism was perhaps necessary at that time. The accumulated refuse was so great as to bury the good; to discard the whole and to begin anew may have been the quickest way to progress. The dominant motive, however, was probably the absorption of interest by the then novelty of physical diagnosis, which tended to the neglect of the traditional duties of the physician: "sometimes, to cure; often, to relieve; always, to console."

The Rise of Rational Therapeutics.—The reestablishment of therapeutics, founded now upon reason, was eventually aided by the physical methods of diagnosis, for these made it possible also to demonstrate the effect of remedies. The isolation of active principles (led by the discovery of morphine in 1817) substituted definite for indefinite drugs. Finally followed animal experimentation, the foundation of modern pharmacology.

Many of the older therapeutic measures, both drugs and physical, have not stood the test of critical examination and have been abandoned or are less used. The same critical methods, however, have confirmed the value of other measures, and established that of new drugs, on a firmer basis. Even the surgeon, whose therapy is mechanical by definition, uses general and local anesthetics, hypnotics, sedatives and analgetics and various antiseptic and antibiotic agents; salines for collapse and for catharsis; tannic and picric acid for burns; radiopaque agents; iodine and thiouracil, thyroid and parathyroid, epinephrine and pituitary, atropine and physostigmine, insulin, vitamins, antisyphilitic therapy and many others.

Psychotherapy.—At the same time, the mystic has been further developed in the many forms of suggestion employed in its milder forms by every physician as "the personal influence" and the "faith in doctor and medicine." It often constitutes all there is of merit in those medical fads which have accompanied medical science.

◆

GENERAL TOXICOLOGY

Toxicology is the science of poisons. The details of the actions and symptoms will be considered in connection with the individual poisons, but certain matters of general application may be discussed here.

Definition.—A poison is any substance which, acting directly through its inherent chemic properties, and by its ordinary action, is capable of destroying life or of seriously endangering health, when it is applied to the body externally, or in moderate doses (to 50 Gm.) internally. This definition excludes injurious mechanical, physical and bacterial agents, which are not commonly classed as poisons. It also excludes substances which are injurious only in very large doses. This is somewhat arbitrary, as are all definitions (see, *f. i.*, the collection by Murray and Frame, 1914).

Etiology.—Poisoning may be classified as criminal, suicidal, industrial or accidental. The statistics for these vary from year to year. Suicidal poisons are likely to follow vogues.

The *incidence of fatal poisoning* in New York City for 1937 may be taken as illustrative. Exclusive of alcoholism and anesthetic accidents, it included 898 persons. Two-thirds of these deaths occurred from carbon monoxide. Next to this, the suicidal deaths were caused by cyanide, barbiturates and mercuric chloride; the accidental deaths by heroin, arsphenamines, methyl alcohol and barbiturates. Homicidal poisoning was rarely diagnosed correctly during life (M. Helpern, 1939). Some 1200 deaths from accidental poisoning occur annually in the United States. About a fourth of these are in young children, and of these about seventy-five are from strychnine, generally in cathartic pills; sixty are from methyl salicylate. Wood alcohol caused about 150 deaths (Metropolitan Life Statistical Bulletin, Feb., 1944).

Industrial exposure to toxic chemicals is of increasing importance. It is most effectively met by preventive measures; by minimizing opportunities for exposure and by eliminating unsuited personnel, individuals "below par" (J. M. Foulger and Fleming, 1941) and those with susceptible skin.

Symptoms of Poisoning.—*Suspicion of poisoning* is aroused if a person, previously in good health, manifests rather suddenly marked pathologic symptoms which rapidly become worse. The suspicion becomes more firm if the phenomena appear a short time after swallowing some substance which may perhaps have an unusual odor or taste, if they agree in character with those produced by some group of poisons, and if they do not agree with any other disease.

Symptomatic Classification of Poisons: The following classes are generally recognized.

1. *Irritants* produce inflammation; if they are taken by mouth, there is pain throughout the alimentary canal, vomiting, purging, delirium, coma. So many poisons are to some extent irritant that these symptoms are commonly present. The irritants can be subdivided into *corrosives*, which produce direct destruction of tissues, and *simple irritants*, which do not. If corrosives are taken by the stomach, the vomit is often bloody.
2. *Nerve poisons* act on the neuromuscular apparatus, and include most of the poisons which are fatal in minute doses. They are subdivided into: *Convulsants*, which cause spasms; *Somnifacients*, causing sleep and coma; and *Cardiac poisons*, which stop the heart.
3. *Blood poisons* alter the hemoglobin or blood corpuscles. These include the toxic gases, the nitrites, etc. Many produce cyanosis.

The actions of a poison are usually not confined to one class of structures or functions. All functions suffer directly or indirectly, and the final *cause of death* is arrest of the heart or paralysis of respiration, preceded by the phenomena of *asphyxia*. In virtue of the latter, or through other causes, the urine often contains sugar.

The duties of the physician in cases of poisoning are twofold: to save life or suffering, and to forward justice. The former object requires the removal of the poison, the administration of chemical antidotes and the treatment of the symptoms. *To detect the poison* and to aid in fixing the guilt on the proper person, the physician must observe the symptoms, take possession of any suspected material, medicine, vomit, etc., and in case of autopsy, preserve the stomach and its contents, the intestines and contents, blood, liver, kidneys and portions of other organs, *separately*, without antiseptics, in clean, hermetically closed glass vessels, which should be sealed with wax. An exact *written record* of all the observations should be made as soon as possible.

TREATMENT OF POISONING

Although every case of poisoning must be considered by itself, certain general principles are widely applicable. These are especially important when the nature of the poison is unknown. The rapid course of poisoning demands that whatever measures are taken, *must be taken quickly*. The physician should be thoroughly familiar with the general rules of treatment, so that no hesitation or delay occurs. The antidote nearest to hand should be used in preference to one which can be obtained only with delay, even if the latter should be theoretically preferable.

The treatment of poisoning is directed against the cause and the symptoms. The former consists in *removing the poison*, or in *rendering it harmless*. Since neither of these objects can usually be attained absolutely, both are generally attempted at once.

Removal of the Poison.—The measures vary with the site to which the poison was applied. *On the skin and on accessible mucous membranes* this is accomplished by thorough washing with water. which is also useful by diluting the poison. If the poison is only sparingly soluble in water (as phenol), alcohol may be employed. Soap may be useful, but should be avoided if the poison is an alkali. The appropriate chemical antidote may be added to the wash water (for acids or bromine: soap or sodium bicarbonate or borax or lime water; for alkalis: diluted vinegar or lemon juice). The chemical neutralizant must be sufficiently diluted so that it is not itself harmful. Further treatment of irritation consists in the application of oils or salves. If the poison has been applied *hypodermically or to wounds*, the systemic effects may be lessened by preventing or retarding the absorption of the poison. If the absorption can be delayed sufficiently so that the drug is excreted as fast as it is absorbed, doses which would otherwise be fatal may cause no effect. The best means for this purpose is a firm ligature applied centrally to the wound. Where this is not feasible, suction, cautery or excision may be practiced. If an irritant poison has been *taken by the mouth*, the oral cavity and the pharynx demand the same treatment as would the skin. With *gaseous poisons*, the treatment consists in free ventilation of the lung, using artificial respiration and oxygen, if necessary. Addition of 5 per cent of carbon dioxide hastens the ventilation.

Removal from the Alimentary Canal.—If the poison was taken by mouth, the stomach should be emptied by lavage or by an emetic, even though vomiting has occurred spontaneously, and even if the patient is not treated till several hours after swallowing the poison; for some poisons remain in the stomach for a long time. Contraindications are corrosion and advanced strychnine poisoning. These require judgment and caution. After the stomach has been evacuated, 15 to 30 Gm. of magnesium sulfate should be administered in water to clean the intestine of slowly absorbable poisons.

Evacuation of the Stomach.—Lavage has advantages over emesis. It cleanses the stomach more effectually, particularly of small undissolved adherent particles; it is less depressant to the patient; and it permits the effective use of chemic antidotes. It is indispensable with depressant poisons which paralyze the vomiting center, such as deep morphine or chloral poisoning.

The complicated stomach pump has been replaced by the more convenient stomach tube. In emergencies, 6 feet of rubber gas tubing, with a funnel attached, answers very well. The tube should not be *forced* down, but should be *gently* pushed to the pharynx, where the pharyngeal muscles will grasp it and push it further. Care should be taken to avoid overdistention of the stomach; it is better to use small quantities of fluid repeatedly. The chemical antidote may be added to the lavage water (for instance, potassium permanganate, 1:2000, against organic poisons), and 100 to 300 cc. of the antidotal solution should be left in the stomach at the end. If there is trismus, or the patient resists, the tube may be passed through the nose.

Emetics have the advantage of greater convenience, and avoid struggling. They should be repeated every fifteen to thirty minutes, if necessary. *Household measures* which may be used before the arrival of the physician include tickling the fauces with the *finger;* gargling with *soap suds; table salt,* a tablespoonful to a glass of warm water, repeated four or five times if necessary; and *mustard,* a teaspoonful stirred in a tumbler of warm water. *The most effective emetic* is *apomorphine,* 5 mg. (grain $\frac{1}{12}$), hypodermically. It is the only emetic which can be given by the skin, and is therefore particularly useful if the patient resists. It is prompt and certain, but rather more depressing than *cupric sulfate or zinc sulfate,* which act promptly and with a minimum of depression, but should not be given if the poison is a corrosive. Zinc sulfate is less irritant than the copper, and nearly as efficient; 2 Gm. may be given in a glass of water. The dose of copper sulfate is 0.5 Gm. at once, or three doses of 0.3 Gm., fifteen minutes apart. If it is ineffective it must be removed by lavage. *Ipecac,* a teaspoonful of the powder in water, or a tablespoonful of the syrup, is uncertain and produces considerable depression.

Hypodermically injected drugs cannot be removed effectively, but their absorption may sometimes be delayed by epinephrine or by a tourniquet, and this may greatly lower the toxicity by permitting excretion or destruction of the poison, or its fixation in the liver. Water should be administered freely to favor diuresis; but diuretics do not generally hasten the excretion of poisons materially (Hatcher, strychnine; Sansum, 1918, tetanus toxin).

Chemical antidotes are often effective locally and in the alimentary canal, but with few exceptions (such as nitrite in cyanide poisoning) they are useless after absorption. They either neutralize or destroy the poison; or precipitate it or envelop it in an impenetrable coating; or adsorb it so as to slow or prevent its absorption. Since these antidotes are hindered in their action by the presence of food, and since the precipitates are not quite insoluble, it is advisable to combine them with lavage or emesis, adding the antidotes to the wash water, or giving them in the interval between vomiting; they must be repeated frequently.

Antidotes which destroy the poison in the alimentary canal include, *against Acids:* Alkalis (burnt magnesia, soap, chalk, baking soda). *Against Alkalis:* Weak acids (vinegar, lemon juice). *Against Organic Poisons* (*Alkaloids, Glucosides, etc.*) and *Phosphorus:* Oxidizing agents, especially potassium permanganate, 0.15 Gm. or a penknife-point full to the tumbler, repeated as often as it is vomited; or for lavage, a liter of 1:2000. It should be strained so that no undissolved crystals are administered. It is quite irritant, and its efficiency is limited, especially by the presence of organic matter. In snake bite, powdered permanganate may be rubbed into the wound, after free incision. Hydrogen peroxide is a useful though less powerful oxidant. *Against Hydrocyanic Acid:* Permanganate, arsenic antidote, hydrogen peroxide, and thiosulfate of sodium ("Hypo"). *Against Formaldehyde:* Ammonium carbonate.

Precipitants.—*Tannic acid* (a teaspoonful in water, or very strong hot tea, ad libitum) tends to precipitate various metals, alkaloids and a number of other organic substances. It is not reliable, but is harmless and does not interfere with other treatment. It is chiefly useful as an adjuvant. The effect is increased by the addition of sodium acetate or bicarbonate, and diminished by alcohol and acids, since the precipitates are soluble in these media.

From the experiments of Kiefer (1892) on tannic acid, and Sollmann (1901) on tea, these would be *useful* against: apomorphine, cinchona alkaloids, hydrastine, strychnine, veratrine, digitalis, antipyrine, colchicine and the metals: Pb, Ag, Al, Co, Cu, Ni, Ur, Zn, Fe. *Scarcely useful* against: cocaine, brucine, aconitine, lobeline, nicotine, pilocarpine, codeine, muscarine, physostigmine, solanine. *Practically useless* against: atropine, coniine, morphine, As, Sb, Hg.

Of other *specific precipitants,* the following should be remembered: For *alkaloids:* tincture of iodine, 15 drops in half a glass of water. For *metals* (especially mercury): raw eggs. For *mercuric salts:* sodium thiosulfate; sodium formaldehyde sulfoxylate. For *arsenic:* arsenic antidote (see Index). For *barium:* sulfates (Glauber's or Epsom salt). For *oxalates:* calcium (limewater, chalk, whiting). For *phosphorus:* cupric sulfate or oxidized (old) turpentine. The former envelopes the phosphorus with an insoluble coating of metallic copper.

Adsorbents act promptly to delay the absorption of many substances, and are harmless in any case. The most effective is "*activated charcoal,*" a tablespoonful in water, before and again after emptying the stomach. *Demulcents* (raw eggs, boiled starch, flour, milk) hinder absorption less effectively than charcoal, but they are useful if this is not promptly available. They also allay local irritation.

Symptomatic Treatment.—The symptoms produced by poisons can often be lessened or removed by the use of drugshaving an opposite action. These *physiologic antidotes* may not abolish the action of the poison, but only mask its symptoms. By tiding the patient over the dangerous period, and by preventing exhaustion, they may save life. Large doses of the antidotes often cause effects similar to those of the poison, which may add to the fatality of the latter. They must therefore be used in a ppropriate small doses. Themeasures which are generally useful are directed, in the *order of their importance*, to: supporting the respiration, heart and vasomotor tone; to lessen cooling, pain, convulsions and coma.

Respiration is usually the first function to fail, and this accelerates the other actions of the poison through the convulsant and paralytic effects of asphyxia. It is advisable to begin with the supporting measures as soon as the respiration shows signs of weakening. The measures consist in direct or reflex stimulation of the respiratory center; in artificial respiration; and in the administration of oxygen. *Reflex stimulation of the respiratory center* is the quickest, but can not be kept up as long as the direct stimulation. It may be secured by inhalation of ammonia water or smelling salts, or by aromatic spirits of ammonia (half a teaspoonful in a glass of water); the alternate application of heat and cold (slapping with wet towels); friction with alcohol; mustard plasters; faradization. *Direct stimulation of the respiratory center* is generally accomplished most effectively by inhaling 5 per cent carbon dioxide in oxygen. Other stimulants (lobeline, nicotine) require dangerous doses to be effective. Caffeine as such or as strong hot coffee, ephedrine and atropine are not very successful. The respiration may also be raised by improving the circulation. Saline infusion is useful. *Artificial respiration* should be employed when these measures are ineffectual. Excessive artificial respiration is likely to induce apnea, so that the patient does not breathe spontaneously because there is not enough CO_2 in the blood to stimulate the respiratory center. If the heart is strong, the artificial respiration should therefore be intermitted occasionally for a short time. *Oxygen* is useful if an asphyxiant gas is the cause of the poisoning.

Circulation.—It is sometimes possible to improve a failing heart by reflex stimulation, by the inhalation of diluted ammonia, by swallowing the aromatic spirit of ammonia, or by intravenous injection of normal saline solution, perhaps with the cautious addition of epinephrine (1:100,000). Lowering the head and bandaging the extremities also add to the blood supply of the brain and heart. Strychnine and atropine are generally ineffective. If a heart has been arrested through asphyxia, rather than through a direct cardiac action of the poison, and if it has not stopped longer than a very few minutes, it may sometimes be resuscitated by cardiac massage, combined with epinephrine by intravenous or, more effectively, by intracardiac injection.

Cooling is prevented by the application of external heat; **pain** by morphine; **convulsions** are controlled by the cautious inhalation of chloroform; **coma** by reflex stimulants, coffee and atropine.

Methods of Administering Antidotes.—Physiological antidotes should be given hypodermically or intravenously, if possible. This obviates the loss of the antidote through vomiting, and the response is prompter and more certain. If the circulation is low, the absorption of hypodermic injections may also be slow. It is therefore well thoroughly to massage the site of the injection, and if the circulation has almost stopped, to employ vigorous rapid rhythmical compression of the heart.

Résumé of the General Treatment of Poisoning.—Promptness is of vital importance. The physician should be familiar with antidotes; he should have these antidotes readily accessible; he should plan his treatment on his way to the patient. If he finds the condition of the patient dangerous, he should at once proceed to relieve the symptoms. Otherwise he should first administer the chemical antidote and evacuate the stomach;

apply heat; attend to the respiration, to pain, to any other symptoms; give a cathartic.

Antidotes for First Aid.—Every physician (and every drug store) should keep the following antidotes together, in a special satchel ("Antidote Bag") so that they can be readily transported. The dose should be written on each container. Amyl nitrite pearls; Apomorphine tablets, 2 mg.; Atropine tablets, 1 mg.; Bicarbonate of sodium; Caffeine-sodium benzoate; Charcoal, activated; Chloroform; Cupric sulfate, powdered; Epinephrine tablets, 1 mg.; Limewater; Magnesia, calcined; Metrazol, ampuls of 1 cc. of 10 per cent; Morphine sulfate tablets, 10 mg.; Nitrite of sodium, ampuls of 10 cc. of 2 per cent; Olive oil; Pentobarbital sodium, ampuls, 0.5 Gm.; Potassium permanganate, 1 per cent solution (to be diluted twenty times); Sp. Ammon. Arom.; Tannic acid; Thiosulfate of sodium, ampuls of 10 cc. of 30 per cent; Tr. iodine; Whisky; also a hypodermic syringe in good order, and stomach tube with funnel. The following may be demanded at the house of the patient: Boiled water; Coffee (strong, hot, and black); Eggs; Hot-water bags; Milk; Mustard; Salt; Soap; Starch, boiled; Tea; Vinegar. An interesting exposure of the contents of the *"doctor's bag"* is given in the Cornell Therapy Conference, New York State Journal of Medicine, August 1, 1943.

◆

MEDICINAL FOODS

These may be useful as adjuvants to other foods, for superalimentation; when digestion is low, as in fevers or convalescence; or to tide the patient over a temporary crisis; and in the feeding of infants.

Rectal feeding would be desirable when the stomach does not retain food or when food by mouth is inadmissible for other reasons, but its practical possibilities are limited mainly to dextrose, water and salt. It suffices only for short periods, depending on the previous condition of the patient, especially the adipose tissue. The rectum and large intestine have practically no digestive power, except to a limited extent for carbohydrates. Water, dextrose and sodium chloride are absorbed effectively from nutrient enemas. Dextrin is easily digested and then absorbed. Amino acids are absorbable, but proteins are not; not even peptones unless they are first broken down by bacterial putrefaction. Fats are practically unabsorbed.

The absorption of *water* is a normal function of the colon, for this resorbs one-half to two-thirds of the water of the colon contents. The entire water needs of the organism can be supplied by this channel, provided that the injections do not contain irritant substances and are not too strongly anisotonic. Many *salts* are absorbed perfectly, including NaCl. The colon expels hypo- and especially hypertonic solutions; 0.8 to 0.9 per cent NaCl is osmotically indifferent, but may cause thirst; 0.6 to 0.75 per cent is the best concentration. The most useful *carbohydrates* are dextrose (Bergmark, 1915) and dextrin, which are both absorbed. *Dextrose* may be used as 6 to 7 per cent for single injection, or 5 per cent for continuous irrigation. If salt is added, the dextrose must be reduced (for instance, 2.2 per cent of dextrose and 0.45 per cent NaCl). *Dextrin* is nonirritant in any concentration, and is easily digested. It may be used as 10 to 15 per cent for continuous irrigation; or 20 to 25 per cent for single enemas. This higher concentration makes it possible to introduce more calories than with dextrose. *Levulose and maltose* excite peristalsis. *Lactose* is not easily absorbed, and *galactose* is poorly utilized. *Saccharose* is absorbed poorly. *Starch*, boiled or raw, is nonirritant, and is somewhat digested, but only in limited quantity.

Proteins must be broken down to amino acids and polypeptids before they can be utilized. The colon readily absorbs these cleavage products, but its peptolytic power is insignificant. Bacterial putrefactive processes are active, however, and through them a fair amount of protein becomes absorbable. *Witte's peptone* may be given as 15 to 20 per cent in single enemas, or 5 to 10 per cent for continuous irrigation. About 75 per cent of its nitrogen is absorbed. Absorbable protein cleavage products can also be secured by pancreatin-digestion of milk carried on for twenty-four hours (Reach, 1901). This may be used as the vehicle for the dextrose (Bywaters and Short, 1913). Practically no protein is absorbed from milk or eggs unless they are predigested to the amino acid state (Bergmark, 1915; Adler, 1915).

Fats.—Only small quantities are absorbable from the colon (Makashima, 1914; Ornstein, 1918); at most 10 Gm. per day. Ordinary oils, such as olive oil, are least absorbable; milk and cream are somewhat better. Egg yolk is absorbed most efficiently, but is liable to putrefaction.

Alcohol is readily absorbed. Three per cent solutions are nonirritant; higher concentrations may be expelled.

Nutrient enemas may be given as "single enemas" or as "continuous drop enemas." With *single enemas*, two should be administered daily, each of 300 cc. They are warmed and injected very slowly through a funnel and soft rectal tube, inserted about 3 inches. The patient remains recumbent for at least two hours, and the anus may be compressed with a warm towel for ten minutes. Small enemas are carried by antiperistalsis to the cecum, but not into the ileum; with larger injections, some of the material passes into the small intestine (Cannon). With nutrient enemas containing albumen, peptone or fat, two cleansing enemas should be given daily; if only carbohydrate and albumen are used, one cleansing enema suffices. *Continuous drop irrigation is preferable.* The usual daily dosage is 1200 to 1500 cc., and not over 2 liters. Nitrogenous and carbohydrate injections are best given separately.

Parenteral alimentation is feasible for water, salt, and dextrose. These may be injected subcutaneously or intravenously when absorption from the alimentary tract is defective, as in acute fevers or shock. Proteins other than homologous plasma are unsuitable for parenteral administration, since they provoke toxic reactions. The injection of amino acids has given good results. Oil is but little absorbed from subcutaneous injection, and it is doubtful whether this is in suitable form for metabolism (van Noorden, 1920).

◆

DIGESTIVE FERMENTS

The digestion of food in the alimentary canal is accomplished mainly by the secretion of organic ferments or enzymes whose presence accelerates chemical changes. They are of enormous importance in the body, but of little practical importance in therapy. Commercial ferments consist of the dried gland, or more or less purified extracts, rich in protein, and dried or preserved by glycerin. The principal ferment preparations are: pepsin, papain, the diastases (malt) and pancreas. The term "fermentation" is derived from *fermentum*, leaven; and this probably from *fervere*, to boil. It was originally applied to all effervescence.

Several enzymes have been isolated as crystallized proteins; some have a prosthetic group, but proteolytic enzymes do not. Active enzymes may be formed from inert proteins by change of temperature or *p*H, by simple hydrolysis, by catalysis with other enzymes, or by autocatalysis, resulting in relatively slight internal rearrangement or rupture of the peptide link (review, J. H. Northrop, 1937). Cleavage ferments may produce syntheses under proper conditions.

Conditions of Action and Deterioration.—The digestive ferments are specifically adapted to the hydrolytic cleavage of the various food products (amylolytic, proteolytic, lipolytic, etc.). Their activity is influenced by various conditions, especially by temperature (40° to 45° C. being optimal for mammalian ferments); by acid or alkaline reactions; by salts, etc. Solutions are unstable. They are destroyed immediately by boiling and more gradually by any excessive conditions, and by putrefaction.

Pepsin is much more resistant to destruction than trypsin, but both deteriorate even in neutral solutions, trypsin often in a few days. Even dry "pancreatin" is unstable (Long and Muhleman, 1914). Pepsin can be completely destroyed by shaking (Shaklee and Meltzer, 1909). Solutions of ferments are *incompatible* with excess of acid and alkali (Long and Muhleman, 1914) or salts; with many antiseptics; with excess of alcohol; and with all protein precipitants. Pepsin in neutral or alkaline solution is destroyed by sodium chloride (W. H. Hamburger, 1915).

Mixtures of ferments digest each other more or less rapidly according to their reaction. Pepsin, in the presence of weak acids, destroys trypsin and amylopsin completely; but trypsin has little effect on pepsin under ordinary conditions (Long and Muhleman). "Compound Digestive Elixirs," supposed to contain pepsin with pancreatin, etc., are practically worthless (J.A.M.A., *48*:434, 1907).

The administration of ferments in digestive disorders has not realized the early expectations (Bastedo, review, 1925). Digestive disturbances are rarely due to deficiency of ferments, and it is difficult to administer ferments so that they can develop their actions.

Persistence of Ferments in the Stomach.—The reaction of the stomach is best suited to pepsin, and is more or less inimical to diastase and trypsin. But when these ferments are thoroughly mixed with food, they may act in the fundus of the stomach for an hour or so (Cannon), before the mass becomes acid (Gruetzner, 1905); and since the acid is largely bound by the proteins, some of the trypsin may pass the stomach unchanged (Long and Hull, 1917). The actual quantity is generally too small for any practical use. The action of papain is too feeble at body temperature to deserve consideration.

Other Uses.—A more rational field for ferments is in the preparation of predigested foods, especially for rectal alimentation, but these also are of little use. **Pepsin and rennin** are employed for curdling milk. Pepsin has been used to dissolve diphtheritic membranes, and as a dressing for fetid ulcers (as mentioned by Wm. Beaumont for gastric juice). *Desiccated stomach* contains an agent which acts on meat to form the "antianemic principle" (see Index), but this is not present in pepsin or other digestive extracts of the stomach.

Pepsin is a proteolytic extract obtained from the mucous membrane of the stomach of the pig, sheep or calf. Solutions deteriorate readily and are incompatible with alkalis, salts, metals and tannins; acid solutions deteriorate gradually in proportion to their acidity. Pepsin is most active in acid solutions of about *p*H 2. Dose, 0.5 Gm., 8 grains.

Liquid Rennet (Liq. Seriparus) consists of extracts of the fourth stomach of calves; used to coagulate unboiled milk (1:100 to 300, 38° C., 100° F.) for the preparation of junket and whey.

Pancreatin, U.S.P., is generally dried pancreas, but is defined as a substance containing enzymes, principally pancreatic amylase (amylopsin), trypsin, and pancreatic lipase (steapsin), obtained from the fresh pancreas of the hog or ox. It converts not less than twenty-five times its own weight of starch into soluble carbohydrates and not less than twenty-five times its weight of casein into proteoses. Lipase is often absent, since it is destroyed by trypsin, which is a collective term for a series of proteolytic enzymes (Northrup, 1937). The amylopsin acts best in a faintly alkaline (0.025 per cent $NaHCO_3$) or neutral medium, and is destroyed by very weak acidity (0.006 per cent HCl) (Long and Muhleman, 1914). Trypsin also is most potent when alkaline (0.2 to 1 per cent Na_2CO_3) but is somewhat active with very weak acidity. The optimal reaction varies for different proteins (Long and Hull, 1917). Excess in either direction is detrimental. It acts best on fibrin or casein, feebly on cooked albumen, and scarcely at all on raw albumen (Long and Muhleman; Sugimoto, 1913). Pancreatin occurs as a cream-colored amorphous powder having a faint, peculiar odor. Slowly sol. in water; insol. in alc. Dose, 0.2 to 0.6 Gm., 3 to 10 grains.

Hypodermic trypsin injections against cancer were advocated by J. Beard, 1905, and Shaw-Mackenzie, 1906, but proved disappointing. They produce local lesions and toxic effects resembling peptone poisoning (Wago, 1919). *Papain* and *takadiastase* act similarly (Kirchheim, 1913). *Intravenous injection of trypsin* is very toxic (W. Hildebrandt, 1890), producing acute symptoms similar to anaphylaxis, even when crystallized preparations are used (Rocha e Silva, 1939; with Dragstedt, 1941). Unanesthetized dogs respond with vomiting, urination, defecation and collapse. Anesthetized dogs show prompt and profound fall of blood pressure, congestion of the liver and viscera, and increase of histamine content of the blood. The blood becomes noncoagulable, probably through heparin. Guinea pigs develop acute pulmonary embolism, with collapse of the lungs instead of the distention of true anaphylaxis. The effects are not due to digestion of the blood or tissues, for they occur within a few seconds. Heat inactivates the trypsin, and repeated injections of small doses desensitize. Animals that recover develop hepatitis and renal damage similar to burns and crushing (Mirsky and Freis, 1944). Excised uterus and intestines are strongly contracted by addition of trypsin to the bath; this effect is inhibited by arginin (Dragstedt and Wells, 1944).

Fresh pancreas also contains *insulin*, but this is easily destroyed and is not present in "pancreatin" or in ordinary extracts, nor does it pass into the pancreatic juice. Excision of the pancreas causes fatal diabetes, which may be prevented by the administration of insulin. Nevertheless, the animals die after some months, with extensive fatty infiltration and degeneration of the liver. This may be prevented and cured by feeding raw pancreas or a substance "*lipocaic*" extracted from it (L. R. Dragstedt *et al.*, 1936, 1940). Choline also furnishes some protection (Best), as does methionine. Lipocaic is fully effective, although its methionine and choline content are below their own effective level (D. E. Clark *et al.*, 1945). It has been reported as curing some obstinate cases of psoriasis, but this requires confirmation.

Papain is the dried milk juice of the unripe fruit of the "melon tree," Carica papaya. It converts proteins to amino acids in acid and neutral media (*p*H 4 to 7), but it is more variable and less active than pepsin. Its optimum temperature is 80° to 95° C. Dose, 0.1 to 1 Gm. Its chief use is in the preparation of "tenderized meat."

Diastatic ferments are obtained from malt and other sources; "takadiastase" is prepared from a Japanese mould. The therapeutic value of these preparations is questionable, as their action is weak and unreliable, and much better results can be secured by managing the diet. *Malt* is the grain of barley, Hordeum vulgare, partially germinated, and dried at a temperature not exceeding 55° C. *Extract of Malt* is prepared by extracting the malt with water at 60° C., evaporating at this temperature, and preserving by the addition of glycerin. It is a viscous, light brown liquid, sweet, has an agreeable odor, and is capable of converting not less than five times its weight of starch into water-soluble sugars. Dose, 15 Gm., 4 drachms.

Lactic acid-producing organisms were introduced by Metchnikoff, with the idea of acidifying the intestines and thereby preventing intestinal putrefaction, which he held responsible for premature senility. This theory of old age was without scientific support; nor does the administration of the organisms advocated by him (Bacillus bulgaricus) or of milk soured by them, check intestinal putrefaction. They succumb promptly to the ordinary putrefactive bacteria of the intestines. The growth of B. acidophilus, which is normally present in the intestines, can apparently be increased by administration of its culture. *Sour milk* is sometimes beneficial, especially in pediatrics, against vomiting, acute and chronic diarrhea, tc., and there are advantages in souring the milk by Ba. ecidophilus cultures.

◆

PROTEIN FOODS AND AMINO ACIDS

Protein foods provide the *amino acids* which are used in the construction of the tissues. Some of these cannot be adequately synthesized in the body, and are therefore essential food constituents. They are liberated during digestion and pass unchanged into the portal circulation. Mixtures of purified amino acids can largely take the place of protein foods (review, W. C. Rose, 1938); but growth of mice and rats is less than when native protein, such as casein, is added (D. W. Woolley, 1946; Womak and Rose, 1946). On the basis of analogous phenomena with certain bacteria, the deficiency is attributed to the absence of an unidentified factor, "strepogenin," which is present in many proteins, including casein, but not in egg albumen or gelatin. It is not an amino acid, nor any known vitamin (Sprince and Woolley, 1944).

Isotope studies of protein metabolism show that most tissue proteins are constantly undergoing synthesis and degradation, so that more than half of the protein of the liver, for instance, is replaced in ten days (Borsook and Dubnoff, 1943). This involves rapid shifts in the amino acids (review, Schoenheimer and Rittenberg, 1940).

Meat and Beef Juices, when prepared extemporaneously by expression of fresh or slightly broiled meat, contain from 2.5 to 9 per cent of coagulable proteins, and 2 to 4 per cent of other proteins and nitrogenous extractives. They have a moderate value as sources of nitrogen. The commercial preparations are supposed to be concentrated; in fact, however, they are inferior, containing but 0.2 to 3 per cent of coagulable proteins; others are reinforced by the addition of defibrinated blood, sugar, glycerin, etc., which are of doubtful utility (Rep. C.P.C., J.A.M.A., Nov. 20, 1909).

Bouillon (beef tea) is prepared by boiling meat with water; the *meat extracts* by evaporating the solution to a semisolid consistency. The coagulable proteins are removed by this process, the extract containing the salts of the meat, the flavoring substances and meat bases (xanthine and creatine products) and noncoagulable protein, in the form of gelatin, albumoses, etc. In the small amounts in which they are used, these preparations contain a *very insignificant quantity of nutriment.* They are *valuable as stimulants.* They owe their action largely to the odorous principles they contain, which are excellent stomachics (Wolff, 1912). American brands of the Liebig (pasty) type of meat extract contain, on the average: flesh bases, 26.4 per cent; gelatin and albumose, 16.5 per cent; N-free extractives, 14.6 per cent; inorganic salts, 22.5 per cent; water, 20 per cent (N.N.R., 1920). *Dry "peptones"* are the dried product of the artificial digestion of meats, usually consisting mainly of albumoses. Their taste is disagreeable and they often cause irritation. Peptones stimulate pancreatic secretion more effectively than acid or secretin (J. E. Thomas and Crider, 1941). Intravenously they are toxic, lowering the blood pressure and rendering the blood noncoagulable (see Index).

Hydrolyzed protein foods have only a limited field in oral therapy, for instance in allergies; but they have an important place in parenteral nutrition. Their usual base is casein. Acid hydrolysis destroys the tryptophane, and synthetic tryptophane is added at the end. Enzyme hydrolysis (by pancreas) does not destroy any amino acid, but it may not break down the protein completely. Alkali hydrolysis is unsuitable, for it destroys methionine and cystine and converts other amino acids into their racemic form.

Intravenous protein nutrition, with nitrogen balance and plasma protein restitution, may be achieved in man as well as in animals by injection of compatible plasma or, more safely and conveniently, of mixtures of protein hydrolysates containing the essential amino acids administered by vein, hypodermically or by mouth (Henriquez and Anderson, 1914). It is useful to offset serious loss of protein in severe burns, wounds, surgical procedures and infections (review, R. Elman, 1945).

Toxic effects occur only if the digestion has not gone far enough to split all true protein; small peptide molecules are not dangerous. Vomiting may be produced by *glutamic acid* above 100 mg. per Kg. of body weight, especially if it is injected rapidly. The other amino acids do not cause symptoms even with 300 mg. per Kg. (S. C. Madden *et al.*, 1945). Mild nitritoid reactions may be avoided by injecting slowly. The addition of 10 per cent of dextrose, however, produced phlebitis in dogs (Howitz *et al.*, 1943). Strict technic should be observed.

Aminogen is a commercial enzymatic hydrolysate of casein and pork pancreas. It is well utilized and adequate. No serious reactions have been reported, and no fever if it is properly prepared. A 5 per cent solution in 5 per cent dextrose neutralized with NaOH to *p*H 6.5 contains 0.5 per cent of NaCl. It should not be injected more rapidly than 500 cc. per hour, to 1.5 or 2 liters per day. Faster injection causes nausea or vomiting. An enzyme digest of casein with added tryptophane and cystine has also been employed successfully (Altshuler *et al.*, 1940).

Amino Acid Deficiency.—Osborne and Mendel, 1912, showed that animals cease to grow if placed on diets deficient in one of the essential amino acids, such as lysine or tryptophane. *Lysine deficiency* in rats also produces vascularization of the cornea (C. H. Hock *et al.*, 1945). Protein deficiency results in massive acute *necrosis of the liver,* differing fundamentally from the acute zonal necrosis of liver poisons. *Methionine* gives complete protection (Glynn and Himsworth, 1944). It also protects against dietary fatty liver (D. E. Clark *et al.*, 1945). Synthetic *dl*-methionine (*meonine*) is available in tablets of 0.5 Gm. for the clinical prophylaxis (0.5 to 1 Gm. daily) and treatment (1.5 to 3 Gm. daily) of liver injury (Report, Council on Pharmacy and Chemistry, 1946, J.A.M.A., *132*). If the food is partly deficient in a constituent, this is not easily compensated by increased food consumption; for the appetite is regulated by the energy requirements, and not by the growth requirements. However, this phase of food deficiency probably does not occur easily under the practical conditions of civilized life. Further work, especially by W. C. Rose (reviews, 1937, 1938), has shown that only ten amino acids need be supplied as such by the food: arginine, histidine, isoleucine, lysine, methionine, phenylalanine, threonine, tryptophane and valine. The others can be synthesized from these more or less readily as needed. Man can synthesize all but eight (W. C. Rose *et al.*, 1942). The indispensability varies with age; for instance, adult rats can synthesize adequate arginine, but young rats need an outside supply (Scull and Rose, 1930). Deficient income of certain of the amino acids (lysine, methionine, cystine, glutathione) inhibits the growth of mouse tumors, as well as the growth of the animal (C. Voegtlin *et al.*, 1936, 1937). Topical application of an amino acid mixture accelerated the healing of *corneal wounds* (A. J. Schaeffer, 1946).

The "dynamic action" of proteins, i. e., the increase of heat production caused by their ingestion, is the sum of the actions of their amino acids; phenylalanine and tyrosine have the greatest effect, valine and histidine have none (Rapport and Beard, 1927, 1928). Some amino acids, including synthetics, favor the *formation of hemoglobin* (Whipple, 1938).

Amino-acetic acid (glycocoll, glycine), $CH_2.NH_2.COOH$, unites with benzoic acid to form hippuric acid. It was reported to produce improvement of muscular strength in myasthenia gravis when administered continuously in large doses (10 Gm., two or three times daily, usually in milk). The action was attributed to conversion into creatine, which is important in muscular metabolism (Milhorat *et al.*, 1932 to 1934; P. Wolff, 1935). The response was variable, however, and further experience has been disappointing, so that it is but little used, especially since neostigmine has proved much more satisfactory. In normal subjects it has no effect on muscular capacity, nor does it increase the normal creatine or creatinine excretion (although it had been reported to raise it markedly in muscular dystrophies). The ordinary diet furnishes ample supplies of amino-acetic acid, and 13 to 17 Gm. can be synthesized from the ingested proteins (review, L. Young, 1939). It constitutes about 25 per cent of gelatin (King, McCaleb *et al.*, 1942; Horvath, Knehr and Dill, 1941).

Amino-acetic acid is soluble in water. Average dose, 30 Gm.

Creatine plays an important role in the phosphate metabolism of muscular contraction and of nerve stimulation; about 98 per cent of the total creatine is found in the muscles as creatine-phosphoric acid (phosphocreatine). Administration of radioactive phosphate or radioactive creatine shows rapid formation of phosphocreatine in the muscles, and a rapid turnover in muscular work. It also shows the conversion of body creatine into urinary *creatinine*, the form in which it is excreted (1 to 2 Gm. per day) after losing an H_2O molecule (Bloch and Schoenheimer, 1939). Once formed, creatinine does not reenter metabolism; practically all that is absorbed is excreted unchanged (R. Dominguez and Pomerene, 1945). *The urinary output of creatine is* increased most markedly by the administration of glycocyamine; next comes amino-acetic acid, but this requires ten to twenty times as much; alanine is still less effective; histidine and glutamic acid have generally no effect; choline and guanidine are quite ineffective (Bodansky, 1936). Creatine excretion is increased by acid-producing foods (oats and corn) and diminished by base-producing foods (carrots). It is increased by carbohydrate deficiency and by starvation (Underhill, 1916). *The blood sugar level* of fasting dogs is lowered by the hypodermic or oral administration of creatine, but not to the convulsive level (R. M. Hill and Mattison, 1929).

Glutamic acid, $C_3H_5(NH_2)\ (COOH)_2$, alpha aminoglutaric acid, occurs as a constituent of the protein, and also free in certain tissues and in blood plasma (6 to 10 mg. per 100 cc.), in the white and yolk of eggs, and in many plants, such as beets. It is apparently related to carbohydrate metabolism, its blood concentration being diminished by insulin and by glucose administration. It is not toxic and is used to impart meat flavor to foods (M. M. Harris, Roth and Harris, 1943). It was tried in place of amino-acetic acid in muscular dystrophy, but with discordant results (R. B. Gibson, 1934; Tripoli and Beard, 1934). *Glutamic acid hydrochloride* was suggested by L. B. Mendel as a possible means of administering acid in solid form to aid gastric digestion, but it was found to hinder digestion *in vitro* (Report of Chem. Lab. A.M.A., 1937).

Tryptophane (indol amino propionic acid) deficient diets fed to young rats for eight to eighty-two days produce *cataract*, corneal vascularization, loss of weight, greasy hair, alopecia and nervousness. The cataract differs from that resulting from riboflavin deficiency or from feeding galactose or xylose (Trotter and Day, 1942).

Tyrosine (p-hydroxyphenyl-alpha-propionic acid), if 10 per cent is added to the diet of rats for one or two weeks, produces purulent keratitis, swelling of the feet, degenerative changes in the pancreas, kidneys and arterioles, ending in death within five weeks (Hueper and Martin, 1943).

Gelatin, a partly hydrolyzed protein, is a fairly useful food in the form of soups and desserts, but is deficient in some of the essential amino acids, notably tryptophane, valine and tyrosine, so that it can not replace more than one-fourth to two-thirds of the protein of the ordinary diet (Murlin, 1907). Gelatin dessert powders contain only about 10 per cent of gelatin.

Gelatin was suggested as a *source of amino-acetic acid* in myasthenia gravis, but to supply the ordinary daily 20 to 30 Gm. dose of this acid would require 80 to 120 Gm., 3 to 4 ounces, of dry gelatin, which is more than it is practical to take (A.M.A. Com. Foods, 1936). The widely advertised claim that it prevents fatigue and increases physical endurance is not supported by adequate evidence. Critical tests show no effect on *muscular work* or fatigue in man (Karpovich and Pestrecov, 1941) or in rats (G. C. Knowlton, 1940). It has been tried as a protective colloid in *gastric ulcer*, but without much success.

Gelatin in saline solutions for intravenous injection increases the viscosity of the blood (Burton, Opitz, 1906; Omunt, 1912), prolongs the sojourn in the circulation through its colloidal properties, but leaves the blood fairly rapidly. It was tried and abandoned because of toxic reactions. These may be avoided by using specially selected preparations. It does not sensitize. It is injected as 6 per cent solution (U. S. National Research Council Report, 1944; J.A.M.A. *125*, 284).

Subcutaneous injections of gelatin have been given to increase the *coagulability of the blood*, especially in aneurysm. They are probably ineffective and have the serious objections of severe pain and danger of infection, since ordinary gelatin solutions are often not sterile, and may carry tetanus. Oral administration of 45 Gm. of gelatin daily for two weeks does not change the coagulation time of the blood (Tainter *et al.*, 1939).

Dastre and Floresco, 1897, and Grau, 1910, described increased coagulability of the blood, lasting for several days. The gelatin was injected subcutaneously (100 to 200 cc. of sterile 1 to 5 per cent solution, injected slowly into the thigh, *not* near the aneurysm, every ten to fifteen days, until ten to twenty injections have been given). F. Wood (1902) claimed that the gelatin is just as effective, only somewhat slower, when given by mouth, and recommended eating 3 or 4 ounces of flavored 10 per cent jelly, three times a day.

Pharmaceutical Uses.—Gelatin is employed as an emulsifying agent, as a coating for pills, for making gelatin capsules, and in the form of glycerinated gelatin as a base for pastilles and for suppositories.

Gelatin, U.S.P., is the purified, air-dried product obtained by the partial hydrolysis of the collagen of animal tissues, as skin, ligaments and bones, by treatment with boiling water. Insol. in cold water, but swells and softens when immersed in it, gradually absorbing from five to ten times its own weight of water; sol. in hot water, acetic acid or glycerin; insol. in alc. Watery solutions of 2 per cent or over solidify on cooling. Precipitated by phenol or tannin; not by dilute solutions of metallic salts. *Glycerinated Gelatin*, U.S.P., is made by dissolving water-saturated gelatin in its own weight of glycerin.

Histadine, glutathione, cystine and allantoin are discussed in other sections (see Index).

◆

CARBOHYDRATE FOODS

These are used therapeutically for rectal and parenteral alimentation (dextrose); for modifying infant food (lactose, maltose and dextrin); in forced alimentation (lactose); and in the diet therapy of diabetes. Starch is considered under Demulcents (see Index).

Dextrose is the form in which carbohydrate circulates in the blood, and is therefore directly available. As it does not require digestion, it may be administered by rectum or hypodermically or intravenously; the last is preferred, especially in fevers, such as pneumonia. It serves also for the introduction of fluid, to restore the blood volume and to increase heat loss in fever. These uses are discussed with Saline Infusion (see Index). Intramuscular injection of 10 per cent solution may be employed in infants.

Dextrose Tolerance in Man.—Normally about 100 Gm. can be ingested before sugar appears in the urine; but as the rate of absorption is limited, the maximum blood sugar level is generally reached with 30 to 50 Gm.; larger quantities only prolong this level. With intravenous injection, glycosuria normally begins when the injection rate exceeds 0.8 to 0.9 Gm. per Kg. per hour (600 cc. of 10 per cent dextrose for 70 Kg.). This is about twice the caloric requirement. *The normal assimilation limits of various carbohydrates* were reviewed by Macleod, 1913 and 1914.

The glycogen content of the liver may be raised to 20 or 35 per cent. Its deposition appears first and is most abundant in the cells adjacent to the central vein of the lobules, and occurs last at the periphery; its withdrawal generally follows the reverse direction (Mann, 1936). The formation of glycogen from its precursor hexose phosphate probably requires alkaline phosphatase (review, Dempsey and Wislocki, 1946).

Intestinal Absorption of Various Sugars.—The concentration of dextrose and galactose solutions does not affect the rate of their absorption from intestinal loops of anesthetized rabbits, thereby implying an active process; while mannose, sorbose and xylose are absorbed proportional to their concentration, indicating passive diffusion. Fructose is intermediate (Verzár, 1935). The intestinal absorption of dextrose is accelerated by the addition of NaCl, if this does not exceed 1 per cent (Glatzel, 1938). The absorption of dextrose from the intestines appears to involve its *phosphorylation*, and is therefore inhibited by phlorhizin and by monoiodoacetate (Gellhorn and Northup, 1934). This is controlled by the adrenal cortical hormone (Verzár *et al.*, 1938).

Absorption of Dextrose from Rectal Injections.—Some of the dextrose is destroyed in the large intestine by bacterial fermentation (E. L. Scott and Zweighaft, 1932), but much is absorbed, sometimes 90 per cent in man, so that the blood sugar level rises by 16 to 25 per cent (Collens and Boas, 1933). In cats' large intestine, the maximal absorption occurs from 6 to 7 per cent solution. A small amount of dextrose is also excreted into the large intestine if it is injected by vein (Büdinger, 1935).

Intravenous Injection of Dextrose on Gastro-Intestinal Motility.—No effects are noted ordinarily if isotonic solutions are used. Hypertonic solutions may augment intestinal propulsion, similar to hypertonic sodium chloride injection (J. P. Quigley and Highstone, 1934). Gastric hunger contractions are not affected even by hypertonic injections (Quigley and Hallaran, 1932; Mulinos, 1933). The addition of 0.1 per cent of dextrose to a bath of Tyrode solution restores the contractions of exhausted excised intestines; d-mannose also produces marked functional improvement; galactose and d-fructose are ineffective, although the galactose is metabolized as well as the mannose (Neukirch and Rona, 1912). Dextrose is indispensable for the contractions of the *perfused mammalian heart*, although this uses less than 0.3 mg. per Gm. of muscle per hour (Cruikshank, review, 1936). Sucrose can not take its place. Increase of dextrose above 0.1 per cent does not cause further improvement (except osmotically), nor does it do so if insulin is added (Geiger and Hambourger, 1938).

***Dextrose, U.S.P.** (Dextrosum; *d*-Glucose), is a sugar ($C_6H_{12}O_6 \cdot H_2O$) usually obtained by the hydrolysis of starch; a white, crystalline or granular powder, odorless and sweet; very sol. in water (1:1), sol. in alc. (1:60). As a nutrient, by mouth, to 180 Gm., 6 ounces daily. Intravenously, 250 to 300 cc. of a 5 per cent (isotonic) to 10 per cent solution, two or three times daily; by enema, 5 to 12 per cent solution. The official dextrose contains 8 to 10 per cent of water. The concentration of solutions must be stated as percentage of this hydrated dextrose. (See Index for *Dextrose Injection* and for Dextrose and Sodium Chloride Injection.) *Liquid Glucose*, U.S.P., is *not* dextrose, but a product of the incomplete hydrolysis of starch, chiefly dextrose, maltose, dextrins, and water; a colorless or pale yellow, sweet, syrupy liquid. Water sol., sparingly sol. in alc. Used as a food.

Levulose is now available at reasonable cost. It is sweeter than saccharose. It has been used in diabetes, but aside from its greater sweetness, its value is questionable. It is readily oxidized in the body, but probably by a different route than is dextrose. A part is converted into dextrose; this involves both the liver and the gastro-intestinal tract (F. C. Mann and Bollmann, 1930). It is deposited as glycogen in pancreatic diabetes, when dextrose is not (E. Neubauer, 1909). *Levulose* (Laevulosum; Fructose) is a white or cream-colored hygroscopic, crystalline powder; prepared from invert sugar or from honey; odorless, a very sweet sugar.

Sucrose, U.S.P. (Saccharose, Saccharum, Cane-Sugar or Beet-Sugar), is inverted in the intestines before it is absorbed or utilized. This occurs so rapidly that the blood dextrose of diabetic patients is increased in a few minutes after its oral ingestion (J. M. Rabinowitch, 1946). On direct intravenous injection, less than a third is inverted and used, practically none in man. The remainder is excreted in the urine, and a small fraction in the feces (Mendel and Mitchell, 1905; Mendel and Kleiner, 1910; N. M. Keith *et al.*, 1933; Power and Keith, 1936; Heilner, 1911; Kuriyama, 1917).

Lactose is a disaccharide which is isolated from milk. Like sucrose, it is not available directly, or on intravenous injection, but must be inverted in the intestines into dextrose and galactose. Since it is less sweet than sucrose, it is used chiefly in infant feeding, and in pharmacy as a diluent for powders and tablets.

Lactose is also a fairly efficient osmotic *laxative* (9 to 15 Gm., 2 to 4 drachms, in warm milk, an hour before breakfast) and *diuretic* (100 to 200 Gm. per day). On *intravenous injection*, lactose is excreted rapidly by the urine if the kidneys are normal (O. Schwartz and Pulay, 1915). Rats, young or adult, fed with large quantities of lactose (50 to 70 per cent of the diet) or galactose or xylose (25 to 35 per cent) develop mature *cataract* within four weeks (H. S. Mitchell and Dodge, 1935; Borley and Tainter, 1938; Darby and Day, 1939). Cataract changes develop in the rat embryo when galactose is fed to the mother (Bannon *et al.*, 1945). Glucose does not have this effect, nor does daily hypodermic injection of galactose (Selle, 1940). Massive doses of thiamine chloride and of riboflavin are not protective (H. S. Mitchell and Cook, 1938). Three groups of experimental cataract may be differentiated in rats (W. Buschke, 1943): (1) *Dystrophic:* tryptophane deficiency, riboflavin deficiency, thallium poisoning. (2) *Tetanic:* dietary and postoperative. (3) *Dietetic:* galactose, xylose, experimental diabetes. Human cataracts may permit the same grouping. The galactose cataract of rats is retarded or even prevented by adding about 40 per cent of wheat-germ to the diet (R. Lecoq, 1943).

An isomer, *beta lactose* (obtained by crystallization above 93° C.) is sweeter and more soluble than the official alpha lactose. It also provides a better medium for B. acidophilus and is therefore more effective for increasing the acidity of the intestinal contents (C. S. Robinson and Gilliand, 1937).

***Lactose,** U.S.P. (Saccharum Lactis, Milk Sugar) $C_{12}H_{22}O_{11} \cdot H_2O$, occurs as white, hard crystalline masses or powder, odorless, faintly sweet taste. Sol. in water (1:5), almost insol. in alc.

Galactose is used for testing hepatic function, since it is metabolized exclusively by the liver, independently of insulin (Shay *et al.*, 1931).

Mannitol (Mannite) and **Dulcitol** are unfermentable sugar-alcohols which occur in different varieties of *manna*, an exudation from an oriental species of ash. They are but slightly metabolized or deposited as glycogen on introduction into the blood, and do not relieve insulin shock, nor do they cause glycosuria in diabetes. Their primary anhydrides (mannitan and dulcitan) and secondary anhydrides (mannide and isomannide) are still less utilizable (M. Jaffe, 1883; Carr *et al.*, 1933; Krantz *et al.*, 1935; Dozois *et al.*, 1935). Mannitol is used intravenously to measure glomerular filtration, as it is neither excreted nor reabsorbed in the tubules. It has been proposed as a sweetening agent in diabetes, but its taste is not very sweet. Doses of 20 to 30 Gm. (5 to 8 drachms) are laxative.

Inositol, inosite, hexahydroxybenzene, $C_6H_6(OH)_6$, has the empirical formula of sugars, but its structure is entirely different. It occurs in animals as "muscle sugar." *Phytin*, a substance present in the seeds, roots and tubers of numerous plants, consists of inosite conjugated with phosphoric acid, presumably as inosite hexaphosphoric acid combined with calcium and magnesium.

Inositol is a food factor or vitamin ("Bios I," E. V. Eastcott, 1928) essential for mice and rats. In these animals its deficiency causes alopecia, deficient growth and other symptoms (Woolley, 1940, 1942; Pavcek and Baum, 1941; Cunha, Kirkwood *et al.*, 1943). It is a **lipotropic agent** (see Index), synergistic with choline, affecting the neutral fat more than the cholesterol (Forbes, 1943). Kultz, 1874, found on feeding inosite that only insignificant amounts appear in the urine, and that diabetic glycosuria is not increased. From this he thought it might serve as a sugar substitute in diabetes. It soon appeared, however, that it is not burned (R. J. Anderson, 1916), the greater part being eliminated unchanged by the feces. Greenwald and Weiss, 1917, claim that it is slowly but completely converted into sugar in phlorhizin-diabetic animals. In man, daily doses of 0.5 Gm. per Kg. cause diarrhea (J.A.M.A., *67*:900, 1916).

Foods for diabetics are intended to reduce the intake of sugar-forming carbohydrates. They fall into two groups: sugars and carbohydrates that do not yield dextrose; and flours for diabetics. None are really satisfactory, and they are little used in the modern treatment of diabetes. Levulose and lactose are sometimes better tolerated than other sugars (v. Noorden, 1910; Goudberg, 1913), but the difference is not important. Grafe, 1914, reported promising results with *caramelized sugar*, which is well absorbed and completely tolerated even in severe diabetes. It does not increase the blood sugar, and the respiratory quotient indicates that it is utilized in the diabetic as well as in the normal organism, but its use has not been extended.—*Flour for diabetics* is intended to form a substitute for bread, as a vehicle for butter, and so forth. High food value is not desirable. *Gluten flours* should not contain more than 10 per cent of carbohydrates. Other flours consist of soy-bean meal or casein.

Inulin, a sweetish polysaccharide occurring in the tubers of "Jerusalem artichoke," dahlia and other plants, was introduced as a nondiabetic carbohydrate, but H. B. Lewis and Frankel, 1914, found it quite useless. It is not digested, although some is burned by the intestinal bacteria. None is converted into utilizable carbohydrate, even in phlorhizin animals. Intravenous injection of inulin is used as a test of renal function. When it is not properly purified it produces febrile reactions (H. W. Smith *et al.*, 1938). Intravenously injected insulin is excreted exclusively through the glomeruli and is used as renal function test. It is harmless if it is pure, but impure products may cause a severe colloidoclastic reaction (W. C. Hueper, 1945).

INSULIN

Insulin is a definite crystallizable substance (a protein of high sulfur content) formed exclusively in the Langerhans islets of the pancreas, essential for the normal metabolism of sugar. It is used in the treatment of diabetes mellitus.

Source of Insulin.—Insulin appears to be formed solely in the "beta" cells of the islets of Langerhans, its output being adjusted in an unknown manner to the blood-dextrose level. It is not stored in any other organ (reviews of Best, 1935; Macleod, 1934). *The insulin content of the pancreas* is quite similar in different species, generally of the order of 1 to 4 units per gram of pancreas. It varies in individuals, especially with age and diet. It is lowered in experimental diabetes by extensive partial excision of the pancreas, by alloxan, and by injection of anterior pituitary extracts. It may also be decreased by conditions which diminish the need for insulin, such as injection of large doses of insulin in rats, by fasting, and by feeding fat. It may be increased by administering estrogens, thyroxin, and certain anterior pituitary extracts. High income of carbohydrates does not raise it above normal. The regulation of its level is complex and little known. Anesthesia by barbiturates does not alter it materially (review, R. E. Haist, 1944). The yield per kilogram of normal human pancreas is 216 to 263 units; reduced in diabetes to 50 to 130 units (Pollak, 1926).

Historical.—Prompted by the dependence of diabetes on injury of the islands of Langerhans, many investigators sought for a sugar-metabolizing hormone in the pancreas. Some rather suggestive but inconclusive data were obtained, for instance by Zuelzer and by Murlin. It may now be seen that the failures of the older workers are to be attributed to the want of sufficiently delicate methods of blood analysis to give definite indications of successful results; to partial destruction of the hormone by tryptic digestion in the course of isolation; and to the high toxicity and local irritation of the insufficiently purified extracts, which complicated and obscured the antidiabetic effects.

F. G. Banting, 1920, conceived the thought of avoiding the tryptic digestion by destroying the ferment-secreting cells by previous ligation of the pancreatic duct. Under the direction of J. J. R. Macleod, and with the aid of Best (Banting and Best, 1922), he put this to trial, and succeeded in demonstrating that the extract of the ligated pancreas lowered the blood sugar level of depancreatized dogs. The practical preparation of the purified insulin from ordinary pancreas was then worked out by Collip, 1923; and the large scale production by the firm of Eli Lilly and Company.

The preparation of insulin requires the prompt arrest of proteolysis, and separation from irritant and toxic proteins. This is secured through the method of Collip, 1923, by extraction of the fresh pancreas of cattle, with cold acid alcohol, and purification of the filtrate by precipitation at the isoelectric point. The precipitate is dissolved in slightly acidulated water (*p*H 2.5), filtered through Berkefeld filters, and standardized by bio-assay. This solution constitutes the "ordinary" insulin. It may also be prepared by other methods; for instance, adsorption on freshly precipitated benzoic acid (Maloney and Findley, 1923).

Chemical Properties.—Insulin is a true and typical levorotatory protein. It is freely soluble in water, except between *p*H 5 and 6. It is also soluble in alcohol, except at the isoelectric point. It is precipitated by half saturation with ammonium sulfate. It is not demonstrably dialyzable. It is readily adsorbed on charcoal, etc. (E. A. Doisy *et al.*, 1923), and its potency is greatly reduced by passing through a Berkefeld filter (Bert and Macleod, 1923). It is not injured by moderate heating with decinormal acid, but dilute alkalis destroy it at blood heat, though rather slowly (Dudley, 1923). Commercial insulin stored at room temperature loses 20 per cent of potency in a year, 25 to 30 per cent in two years (R. L. Grant, 1946). Its activity is completely destroyed by the proteolytic ferments, pepsin, trypsin and papain (E. J. Witzemann and Lioshis, 1923). Its action is apparently connected with a peculiar linkage of its amino acids, involving among others the dithio (-S-S-) linkage (review, Geiling, Jensen and Farrar, 1937). It is an active antigen, but without species specificity (J. H. Lewis, 1937; C. Bernstein *et al.*, 1938).

Crystallized insulin was first prepared by Abel, 1926. It occurs as minute crystals and is levorotatory. It is a typical protein, with a rather high sulfur content (3.2 per cent, exclusively in disulfide linkage), and a high molecular weight, estimated between 20,000 and 50,000. The activity is uniformly about 24 units per mg., regardless of the source; it is destroyed by hydrolysis; none of the fractions are active in any degree (Jensen and Evans, 1934).

Crystalline Zinc Insulin.—Attempts to crystallize insulin by Abel's method often gave unsatisfactory yields, till D. A. Scott of Toronto found that the addition of traces of zinc chloride to buffered solutions of insulin results in ready crystallization and high yields. It is probable that the insulin exists in the pancreas as a zinc compound, for the pancreas normally contains relatively considerable zinc (Lutz) and cobalt and nickel (Bertrand), and the zinc content falls in diabetes even more than the insulin content (Scott and Fisher, 1938). Zn, Co, Ni and Cd all facilitate crystallization, but zinc is the most satisfactory. Crystalline zinc insulin is perhaps somewhat more slowly absorbed than the ordinary insulin, and its action therefore slightly more lasting, but the difference is not significant (Marble and Vartiainen, 1939; Ricketts and Wilder, 1939).

Protamine Zinc Insulin.—Hagedorn *et al.*, 1936, found that suspensions of the precipitate which is formed by adding a solution of protamine (spermine) to insulin, are absorbed from hypodermic injections much more slowly than insulin solution and therefore give better utilization and more prolonged action. D. A. Scott and Fisher, 1936, found that this occurs only if the solution contains zinc (or the related metals), and therefore insure this by the addition of zinc chloride to the solution (A. M. Fisher and Scott, 1937). A great variety of analogous compounds are easily prepared, but it is undesirable to multiply therapeutic forms unless they have definite advantages. *Globin insulin* ranks in speed of absorption between plain insulin and protamin insulin. Tannic acid precipitation of insulin also prolongs the action (F. Bischoff, 1936).

Standardization.—Insulin solutions are standardized in "units" by comparing their ability to lower the blood sugar level of rabbits with a reference standard sample of U.S.P. Zinc Insulin Crystals. The official directions must be followed. The production of convulsions in mice is also used for experimental work. It likewise requires comparison with the reference sample. The *unit* is equivalent to 0.125 mg. of the standard powder, or about 0.04 mg. of crystallized insulin (the application of statistical methods is described by C. I. Bliss and Marks, 1939).

Phenomena of Insulin Deficiency.—Insulin is an important factor in the endocrine balance that determines the normal blood sugar level. It is necessary for the first and final stages of the normal metabolism of sugar, for the deposition of glycogen, and for the oxidation of the dextrose. Deficiency of insulin, resulting from excision of the pancreas or from degeneration of the islands of Langerhans as in diabetes mellitus, results in rise of the blood sugar from the normal level of 0.08 to 0.12 per cent (of the whole blood) to 0.2 per cent in moderate and 0.3 per cent in severe diabetes, with temporary values up to 1 per cent or higher when sugar or other glycogenic substances are ingested. In pancreatectomy, these levels may be reached within twenty-four hours. When the level exceeds the "renal threshold," which varies between 0.1 to 0.23 per cent, but is generally about 0.15 per cent to 0.18 per cent, dextrose may be demonstrated by the ordinary qualitative tests in the urine (glycosuria). The volume of the urine and the consumption of water are greatly increased. Other phases of metabolism are also deranged, chiefly secondarily. Overproduction as well as deficient utilization of sugar are probably both concerned in the hyperglycemia. The nitrogen excretion is increased, the phosphate excretion diminished. The glycerol of fats may be converted into glucose. The combustion of fats is incomplete, resulting in mobilization of fat deposits, lipemia (also increase of phospholipids and cholesterol esters), ketosis and acidosis, which culminate in diabetic coma. Before this, the subject becomes emaciated, with a marked decrease of resistance to surgical operations, gangrene, infections and any other heavy demands. Dogs die within two weeks after excision unless insulin is administered (Best, 1935).

Actions of Insulin.—The best established effects of insulin are: (1) withdrawal of sugar from the blood and its deposition as glycogen in the muscles; (2) decrease of hepatic glycogenolysis; (3) decrease of hepatic gluconeogenesis from noncarbohydrate precursors. The immediate cause of the diabetic hyperglycemia is failure to regulate the blood sugar level. There is no absolute decrease in the rate of sugar utilization by the tissues at large, but the liver fails to respond normally to the inhibitory stimulus of hyperglycemia. Instead, it wastes the protein and fat of the body to pour unneeded sugar into the blood (review, S. Soskin, 1941).

The mechanism of action of insulin appears to consist in abolishing the inhibitory effect of an anterior pituitary hormone on the hexokinase which phosphorylates glucose into the form in which it is metabolized, glucose-6-phosphate, by the aid of adenosine triphosphate (W. H. Price, Cori and Colowick, 1945). Excess of insulin produces too rapid phosphorylation, with fall of blood sugar and accelerated glucose metabolism. Excess of the anterior pituitary hormone has the opposite effects Several questions, however, remain to be cleared up (review, D. Stetten, 1946).

The *normal blood sugar level* is similar in the different mammals, the mean ranging between 0.07 per cent in sheep to 0.12 per cent in rabbits. It is much higher in birds (0.21 per cent), and these are much more resistant to insulin than are mammals, and the latter much more than cold-blooded animals (Macleod, 1934). A carbohydrate meal may raise the level in normal man by 0.2 per cent; glucose may raise it above 0.15 to 0.16 per cent (V. C. Myers, 1924). The sugar exists in the plasma practically entirely as ordinary fermentable dextrose. The 10 to 30 mg. per 100 cc. of reducing substance that is not fermented by yeast (Hiller *et al.*, 1925) consists chiefly of glutathione (R. S. Benedict and Newton, 1929). The corpuscles contain a fairly constant concentration of dextrose over a considerable range of plasma concentration; but the plasma concentration is always the higher (M. H. Power and Greene, 1931).

Ketosis.—The disturbance of fat metabolism is indicated by the increase of ketone substances, beta-oxybutyric acid, aceto-acetic acid and acetone, in the blood and urine. These are probably not abnormal products of the incomplete combustion of fats, as was formerly thought, but normal intermediates in the conversion of fat into sugar, and therefore produced in excessive amounts when the formation of sugar from fat is large (review, S. Soskin, 1941). They lead to loss of fixed base and so to acidosis. Their effects may be so severe that animals die of coma before the fat depots are depleted. The coma is perhaps due partly to acidosis, partly to the special toxicity of aceto-acetic acid, which causes air hunger or depression of the respiratory center. It is decomposed in the body into acetone and CO_2. Beta-oxybutyric acid is relatively nontoxic (Best, 1935).

Ketosis may also result from other conditions that accelerate oxidation of fat to compensate for deficiency of glycogen; by hypersecretion of thyroid or pituitary; by hepatitis, infections, surgical procedures, vomiting, etc. (I. A. Mirsky, 1942).

Oxidation of pyruvic acid by brain dispersions is increased by insulin (Banga, Ochoa and Peters, 1939), but this is not very striking (W. C. Stadie, 1943). Insulin administration to depancreatized dogs increases the formation of pyruvic acid after administration of dextrose (Bueding, Fazekas *et al.*, 1943). K. O. Kaplan and Greenberg suggest that the increase of adenosine triphosphate of the liver by insulin administration indicates that the action of insulin consists in augmented oxidation of pyruvic acid. Insulin increases the consumption of oxygen by slices of liver, if succinate, pyruvate or citrate are present (Corley and Somers, 1946). It appears necessary for the phosphorylation and utilization of *thiamine* (Foa *et al.*, 1946).

Effects of Insulin Administration.—The injection of insulin increases the combustion of sugar and at the same time increases the deposition of glycogen. Both actions combine to lower the level of the blood sugar, and therefore suppress all glycosurias that are due to hyperglycemia, such as pancreatic, puncture, epinephrine, asphyxia, carbon monoxide, ether, morphine, iodo-acetate (Irving, 1934). Phlorhizin glycosuria is diminished.

Appropriate doses of insulin relieve all the phenomena of diabetes mellitus and pancreas excision. They restore the ability to metabolize sugars and fats in the normal manner; they prevent excessive breakdown of proteins; the ketosis disappears rapidly; glycogen accumulates in the liver in normal amounts; the muscle glycogen may be increased; the respiratory quotient rises. Adult depancreatized animals survive for years if insulin is administered with a suitable diet (including raw pancreas to furnish lipocaic or choline).

The fate of the blood sugar that disappears after the insulin is not identical in diabetic and in normal animals. In diabetic animals the sugar is fully accounted for by the increased sugar combustion (increased oxygen consumption and rise of respiratory quotient) and by the storage of glycogen in the liver, and sometimes in the muscles. These changes are also produced in normal animals, and are considered an adequate explanation by Dale, and by Cori and Cori. Increased glycogen deposition by insulin occurs only if the blood sugar level is high (J. J. R. Macleod, 1934). It is more marked in depancreatized animals because their liver is poor in glycogen, while that of normal animals is already optimal. The muscle glycogen is not mobilized by insulin, even after pancreatectomy or epinephrine (review, S. Soskin, 1941). Insulin is not essential to the deposition of liver glycogen (Cori and Cori, 1929).

The *addition of insulin to shed blood* does not accelerate its glycolysis, but if the blood is perfused through an excised heart, the insulin hastens the disappearance of its sugars (Burn and Dale), although this does not appear to be oxidized, for there is no proportionate increase of oxygen consumption or rise of respiratory quotient. Similarly, after large injections of dextrose into normal animals, only some 70 per cent can be satisfactorily accounted for (Kay and Robison). Addition of insulin *in vitro* to minced pigeon muscle maintains a better oxygen consumption (Krebs and Eggleston); but this effect is not seen with mammalian or chicken muscle, and therefore is not of general significance (Shorr and Barker, 1939).

Primary Hyperglycemia.—Intravenous injection of ordinary insulin solutions may cause a temporary rise of the blood sugar level, apparently by direct mobilization of liver glycogen (M. Burger and Kramer, 1929), but this is due to an impurity, for it is not produced by pure crystalline insulin (E. M. K. Geiling and De Lawder, 1930).

Inorganic Serum Phosphate.—The insulin fall of blood sugar is accompanied by a simultaneous fall of the potassium and phosphate concentration of the blood (Harrop and Benedict, 1924), while the calcium concentration rises (Hausler and Heesch, 1925). The phosphate fall may be followed by a rise, often higher than the control level (R. Ellsworth and Weinstein, 1933). Tracer experiments with radioactive phosphate show that insulin facilitates the transfer of inorganic phosphate from the blood to the tissues, especially to the liver, and promotes the phosphorylation of dextrose (Kaplan and Greenberg, 1944). Removal of the pancreas raises the phosphate level, and this is not promptly lowered by the administration of sugar or by epinephrine, as in normal animals. *The amino acid level of the blood* is lowered by insulin, and also by epinephrine in normal rabbits. Insulin becomes ineffective after excision of the adrenals (while epinephrine continues effective). This insulin action is, therefore, due to stimulation of the secretion of epinephrine (B. L. Davis and Winkle, 1934). *The uric acid excretion* is increased by insulin, in rabbits, through the mobilization of epinephrine in response to the low blood sugar level (S. P. Miller and Kuyper, 1938).

Endocrine Antagonists of Insulin.—*Epinephrine* and *thyroxin* antagonize insulin by mobilizing liver glycogen; but with thyroxin this is more or less offset by the increase of basal metabolism. Hypodermic injection of *posterior pituitary extract* raises the blood sugar and inhibits insulin convulsions (Burn, 1923); but this does not occur with intravenous injection. It is therefore attributed to decreased absorption by vasoconstriction (M. Griffiths, 1941). The *anterior pituitary* is the most important antagonist, so that its removal allows depancreatized animals to live over a year without insulin, with very mild symptoms of diabetes, which become severe when anterior pituitary extract is injected (Houssay; review, E. M. Geiling *et al.*, 1937). *Excision of liver* does not prevent insulin hypoglycemia, but hinders the subsequent restoration of the blood sugar level (F. C. Mann and Magath, 1923). Removal of the *suprarenal cortex* results in hypoglycemia in some animals. A diabetogenic factor is found in aqueous extracts of *crustacean eyestalks*, probably formed in the sinus gland of Hanstrom (Abramowitz *et al.*, 1944).

Injection of insulin into chicken eggs before incubation results in lack of caudal vertebrae (rumplessness). The action appears to require the intact insulin molecule (Landauer and Lang, 1946).

Other Interrelations.—*Phlorhizin* does not modify the depressant action of insulin on the blood sugar; insulin therefore diminishes the glycosuria, though it may not suppress it entirely. The indirect effects on the nitrogen excretion have not been sufficiently cleared up (F. P. Nash, 1923; M. Ringer, 1923; C. T. Cori, 1923). *In vitamin B_1 deficient pigeons*, insulin administration restores the ability to store glycogen, and therefore improves the assimilation of the polished rice; but it does not remove the polyneuritis (Bickel and Collazo, 1923). *Cysteine*, administered hypodermically, diminishes the hypoglycemic action of insulin (H. R. Jacobs, 1938). *Cooling* rabbits below 30° C. prolongs the hypoglycemic action of small doses, and the survival after large doses (D. B. Tyler, 1939).

Anesthetics decrease the response to insulin; chloralose and amytal relatively little (review, Geiling *et al.*, 1937). *Acidosis* decreases and alkalosis increases insulin efficiency. Severe diabetic acidosis therefore requires larger doses (Battie and McDowall, 1927).

Alloxan Diabetes.—Intravenous injection of alloxan, 50 to 75 mg. per Kg. for dogs (Goldner and Gomori, 1943); 200 to 400 mg. per Kg. for rabbits (Dunn *et al.*, 1943), rats (Shaw and McLetchie, 1943), and monkeys (Banerjee, 1944), produces almost complete coagulative *necrosis of the beta cells of the islands* of Langerhans within twenty-four hours, without change of the alpha cells or acinar tissue (E. Duffy, 1945). Larger doses cause fatty changes in the liver and necrosis of the renal tubules. The blood sugar goes through three stages: (1) a temporary rise, attributed to direct action on the liver; (2) transitory hypoglycemia probably by lack of dextrose production in the liver, occurring also in pancreatectomized animals (Houssay, Orias and Sara, 1945); (3) hyperglycemia, due to the destruction of the Langerhans cells, persisting indefinitely (rabbits survive up to nine months; Duffy, 1945) and closely resembling clinical diabetes (Dunn, Sheehan and McLetchie, 1943). Insulin, if administered, is not inhibited by alloxan. *Alloxantin* is similarly diabetogenic (Koref *et al.*, 1944); also *styryl-quinoline*. Many closely related compounds are not (Goldner and Gomori, 1944); nor is uric acid, violuric acid, etc. (Thorogood, 1944).

The susceptibility of rats to alloxan is increased by thyroid administration, decreased by thyroidectomy (Houssay and Sara, 1945; C. Martinez, 1945). Reports as to diet appear contradictory (Martinez, 1945; J. H. Burn, Lewis and Kelsey, 1944).

Actions of Insulin on the Gastro-Intestinal Tract.—In intact normal animals, injection of insulin tends to increase the activity of the stomach and intestines. It is mildly depressant for isolated intestines.

In normal human subjects, injection of 40 to 50 units of insulin shortens the *emptying time* of the stomach by about ninety minutes (E. Wiechmann and Gatzweiler, 1927). Intravenously it causes immediate depression, followed within twenty minutes by hypermotility and accelerated evacuation (D. Simici *et al.*, 1927). The increased tonus and hunger contractions may usually be inhibited by injecting sugar into the duodenum, or by atropine or epinephrine hypodermically (J. P. Quigley, Johnson, and Solomon, 1929). Clinically, the tonus of hypertonic stomachs is diminished within fifteen minutes after injection of 30 units, in contrast to the increased tonus observed with hypo- and orthotonic stomachs (P. Marcovich and Decleva, 1929). *Gastric secretion* is also stimulated by the hypoglycemia (La Barre, 1931). This effect is chiefly cerebral. It is transmitted by the vagus and abolished by atropine.

With segments of rabbits' small *intestines* in Ringer's solution, insulin produces a brief depression, followed by more lasting stimulation. The depression appears to be due to sympathetic stimulation, for it is prevented by ergotoxine. The augmentation is probably muscular, for it is not inhibited by atropine (Barlow, 1931). However, I. Cavel and Milcou, 1933, claim that atropine antagonizes the stimulation of guinea pig intestine.

Actions of Insulin on the Heart.—Insulin increases the efficiency of the mammalian heart-lung preparation (M. B. Visscher and Miller, 1927). Moderate concentrations also augment the rate, amplitude and tonus of the perfused frog heart, probably by sympathetic stimulation, for electric stimulation of the accelerator nerve does not result in further quickening, and ergotoxine inhibits the action. The response to vagus stimulation and to atropine is not affected. High concentrations of insulin paralyze the cardiac muscle (O. W. Barlow, 1931). The cardioinhibiting center is stimulated when insulin is perfused through the turtle brain (Barlow). In the Starling heart-lung preparation, the addition of insulin increases the output, with tendency toward systole, and diminishes the coronary flow (Bodo, 1928).

Phenomena of Hypoglycemia "Insulin Shock."—If the dosage of insulin is such as to reduce the blood sugar too much below the normal level, depressive and convulsive symptoms develop, both in normal and in diabetic individuals. They can be promptly and completely removed by restoring the normal blood sugar level by the administration of sugar. The hypoglycemic symptoms start with listlessness, weakness and fatigue, tremor, profuse sweating (which is especially significant) of the hands and forehead; then palpitation, hebetude, mydriasis, diplopia, pallor. The respiration and blood pressure are normal, the pulse normal or sometimes rapid. If the course is not checked, it progresses to acute distress, mental disturbances and coma, followed by irregular convulsions, which may last for hours. These may lead to death, but clinical cases infrequently progress so far (Joslin, 1935). Untreated convulsions are fatal in 40 per cent of the animals. Normal rabbits of 2 Kg. require about 3 mg. for convulsions.

Hypoglycemic Level and Symptoms.—The phenomena are proportional to the lowering of the level of the blood sugar; but the critical level varies somewhat for different species, individuals and conditions. They depend on the rate as well as the extent of the fall; they occur at a higher level if the fall is rapid. In man, symptoms begin usually at the blood sugar level of about 0.07 per cent, and coma at about 0.035 per cent (Banting, Campbell and Fletcher, 1923); but these levels are raised if the blood sugar has been persistently high, and if the reduction is abrupt. Rabbits become convulsive between 0.047 and 0.037 per cent; dogs are very resistant, 0.018 per cent, Banting). *Birds* are more resistant than mammals as regards blood sugar and convulsions (K. K. Chen, Anderson and Maze, 1945). Pigeons, which have normally a rather high sugar level (0.15 to 0.185 per cent), do not show any noticeable symptoms at 0.08 per cent, but their ovulation is decreased (O. Riddle, 1923).

Localization of the Hypoglycemic Convulsions.—The type of the asymmetric and irregular convulsions, similar to those of asphyxia, points to the midbrain or medulla. The latter may suffice, for decapitated cats also go into convulsions when the blood sugar falls to 0.045 per cent. (Ohmsted and Taylor, 1926); but the dominant location is probably in the midbrain.

Insulin fatalities in the clinical shock treatment of schizophrenia show diffuse lesions, most marked in the medulla; aseptic meningitis, edema of the cerebral parenchyma, diffuse degenerative changes in the ganglion cells, insignificant reactions of the neuroglia, absence of perivascular infiltrations. The changes in the ganglion cells are reversible and therefore are not the cause of death. Similar but less marked changes are seen in death from metrazol and from barbital, and in poisoning by strychnine, phosphorus, and arsenic (G. B. Hassin, 1939). Ferrac, 1942, describes rarefaction in cortical areas, due to the gradual disappearance of the nerve cells that had undergone degeneration and disintegration as the result of insulin in schizophrenia treatment. In animals, metrazol produced much less damage than insulin (Winkelman and Moore, 1940). The brain of dogs and rabbits shows diffuse and focal histologic changes from the cortex to the medulla, after acute or chronic insulin poisoning, parallel to the dosage and the duration of the intoxication; with degeneration especially in the temporal lobe, and with convulsed rabbits in the Ammon's horn. The vessels are engorged and sometimes hemorrhagic. Similar changes are observed in morphine, lead and cyanide poisoning, and in uremia (A. Stief and Tokay, 1932).

There are reasons for believing that the convulsions are not due to the hypoglycemia directly, but to some secondary process involving *increased intracranial pressure;* for the cisternal pressure rises rapidly during insulin convulsions in normal dogs, while dogs that have been dehydrated by thirst are not convulsed by insulin, even in massive doses, and in these the cisternal pressure does not rise (D. L. Drabkin and Ravdin, 1930). The lactic acid content of the brain is lowered by insulin (W. E. Stone, 1938). The toxicity has been attributed to *methylglyoxal,* which may be formed by the rapid destruction of glucose and produces convulsions similar to those of insulin, on intravenous injection; but this is difficult to reconcile with the rapid recovery by dextrose injection. The *brain potentials* of rabbits show progressive increase of wave activity, which persists after the convulsions and is abolished by dextrose injection (Goodwin *et al.*, 1938).

Composition of Blood Serum.—At the height of the shock reaction, as induced in schizophrenic patients, and in dogs, the potassium is markedly reduced, by an average of 18 per cent, attributed to hyperactivity of the adrenal glands provoked by the hypoglycemia. The sodium is slightly increased. The nonprotein nitrogen is insignificantly decreased, the protein moderately increased (Keys, 1938).

Antagonism with Narcotics.—Insulin convulsions may be suppressed by narcotics, for instance barbiturates, even with very low blood sugar; but this does not prevent the fatality, which is therefore not due to the convulsions (E. L. Jackson, 1931). The cortical narcotics, urethane and chloral and bromides are also effective against the convulsions (I. Ishigami, 1928), but less so than the barbiturates, whose action is predominantly on the midbrain (Holster and Rusch).

Influence of Other Drugs and Conditions on Insulin Convulsions.—Increase of temperature (Voegtlin and Dunn, 1922) and low barometric pressure (Glickman, 1936) are synergistic, probably through anoxemia. Epinephrine arrests the convulsions by raising the blood sugar, if glycogen is available. Large doses of atropine also delay the convulsions by increasing the blood sugar (X. Chakovitch, 1929), but this is followed by synergistic psychic disturbances (Quigley, 1937). Insulin increases the convulsant action of strychnine and picrotoxin, not that of hexetone, barium or phenol (I. Ishigami, 1928).

The cause of death in insulin hypoglycemia appears to be the inability of the brain to accomplish the oxidation of sugar on which its metabolism depends.

The immediate cause of death is failure of respiration, which does not resume after the postconvulsive apnea; but neither the suppression of the convulsions by narcotics nor artificial respiration prolongs life or raises the lethal dose materially. Nor is there any change in the ability of the tissues at large to utilize oxygen, for the systemic arterial and venous bloods present the normal differences (E. L. Jackson, 1941). In the cerebral vessels, however, the oxygen difference between arterial and venous blood is markedly lowered in insulin coma, and this must be due to decreased metabolism of the brain, for there is no significant change in the intracranial blood flow (Ferris *et al.*, 1941). Himwich *et al.*, 1939, found that the oxygen consumption of the brain is reduced to less than half in hypoglycemic convulsions, due to the diminished supply of carbohydrate for its metabolic needs. This was confirmed for man by W. Goldfarb and Wortis, 1940, who found that alcohol cannot be oxidized in place of sugar.

Relief of Hypoglycemia.—This occurs usually in a few minutes after the oral administration of 5 to 20 Gm. of dextrose, or any other form of sugar (candy or orange juice). If the patient is comatose, the dextrose is injected intravenously, as 50 per cent sterile solution; the patient has usually recovered before 10 cc. have entered the vein, but more may be needed in severe cases (Joslin, 1935). It may be repeated if necessary. If sterile dextrose solution is not available, epinephrine may be injected hypodermically (0.3 to 0.6 cc. of 1:1000), always followed by sugar by mouth. Epinephrine is effective only by mobilizing stored glycogen, and is therefore likely to fail in diabetes (R. S. Lyman *et al.*, 1923).

Other sugars than dextrose, d-fructose and mannose are not effective antidotes. Alkalis and sodium lactate have no effect (E. C. Noble and MacLeod, 1923). Glycerol is effective in rats (Voegtlin, Dunn and Thompson, 1925); dihydroxyacetone and lactic acid are also somewhat effective.

Clinical Efficiency of Insulin in Diabetes Mellitus.—The properly dosed and spaced administration of insulin abolishes the glycosuria, and the excessive glycemia diminishes the thirst and polyuria, removes the emaciation, the edema and the mental inertia, controls the acidosis, lowers nonprotein nitrogen and the creatinine of the blood to the normal level, and restores patients from coma (C.B.F. Gibbs and Sutter, 1923). The effects usually last only during the continuance of the insulin administration; although in the relatively lighter cases a partial restoration of the functions of the pancreas seems sometimes to occur, presumably as an indirect result of the improved health of the patient, by the more liberal diet which is possible with insulin administration.

As pointed out by E. P. Joslin, 1935, clinical diabetes is practically never complete: the manufacture of insulin is not abolished but merely diminished to a degree which varies from time to time. It is improved by careful diet, and deteriorates if the diet is extreme in any direction. Insulin, by making possible a better diet, increases the chances of improvement, so that many patients can progressively reduce the insulin dosage and sometimes dispense with it entirely, although the pancreatic lesion proper is not cured.

The administration of insulin must be adjusted so as to secure a continuous supply and must be augmented when the sugar level rises during digestion. The dosage must be adapted to the individual requirements to permit an optimal diet and to avoid the toxic effects of overdosage. Oral administration is practically ineffective because insulin is not readily absorbed from the digestive tract. Intravenous injection acts promptly, but the total effect is only an eighth to a half of the same dosage hypodermically (Sahyun and Blatherwick, 1928; Aubertin and Tringuier, 1932) because the insulin is too rapidly excreted by the urine (Kepinov and Petit-Dutaillis, 1929). It is, therefore, administered hypodermically. Even with this, considerable insulin is lost by excretion, and the action is relatively short, so that it must be injected two or three times a day. Protamine zinc insulin and globin insulin secure slower and more lasting absorption and action. The hypodermic injection of insulin is somewhat irritant (D. J. Bowie and Robinson, 1923) but not sufficiently to constitute a serious objection, and the irritation becomes less noticeable with continued use (M. Sturtevant, 1924). The site of injection should be changed so that not more than one injection is made in the same spot in a month.

The inefficiency of oral and rectal administration is due chiefly to poor absorption, rather than to destruction of insulin in the intestines or liver (D. Campbell and Morgan, 1933). Insulin is not entirely inert by these channels, but its efficiency is uncertain and therefore does not permit the precision of dosage which is indispensable. Various ways have been tried to produce effective absorption from oral administration, but none has given satisfactory results (Geiling *et al.*, 1937). Various substances do increase intestinal absorption somewhat (R. L. Driver and Murlin, 1941; quinine, Hanzlik and Cutting, 1941). It was claimed (Lesch *et al.*) that *saponin* has this effect: but the difference lies within limits of accidental variation.

Absorption from Other Surfaces.—Absorption from the tongue may amount to a third of the hypodermic, but only with small doses and favorable conditions. It is therefore wasteful and uncertain (B. Mendel *et al.*, 1924). The *conjunctiva* gives quite good absorption, about two-thirds as efficient as hypodermic in rabbits, without material irritation (C. D. Christie and Hanzal, 1931). *Spraying or snuffing into the nostrils* is effective but not uniform (S. Horwitz, 1931). Absorption has been observed from the *vagina* and from the scrotal sac (N. F. Fisher, 1923); and from the intact skin (R. H. Major and Delp, 1937), but is not constant. *Peritoneal injection* is practically equal to intravenous in degree and rapidity of response in dogs (Banting *et al.*, 1923), but it is too irritant for clinical use.

Persistence of Action, Fate, Excretion.—The maximal effect of the blood sugar is reached in two to five hours after the hypodermic injection of unmodified insulin, and in twelve to twenty-four hours after protamine zinc insulin. It then declines gradually. The duration of insulin action, in fasting depancreatized dogs, is proportional to the logarithm of the dose; *i. e.*, to double the duration requires ten times as much insulin; so that the rate of its disappearance increases with the dosage (Greely, 1940). With intravenous injection the maximum occurs promptly, and the decline is rapid. Almost the entire amount can be recovered from the urine, but only 25 per cent after hypodermic injection (N. F. Fisher and Noble, 1923). The remainder is presumably destroyed.

The liver and spleen do not participate in the destruction, for the hypoglycemia is of the same degree and duration if the insulin is injected directly into these organs as when it is administered hypodermically. Incubation with blood for four hours at 37° C. does not inactivate insulin (Mark and Lewis, 1943).

Dosage and Spacing of Injection.—The dosage is expressed in "insulin units"; but the amount of carbohydrate which may be metabolized by a unit varies somewhat with conditions, such as exercise, diet, acidosis, infections, the size of the dose, the nature of the preparation and the frequency of administration. The dosage must, therefore, be adjusted to the individual, eventually by trial.

The insulin output of the normal human adult pancreas is probably between 45 to 80 units daily, and this includes a considerable factor of safety. It has been estimated that 48 units would be adequate even if the diet were chiefly carbohydrate, and that 8 units would suffice in starvation. This natural output is better adjusted to the needs of the moment, however (probably by directive action of the dextrose concentration on the islet cells), and is therefore utilized to better advantage than is the case when the insulin is supplied by injection.

Goldner and Clark, 1944, report that two patients with total pancreatectomy were controlled with less than 50 units of insulin daily, with a dextrose intake of 150 to 200 Gm. Many diabetic patients require more than this amount, so that clinical diabetes appears to involve some interference with insulin action. Sometimes even 1000 units are ineffective (Root). Interfering factors are infections (the mechanism is unexplained), acidosis, overactivity of physiologic antagonists, especially anterior pituitary, thyroid, adrenal, and liver.

A continuous supply gives a more complete utilization, and frequent injections are therefore more economically used than widely separated ones. The slowly but continuously absorbed protamine zinc insulin gives about 20 per cent better utilization than unmodified insulin. The histone zinc insulin compound is absorbed slower, globin zinc insulin faster, than the protamine compound (Bailey and Marble, 1942). Intravenous injections of such preparations do not differ significantly from unmodified insulin (Longwell and Ravin, 1936). Crystallized insulin can suffice for every need if it is injected sufficiently often; but in many cases it may be usefully supplemented by the less absorbable forms (Joslin, 1942). With unmodified insulin a unit metabolizes usually between 1 and 2 Gm. of dextrose, sometimes as high as 5 or 6 Gm., but under ordinary clinical conditions it is safer to assume the average equivalent as 1.5 Gm.; so that two-thirds of a unit of insulin would need to be administered for each gram of dextrose excreted in the urine, on a given diet. Patients whose glycosuria can be suppressed by an adequate diet do not require insulin, except when they face emergencies such as infections or surgical operations. Cases of moderate severity require 5 to 60 units daily; 30 is perhaps the average. Many patients do sufficiently well with one daily injection into the loose subcutaneous tissue before breakfast. With more severe cases, a second injection is made before supper, and a third at bedtime if necessary. The effect lasts about eight hours. In infections, it may be injected at six-, four- or even two-hour intervals (review, Joslin, 1935). *Allergic hypersensitiveness* to insulin, with local and systemic reactions, occurs rather rarely, although the insulin molecule itself may act as antigen (J. H. Lewis, 1937). Sometimes it is species specific, and may then be avoided by employing insulin prepared from another species.

Protamine zinc insulin permits a wider spacing of dosage because of its slower and prolonged action (H. C. Hagedorn *et al.*, 1936; A. Sindoni, 1937). This must be remembered in relation to diet and exertions for the next twelve to twenty-four hours. Hypoglycemic reactions are less frequent than with ordinary insulin, but are likely to set in more insidiously, without premonitory symptoms, and a severe attack may be precipitated abruptly, for instance by exercise (Joslin, 1938). It may be injected once a day, an hour before breakfast or supper time or on retiring, beginning with two-thirds of the dosage of unmodified insulin, and supplementing with one or two injections of the latter if necessary. A mixture of one part of protamine insulin with two parts of ordinary insulin has been used (Colwell and Izzo, 1943). Its delayed action makes it unsuited for the treatment of emergencies. It should never be administered by vein.

Globin insulin with zinc is intermediate between the unmodified and protamine forms. It is administered by deep subcutaneous injection, never by vein. Its effect is maximal between eight and sixteen hours after injection. The daily dose is two-thirds to three-fourths that of unmodified insulin.

In diabetic coma, 30 to 60 units of unmodified insulin should be injected, half by vein and half subcutaneously, followed by 20 units subcutaneously at intervals of one-half to three hours, as needed. It is rarely necessary to use more than 150 units in twelve hours, but 800 have been given. It is important to guard against hypoglycemia; the urine should be examined every hour, and if it becomes sugar free, dextrose should be administered. Normal saline solution may be injected hypodermically or intravenously to offset dehydration. Alkali is not needed (review, Joslin, 1935).

Use of insulin in nondiabetic conditions has been suggested to protect the liver against anesthesia and hepatotropic poisons; and in the management of nondiabetic malnutrition. The hypoglycemia is used in the treatment of schizophrenia and has been suggested (but without good foundation) in opiate addiction.

Insulin in Nondiabetic Malnutrition.—In thin persons, for instance those with tuberculosis, 10 units, three times daily, with a liberal diet, often increases the appetite and starts a prompt gain of weight, at first rapid and then flattening as the normal weight is approached. The gain is generally held after insulin administration is stopped. Patients feel stronger and more active. The red count rises and the effects are probably due to increased food consumption and better assimilation, perhaps by the direct effect of insulin or hypoglycemia on gastric motility and secretion. The nitrogen excretion rises parallel to the weight. The basal metabolism is not affected (review, H. Blotner, 1933).

The hypoglycemic "shock" treatment in schizophrenia was introduced by M. Sakel, 1935. A severe degree of hypoglycemia is induced, and when the patients recover from the collapse and convulsions, the sensorium seems to clear, the patients are more accessible, and marked improvement may persist (J. Steinfeld, 1937). The improvement is probably due to the psychic impression, shocking the patient out of a rut (R. L. Osborne, 1940), but the hypoglycemia has been invoked for insulin (S. Soskin, 1939). The results are variable, and fatalities have occurred from the hypoglycemia. The treatment obtained considerable vogue in psychopathic hospitals, but it has been largely displaced by metrazol. Insulin is now generally preferred for schizophrenia; metrazol and electric convulsions for emotional and other depressions, including the manic depressive syndrome (N. D. C. Lewis, 1945). The results vary widely, depending partly on conditions, partly on criteria. The improvement is generally greatest in patients who are amenable to other methods. Gottlieb and Huston, 1943, conclude that their series did not show better permanent results with insulin than with more conservative methods. Brooklyn State Hospital, 1944, reports marked benefits from insulin shock; a larger proportion of patients returned to gainful occupations and a much larger proportion were able to leave the hospital.

Sakel's routine consisted of an initial *dose* of 60 units, increased daily by 10 to 30 units until the shock-dose had been determined, at 70 to 240 units, then similar reduction to the just effective dose, the total treatment lasting at least sixty days, or ninety days for older cases. *Dangers:* The treatment requires deep and fairly prolonged coma and probably often causes mild and sometimes severe pulmonary edema and embolism (Nielsen *et al.*, 1938). Two-thirds of the patients show various cardiac irregularities, sometimes auricular fibrillation and S. A. block (Bellet *et al.*, 1939). Residual nervous symptoms may occur, analogous to those of prolonged asphyxia (Himwich, Frazekas *et al.*, 1938), and similar irreparable anatomical cerebral lesions (A. B. Baker, 1938). Fatalities are reported in the ratio of 73:10,000 for insulin, 23:10,000 for metrazol (J. L. Kinsey, 1941).

Other Antiglycemic Agents.—Patients sometimes report striking results following the use of various substances, especially plants and plant extracts; but carefully controlled observations generally show that the response is uncertain and scarcely exceeds the ordinary variations of the disease (review, Geiling *et al.*, 1937). The most important of the suggested substitutes is a synthetic guanidine derivative, *synthalin* (see Index), introduced by E. Frank of Breslau, as an auxiliary, with the advantage that it can be used orally. It does have a definite action, but is variable and inferior to insulin, and by a quite different mechanism. Effective doses are likely to damage the liver, so that its use has been practically abandoned.

The *glucokinin* of Collip, a supposedly insulin-like principle from various animal tissues and plant sources, has not been confirmed (C. H. Best, Jephcott and Scott, 1932). *Diastase* is reported to lower normal blood sugar (Deichmann and Myers, 1936). *Scoparia dulcis* is reported to contain an antidiabetic principle (M. C. Nath, 1943). *Myrtillin* extracted from *blueberry leaves* was introduced by Allen as a minor adjuvant to insulin, but has been abandoned (J. J. R. Macleod, 1930). Administered by mouth to cats and rabbits, it does not lower the blood sugar, but in fasting animals it produces a marked rise. Large doses cause initial stimulation and subsequent paralysis of the central nervous system. Continued administration results in cachexia, anemia, icterus and death (Dietering, 1938).

Jambul, the fruit of *Syzygium jambulana*, of Eastern Asia, has been used in diabetes mellitus, in doses of 0.3 to 0.5 Gm., but its efficacy is doubtful. Its constituents are discussed by Hart and Heyl, 1917. It contains an essential oil, tannic acid, and probably a glycoside.

PREPARATIONS.—**Insulin Injection**, U.S.P., is "an acidified aqueous solution of the active principle of the pancreas which affects the metabolism of glucose." It is so standardized that each cubic centimeter contains 20, 40, 80 or 100 U.S.P. units, and is marketed in vials of 10 cc. The concentration should be selected so that the injection approximates ¼ to ¾ cc. It is a clear, colorless liquid, contains 0.1 *to* 0.25 per cent of phenol or cresol, and has a *p*H of 2.5 to 3.5. It may be prepared from highly purified amorphous insulin or from **Zinc Insulin Crystals.**—This contains 0.4 to 0.9 per cent of zinc, or 0.2 to 0.4 mg.

per 1000 units, chemically combined with the active principle. Each milligram of the crystals equals 22 units of insulin.

Protamine Zinc-Insulin Injection, U.S.P., is a suspension, in a buffered water medium, of insulin modified by the addition of zinc chloride and protamine, and marketed in 10 cc. vials as a uniform aqueous suspension, each cubic centimeter containing 40 units of insulin and 0.08 to 0.1 mg. of zinc, or 80 units of insulin and 0.16 mg. of zinc, with about 0.4 mg. of protamine buffered with phosphate to *p*H 7.1 to 7.4. Initial dose about two-thirds that of insulin. It should be shaken before injecting.

Globin insulin is insulin modified by the addition of globin (from hemoglobin) and zinc chloride. It is a clear, aqueous solution, of *p*H 3.7, containing 80 units per cubic centimeter. Daily dose, about two-thirds to three-quarters that of insulin.

◆

PHLORHIZIN

Injection of this glucoside, which occurs in the apple tree, produces *glycosuria* by blocking the tubular reabsorption of dextrose. It also interferes with other tubular processes and lowers the rate of glomerular filtration (reviews, J. A. Shannon, 1939; F. W. McKee and Hawkins, 1945). It has no therapeutic applications.

The amount of glucose in the urine may be high, above 12 per cent. It persists for several hours after a single injection, but may be prolonged indefinitely at its highest degree, by administering 1 Gm. of the glucoside per kilo of body weight, by mouth, three times a day. Larger doses do not increase the glycosuria. The loss of sugar leads to hypoglycemia, which is compensated by mobilization of the liver glycogen, and by formation of dextrose from protein. The nitrogen excretion is therefore greatly increased. In fasting animals it may rise to four or five times above hunger alone (Reilly, Nolan and Lusk). If the action is continued for some days, the ratio of urinary dextrose:nitrogen becomes stabilized between 2.8 and 3.65, with a respiratory quotient about 0.69. The ability to oxidize sugars appears impaired, probably by the hypoglycemia (Stiles and Lusk). If the depletion of hepatic glycogen is kept up, it leads to fatty degeneration of the liver cells. Diuresis occurs (Loewi and Neubauer, 1908), presumably as a result of the glycosuria, but is relatively small. The excretion of the other solid constituents, salts, protein, etc., shows no constant abnormalities. The oxygen consumption of the kidneys is largely increased. The *milk* after phlorhizin contains the normal amount of lactose, and no dextrose. Traces of sugar appear also in the saliva and gastric and pancreatic juice (R. G. Pearce, 1916). The phlorhizin is *excreted* for the most part unchanged (Pietkiewicz) within two days (Prausnitz). The glycosuria outlasts the excretion.

Historical.—Phlorhizin was isolated by Koninck, 1835, from the root bark of apple, pear, cherry and plum trees. Stas, 1839, showed it to be a glucoside decomposed by acid hydrolysis into dextrose and phloretin; and the latter again into phloretinic acid and phloroglucin. Phloretin has a similar but weaker action. The characteristic glycosuria was discovered by Mering, 1886. It has been produced in all vertebrates tried: mammals, birds, frogs and reptiles.

The Glycosuria Is Not Pancreatic.—The symptoms after phlorhizin resemble those of pancreatic diabetes, but their mechanism is in fact totally unrelated. The most striking difference is the absence of hyperglycemia. With phlorhizin, the sugar of the blood is diminished (Mering)· if the kidneys are excised, or the ureters tied, the blood sugar remains normal (Minkowski).

The Action Is Renal.—It is evident from these experiments that the glycosuria is essentially renal. The effect is peripheral, for it occurs after destruction of the medulla and cord, and after section of all renal nerves (Frey). If the phlorhizin is injected into one renal artery, glycosuria occurs in this kidney and not in the other (Zuntz). As the reabsorption of water is not impeded to a corresponding degree, the concentration of dextrose in the urine rises far above that in the blood (Walker and Hudson, 1937). Histologic changes have been described in the renal epithelium. Carmine and methylene blue, which are excreted by the tubules, may suppress the glycosuria. Minkowski suggested that the phlorhizin acts as a glucosidal vehicle, splitting off its sugar in the kidneys, and again taking up sugar from the tissues; but the quantity of sugar excreted when phlorhizin is injected into the renal artery speaks against this view.

Phlorhizin inhibits *phosphorylation* and dephosphorylation *in vitro*, with yeast and with muscle; also the formation of lactic acid from dextrose or glycogen. Lundsgaard attributes the glucosuric action to disturbance of the phosphorylation mechanism in the renal tubules, interfering with the absorption of dextrose. Kalckar, 1937, showed that low concentrations of phlorhizin inhibit the phosphorylation of hexoses by rabbits' kidneys. Anderson and Squires, 1938, reported marked increase of the phosphatase activity of the serum. Phlorhizin inhibits the oxidation of carbohydrates by slices of rat liver (Wetzel and Meadows, 1937), and also the oxidation of alcohol (Leloir and Munoz, 1938).

The glycosuria is suppressed in severe nephritis (H. W. Hoffmann, 1931), and the injection of phlorhizin (*phlorhizin test*, 5 mg. in warm water, hypodermically) (or 10 mg. in 1 cc. of saline intravenously, Krotozyner and Stevens, 1917) has been proposed as a means of diagnosis. The result, however, is not decisive in either sense. *Oral administration* of large doses (to 32 Gm. in divided doses over three days) causes transient glycosuria and significant lowering of the clearance of urea, xylose and creatinine, without lasting toxic effects (W. Goldring, 1934).

Sources of the Sugar.—The stock of carbohydrates in the body disappears first, although some glycogen is persistently retained (Mering), even in fasting (Sansum and Woodyatt, 1915). Phlorhizin does not mobilize the *hepatic glycogen* directly, but only as a result of the hypoglycemia. On the contrary, when the kidneys are excluded, phlorhizin leads to a reaccumulation of hepatic glycogen. Since there is no hyperglycemia, it appears that phlorhizin stimulates directly the synthesis of glycogen. When the kidneys are intact, this action is overcome by the glycosuria (Epstein and Baehr, 1916). With persistent administration, the sugar is derived from the carbohydrates of the food; and if these are excluded, from the proteins. Pavy, Brodie and Siau (1903) showed that the quantity of sugar which is excreted when the abdominal viscera are excised exceeds the quantity of sugar which disappears from the blood, and that which could be obtained from the limited glycogen depots of the muscle. The D ÷ N ratio shows that this is derived chiefly from protein.

Arbutin, a glucoside found in the leaves of Uva Ursi (see Index), is reported to have glycosuric effects similar to phlorhizin. Both are phenol glucosides. The action is possessed by the alcohol glucoside *salicin*, not by the aldehyde glucoside amygdalin (F. Y. Michel, 1937).

FATTY FOODS

Fats are used therapeutically chiefly for their local protective action and will be considered under Emollients. They are not indispensable in nutrition, but are normally useful because of their high caloric value and their easy storage as reserve fat. This intake should not be reduced below the customary limit. If the intake of fats exceeds the digestive and absorptive capacity of the intestines, they act as laxatives and cause digestive disturbance. If fats are incompletely burned, as in diabetes, or with "*ketogenic diets*" (see Index) rich in fats and poor in carbohydrates, they give rise to ketone acids which render the urine acid and antiseptic.

Fats affect the availability of a number of dietary factors by facilitating their absorption or hindering their oxidative destruction; for instance, carotene and vitamin A (review, Burr and Barnes, 1943). On the other hand, rancid fats destroy most of the vitamins, especially A and E (Fitzhugh *et al.*, 1944).

Some edible fats are important *carriers of fat-soluble vitamins* (review, Cowgill, 1945). *Fish liver oils* contain vitamins A and D; *butter* contains A, carotene, variable amounts of D and small but significant quantities of E; *vegetable oils contain carotene;* oils of *seed embryos* are the richest source of E. *Adipose tissue* and the fats prepared from it, lard, suet and oleomargarine, are practically devoid of vitamins, but margarine is often modified by adding vitamin A.

True fats, the glycerides of fatty acids, constitute the *simple lipids. Compound lipids* include phospholipids, in which one of the fatty acid radicals is replaced by phosphoric acid and choline; glycolipids, and amino lipids. *Derived lipids* include the sterols (Bloor).

The *rate of absorption* of the various true fats does not differ greatly; in rats it ranged from 53 to 58 per cent for partially hydrogenated vegetable oils, and for lard and corn oil, to 68 to 71 per cent for fish liver oil and butter oil (Steenbock *et al.*, 1936).

Absorption of fat from the intestines requires that it be miscible or soluble in water, by emulsification and hydrolysis. The *lipase* of the pancreatic juice splits the fats into glycerol and fatty acids. Free fatty acids combine with free alkali to form *soaps*, which are emulsifying agents, and so give the lipase better access to the fat. This mechanism plays a minor part in the absorption itself, for the formation and the action of soap take place only in freely alkaline reaction, and this exists only temporarily when pancreatic juice and bile are discharged into the duodenum. The fine emulsification is effected chiefly by the *bile salts*, acting on the partly hydrolyzed fat. Bile salts can actually dissolve palmitic and stearic acid into diffusible complexes (Verzár and Kúthy, 1929), but the lipase action does not suffice to carry the hydrolysis of the major part of the fat to this stage, and triglyceride fats are only coarsely emulsified by bile. A. C. Frazer, 1946, finds that bile salts emulsify partly hydrolyzed fats much more effectively, reducing the particle size to less than 0.5 microns, as is the case in the chyme. He believes that particles of this size can pass intact through the canaliculi of the brush border into the absorbing cells of the intestinal epithelium, therefore obviating the necessity that all the neutral fat be brought into actual solution, for which there is no direct evidence; there is, however, evidence of the intact absorption of mineral oil particles of this size. Other agents may presumably substitute for bile, for experiments with deuterium containing dietary fats show that about two-thirds are absorbed in the absence of bile (A. Shapiro *et al.*, 1936). Short chain fatty acids, such as butyric, are sufficiently soluble in water to be absorbed as solution, but of the ordinary fats at least two-thirds would usually be absorbed as unhydrolyzed particles. The absorption of phospholipids, lecithin and cephalin also requires their hydrolysis (presumably partial). Difficultly hydrolyzable fatty acid compounds such as cholesterol esters are not absorbed (review, W. R. Bloor, 1939).

Somewhat more than half of the absorbed fat appears as finely emulsified triglyceride fat in the chyle of the lacteals; the remainder is carried by the portal blood. The chyle fat would correspond to the portion absorbed as particulate emulsion and passed as such through the protoplasm of the absorbing epithelium. The fats of the portal vein would represent chiefly the short chain fatty acids that were absorbed as solution (Frazer). The assumption that the intestinal cells absorb only the hydrolyzed fatty acids would require that they resynthesize these into neutral fats before they pass into the chyle. R G. Sinclair, 1929, suggested that this occurs by phosphorylation; but there is no evidence for either of these assumptions, although there is evidence that some phospholipid may be formed in the intestinal epithelium (Frazer).

The further course of the absorbed fats has been traced by the substitution of deuterium. A small part goes into the liver and other parenchymatous cells. A large part, 20 to 40 per cent, is deposited in the *adipose tissue* before it is utilized, but the fatty acids are generally modified before deposition. Stearic acid may be formed from oleic or palmitic acid. Fatty acids with short carbon chains (butyric to caproic) are not deposited even when fed in large quantity, but are rapidly and completely burned (Schoenheimer and Rittenberg, 1938). The fat depots (even exclusive of the liver) have a steady turnover, with a half-life of six to eight days.

The fat of the liver is of two kinds: (1) that which is an essential part of the cell structure of the gland and does not vary under ordinary conditions, and (2) metabolic lipids, consisting of glycerides, phospholipids, and cholesteryl esters, which vary considerably. The glycerides may come directly from food, or from fat depots: from the latter especially when liver function is depressed by poisons, or perhaps because the liver does not use up fat at the normal rate (review, A. C. Frazer, 1940). Storage of fat in the liver probably involves phosphorylation into lecithin.

The *liver fat* consists of 40 to 70 per cent neutral fat, the remainder being chiefly phospholipids. In dogs on a well balanced diet it is fairly constant at 2.5 per cent of the organ weight, but may be increased to 50 per cent by fatty food. The fat changes are slower than those for glycogen, and are generally in the opposite direction. The liver fat tends to increase in starvation and in chloroform or carbon tetrachloride poisoning, by withdrawal of fat from the other depots (McHenry and Patterson, 1944). Alcohol tends to increase the liver deposition of fed fat. The transformation of fat to carbohydrate is doubtful for normal conditions, but carbohydrate is readily transformed to fat (review, Mann, 1936). Deuterium studies show that the increase of liver fat in fasting, and by anterior pituitary administration, is due largely to transport of fat from other depots. The liver fat that accumulates on high carbohydrate: low choline diet is derived largely from sources other than the depots, probably from the carbohydrates and proteins of the diet (H. M. Barrett *et al.*, 1938).

Liver injury, diffuse or focal necrosis or cirrhosis, is produced in rats by the same dietary changes that produce fatty infiltration of the liver. This is aggravated by excess of l-cystine and diminished by choline, especially with dl-methionine (P. György and Goldblatt, 1942).

Accumulation of fat in the liver may be due either to failure to transport fat out of the liver or to the transfer of fat into the liver from other depots. *The accumulation of fat by diet or after pancreatectomy* is due to failure of transport out of the liver, owing to deficiency of phospholipids. It can be corrected by feeding lecithin (Hershey) or its constituent choline (Best; see under choline) This action of choline was designated as *lipotropic* (Best *et al.*, 1935). *Inositol* acts as a lipotropic factor in rats, probably also by intermediation of phospholipids. Alteration of Vitamin B income renders the liver more resistant to choline, but more susceptible to inositol (review, McHenry and Patterson, 1944).

Lipocaic.—Dragstedt *et al.*, 1936, 1940, demonstrated another distinctly lipotropic substance in alcoholic extracts of beef pancreas, and gave it this name. Its oral or hypodermic administration prevents fatty infiltration and degeneration of dogs' liver after pancreatectomy. It is about twenty times more potent than choline. Its chemistry and mechanism are not known. It is not present in the external secretion of the pancreas, is not related to insulin, and has not been found in any other organ. Its administration is reported to have improved psoriasis in some patients, but its status is experimental (report, Council of Pharmacy and Chemistry, J.A.M.A., *115*, 1454).

The *fecal fat* is, under normal conditions, derived chiefly from the secretions of the intestinal tract, and not from unabsorbed food fat or bacteria (A. Krakower, 1934; A. Shapiro *et al.*, 1936, deuterium method).

Hypodermic and intramuscular injection of fats and oils is used for the conveyance of drugs. It was also suggested for parenteral alimentation, but the absorption is so slow that it is practically worthless (Winternitz, 1903; Henderson and Crofutt, 1905), and the unabsorbed fat leads to fibrosis. Iodized oil, for instance, may be demonstrated for months. Olive oil persists as unchanged globules and causes but little irritation. Cod liver oil is partly converted into amorphous insoluble material and provokes complex reactions. Methyl esters of all acid fractions are hydrolyzed (Hass, 1938). Fat introduced in emulsion intravenously is also burned (Murlin and Riche, 1915), but the utilization is limited and severe secondary anemia may follow (Dunham and Brownschwig, 1944).

Fate of Lipids in the Lungs.—Oils that have entered the bronchioles flow readily into the alveoli and are there engulfed by macrophage cells; but these have little or no capacity for digesting the lipid, nor are they apparently injured by it. The phagocytosis begins in less than half an hour, but with liquid paraffin and with cod liver oil very little has been taken up in seven days. The state of emulsification is important. Vegetable oils are largely eliminated without phagocytosis (J. L. H. Patterson, 1938). The more irritating mineral and fish oils produce gradual proliferation of the septal and interstitial cells, without mobilizing the leukocytes. The oil-filled macrophages persist for long periods in the alveolar spaces. Cod liver oil is particularly irritant and may lead to necrosis of the lung tissue (review, O. H. Robertson, 1941). *Linoleic and linolenic acids*, in contrast to all other fatty acids so far investigated, are not synthesized in the body (deuterium studies, Bernhard and Schoenheimer, 1940) and are therefore indispensable dietary constituents (Burr and Burr, 1930); but so little is needed that they are probably not of practical dietary significance (review, Cowgill, 1945), Their deficiency leads to malnutrition and skin lesions in rats. Minute amounts of linoleic acid are effective against this condition (H. M. Evan sand Burr, 1928; Burr, 1929). and it was misnamed "*vitamin F.*" Prolonged administration of excessive amounts of unsaturated fatty acids acuses hemolytic anemia (Yonechi, 1935).

◆

CHOLESTEROL

Cholesterol is familiar expecially as a constituent of gallstones, but it occurs in all animal cells. It is a difficultly soluble lipid and a chemically inactive monatomic alcohol. Its role in the economy of life has been puzzling. It forms chemical compounds with saponins and therefore protects against hemolysis by these poisons, but this, of course, is not a natural function. The cholesterol content of the blood changes with its other lipids, but this might be a secondary phenomenon. Its administration to rabbits produces arterial lesions, but these are not paralleled in man. Irradiation with ultraviolet light transforms it into viosterol derivatives, and through these it plays a part in growth. It is structurally related to the sex hormones, but does not produce their actions. The protective action of cholesterol against saponin hemolysis led to therapeutic trials in hemolytic diseases, but the results are not convincing.

Chemical Characters.—Cholesterol is a monatomic alcohol, $C_{27}H_{45}OH$, with the solubility characters of fats. It is therefore but poorly absorbed (Stadelmann, 1898; Klein, 1910). Its oxidation products produce effects (digitalis and saponin) resembling those of bile acids and of the poisons of toads and snakes. Indeed, all these are probably derivatives of cholesterol (Faust, 1911; Flury, 1911).

Occurrence.—Cholesterol is an essential constituent of animal cells, and therefore occurs in most foods. Egg yolk is especially rich, one yolk containing about 0.25 Gm. (Klein, 1910). It is generally prepared from gallstones. Its esters and homologues constitute wool fat (see Index). About three-fourths of the total fat of blood plasma consists of cholesterol esters. Small quantities are present, partly free and partly as esters of the higher fatty acids, in the blood plasma, red corpuscles, and especially in the leukocytes, in fairly constant quantity under normal conditions. Cholesterol plates may be found in any tissue when the cells have undergone slow destruction and where absorption is poor.

Formation of Gallstones.—According to Schade, cholesterol that exists in the bile as a colloidal solution is protected by the cholates, soaps and other constituents. Acidification precipitates the cholesterol by disrupting the protecting salts. Bacteria that produce acid, such as typhosus, pyocyaneus and proteus tend to precipitate the cholesterol, while infections with nonacid-forming bacteria, such as staphylococcus aureus, do not have this tendency (Lichtwitz).

Cholesterol Income.—The cholesterol content of the body is increased by feeding cholesterol (Lehmann, 1914). Mice can *synthesize* cholesterol, probably from intermediates of fat and carbohydrate metabolism, when it is absent from their food (Schoenheimer and Rittenberg, 1938); but higher animals appear to depend chiefly upon the food and therefore eventually on plants. Ordinary food contains adequate amounts; but when the diet is restricted, or when there are extraordinary demands, as in growing children, it may conceivably be deficient (Mendel, 1914).

The liver appears to be the chief site of cholesterol synthesis. Liver slices, but not other tissues, utilize the C atoms of acetic acid or ethanol for cholesterol synthesis (Borek and Bloch, 1946).

Absorption.—Food cholesterol is not absorbed effectively unless fat is also present in quantitative relationship (R. P. Cook, 1937). Other closely related sterols, such as phytosterols, coprosterol and even allo-cholesterol are practically unabsorbable (Schoenheimer *et al.*, 1935). Ergosterol becomes absorbable when changed to viosterol by irradiation. Cholesterol is absorbed from the alimentary tract into the lymph, being demonstrable in the thoracic duct. During absorption from the intestines, free cholesterol is partly esterified, and the esters are partly hydrolyzed (J. H. Mueller, 1915). Illingworth, 1921, reported that it is absorbed from the bile in the gallbladder, but this was denied by Elman and Graham, 1932, who found that the gallbladder secretes cholesterol into the stagnant bile. In cholesterosis of the gallbladder, the bile contained only 0.135 to 1.248 mg. per 100 cc. (McEachern and Gilmour, 1932). *Hypodermic injection* into rabbits produces marked inflammation and necrosis of the subcutaneous tissue. This gradually subsides with the disappearance of the cholesterol, which is effected mainly through the leukocytes (Basten, 1915).

Fate and Excretion.—Considerable cholesterol is destroyed, increasing with the income (Schoenheimer and Breusch, 1933; F. Fitz and Bruger, 1936); a part is excreted into the bile, but is reabsorbed almost quantitatively; a part is oxidized to dihydrocholesterol and excreted by the mucosa of the large intestines, and is there reduced to coprosterol by the fecal bacteria (review, C. F. Bills, 1935). A part of the excess cholesterol is deposited in the tissues, partly as such, partly as esters, the latter especially in the liver (Sperry and Stovanoff, 1935). Cholesterol administered by mouth, as such or as food, produces marked increase in fatty acids and cholesteryl esters in the *liver*. This is prevented by lipocaic and inositol, not by choline.

Blood cholesterol is about equally distributed between the plasma and corpuscles. The normal cholesterol content of human serum ranges between 130 and 220 mg. per 100 cc.; mean, 160. It is not affected by feeding 2 to 10 Gm. of cholesterol. It varies in the same direction as the other lipids of the blood, and is *increased* with diets rich in fats, in diabetes mellitus, icterus, arteriosclerosis, nephritis, alcoholism, anesthesia, pregnancy, syphilis, excision of adrenals, hyperthyroidism. It is *diminished* with diets poor in lipids, by high body temperature, and in cachexias (McEachern and Gilmour, 1932; Cutting and Tainter, 1934). The reasons for these changes are not clear. A part of the blood cholesterol is derived from disintegration of the erythrocytes. Cholesterol probably plays a role in *fat metabolism*, but this is not understood (Bloor, 1917). If cholesterol is injected *intravenously*, it leaves the blood rapidly, and is deposited in various organs, and partly excreted by the intestinal tract and urine (not by the liver; Bentner and Hepner, 1928). The kidneys show degenerative changes and focal infiltration with cholesterol (K. Dewey, 1916).

Atheroma.—Feeding or injections of cholesterol produce arteriosclerotic lesions in rabbits, with deposits of anisotropic lipids in the intima and especially the media of the aorta and less frequently in other vessels (Adler, 1914; Denny and Frothingham, 1914). The deposition of lipids is the result, not the cause, of injury to the media (Duff, 1936). There are also degenerative changes in the suprarenal cortex (Knack, 1915). Less marked arterial changes are produced in guinea pigs (Bailey, 1915). Chicks invariably develop atherosclerosis of the large arteries, including the coronary, if 2 per cent cholesterol is added to their basic diet for six months (Dauber and Katz, 1943). The atheroma in rabbits may be prevented by feeding iodine compounds (J. H. Page and Bernhard, 1935) and by the administration of large doses of choline (300 mg. daily; C. A. Baumann and Rusch, 1938). Lipocaic, which does not affect the level of blood cholesterol in normal rabbits, prevents the rise and the atheroscleroma of high cholesterol diet (M. J. Huber *et al.*, 1937). *Polyvinyl alcohol*, when injected into dogs, induces atheromatosis similar to that of cholesterol. It is attributed to disturbed metabolism of the vascular walls by the physicochemical changes (W. C. Hueper, 1941).

By *intravenous injection* of cholesterol into rabbits over long periods, Adler, 1917, produced arterial lesions closely resembling those of human arteriosclerosis. They were most marked in the pulmonary artery. Adler was inclined to attribute them to the intermittent but extensive blocking of the vessels by the injected oil, and therefore not to the chemical properties of cholesterol.

Arteriosclerosis in man has no relation to the blood cholesterol level (Landé and Sperry, 1936), but hypersensitive patients average a higher cholesterol content in the renal arteries and thoracic aorta. This increases with age (Bruger and Chassin, 1941). Increase of the cholesterol blood level may favor the development of *senile atherosclerosis*, but it may be absent in the spontaneous disease. The fatty deposits in the intima of the arteries often have the same lipid composition as in the blood plasma and normal intima (review, E. F. Hirsch and Weinhouse, 1943).

Xanthoma.—Young rabbits on diets containing one-fourth per cent of cholesterol for six to ten months develop xanthomas in the subcutaneous tissue of the feet. The tumors averaged 46 per cent of fat, and 4.6 per cent of total cholesterol, in the dry weight. The cholesterol level of their blood averaged 6.2 mg. per cubic centimeter, the controls averaged 1.4 mg. (Rusch *et al.*, 1939).

Effects on Cancer.—The injection of cholesterol emulsions was reported to accelerate the growth of experimental cancer (Burnett, 1913) and to promote the formation of metastases, but it does not originate cancers, or increase the rate of natural incidence.

Effects on Growth.—Sperry and Stovanoff, 1935, found that the slowed growth of rats with long-continued cholesterol feeding is associated with diminished consumption and utilization of food. They believe this related to the large deposits of cholesterol esters in the liver.

Protection against Poisons.—Free cholesterol neutralizes a number of poisons, especially hemolytic (saponin, tetanolysin). *The antihemolytic action* is not very potent. Saponin hemolysis is retarded only if relatively large quantities remain in contact for a considerable time before the erythrocytes are added. Cholesterol retards bile salt hemolysis as does lecithin. It does not materially hinder the action of sodium oleate, or cobra, vibrio and streptococcic hemolysins (Roy and Biswas, 1943). The phenomena are quite complex (J. S. Lee and Tsai, 1942). It is also said to protect against strychnine, but only if the two substances are mixed (Fizzoni and Perucci, 1919). It is reported to be somewhat stimulating to the *heart muscle* (Danilewsky, 1907).

Therapeutic Uses.—The protection against hemolytic poisons suggested the trial of cholesterol in pernicious anemia (Reicher, 1908), and in paroxysmal hemoglobinuria (Pringheim, 1912 and 1913), but it did not prove successful. The dosage was six intramuscular injections, on alternate days, each of 5 cc. of 10 per cent cholesterol emulsion; or by mouth, 3 Gm. in 100 cc. of olive oil, daily, in tablespoon doses. The preparation of a watery emulsion for intravenous injection was described by Dewey, 1916. Cholesterol is official in the U.S.P.

◆

LECITHINS

Lecithin was exploited as a "tonic," but it did not achieve a place in therapeutics. The ordinary diet furnishes a liberal supply of lecithins, and the small quantities that may be added in the form of rather expensive medicines could only have imaginary effects.

Chemical Structure.—Lecithins are esters of fatty acids, glycerophosphoric acid, and a nitrogenous base (mainly choline). The various lecithins differ according to the fatty acid and the base. They occur in animal (not in vegetable) cells, generally combined with proteins. Their place may be taken by related compounds or "phosphatides," which are but little understood. Lecithins are conveniently isolated from brain substance or egg yolk ("vitellin"). The commercial products are quite impure. They contain 3.84 to 4.12 per cent phosphorus. H. MacLean, 1915, states that ordinary lecithin is a mixture of cephalin, which tends to become insoluble in alcohol, and true lecithin, which remains alcohol soluble.

Properties.—Lecithin is a white to orange colored substance, usually amorphous and waxy when dry. It is hygroscopic, softening to a semifluid mass in the air. It also oxidizes readily, becoming darker. It dissolves in alcohol or most fat solvents (not in acetone). It is insoluble in water, but readily takes up water, swelling to a gelatinous mass and finally to a colloidal solution, from which it is precipitated by certain acids and salts; while other salts prevent the precipitation (W. Koch). It is decomposed by prolonged contact with water; alkalis saponify it readily into choline, fatty acid and glycerophosphoric acid. Further cleavage results in ordinary phosphoric acid. The cleavage with dilute acids is quite slow.

Cephalin is a highly unsaturated monamino-monophosphatide. Its nitrogenous base is probably not choline; otherwise it is closely related to lecithin. Koch and Woods, 1915, believe that it is distributed as widely as lecithin. The number of *other phosphatides* is probably limited, the various phosphorized fats prepared from different tissues being probably mixtures of lecithin and cephalin, with closely related homologous fragments (Levene and Komatsu, 1919). *Plant phosphatides* were formerly considered identical with lecithin, but are now known to be quite distinct. They usually contain a sugar molecule.

Phytin consists of the salts (usually calcium) of an organic phosphoric acid, probably containing inosite (presumably inosite-hexaphosphoric acid). It is widely distributed in plants (bibliography, A. R. Rose, 1912). It is absorbed and metabolized, but must be decomposed before it can be used by the tissues. Abundant amounts are contained in ordinary food, and there is no clear evidence that it is superior to inorganic phosphates.

Lecithin Content of Food.—The ordinary mixed diet contains at least 5 Gm. of lecithin daily; and this can be doubled by adding two eggs (egg yolk contains 6.8 per cent of lecithin), or liver or sweetbreads, which are also rich in phosphorus. Milk is rather poor in lecithin (a pint contains 0.3 to 0.4 Gm.; W. Koch, 1905).

Fate of Lecithin.—Little, if any, lecithin is absorbed as such; the fat-splitting enzymes of the intestines split off the glycerophosphoric acid, which is further decomposed into phosphoric acid before it is absorbed (Bokay, 1877; Plimmer, 1913). Possibly a fraction of the glycerophosphoric acid, and even of undecomposed lecithin, is absorbed before the cleavage is completed. In this case, or if the lecithin is introduced parenterally, the cleavage occurs in the tissues; the excretion is entirely as inorganic phosphates.

Synthesis.—Lecithin is readily synthetized in animals from inorganic phosphates, for when radioactive phosphate is administered it can soon be demonstrated in the phospholipids (Hevesy and Lundsgaard, 1937). The lecithin synthesis occurs chiefly in the liver; some also in the intestinal cells with phosphorylation of fatty acids as intermediate (review, A. C. Frazer, 1940). Roehmann, 1908, showed that mice can be maintained for two generations on lecithin-free food.

The functions of phospholipids are obscure, although the presence of considerable quantities in all the tissues indicates that they are important. It has been suggested that they are intermediates in the metabolism of fatty acids; that they act as acceptors of oxygen and hydrogen through their double bond linkage; and that the peculiar physical and solubility properties are essential to cell structure; but none of the suggestions are proved (review, Sinclair, 1934).

Nutrition and Growth.—The statements of different investigators are so contradictory as to indicate that the effects of phosphatide administration are unimportant; and this would be expected, since animals are able to synthesize all the lecithin they require. The subject is reviewed by Forbes and Keith, 1914. Best and Campbell, 1936, found that feeding or injecting lecithin diminishes the deposition of fat in the liver, in phosphorus poisoning, or when a large quantity of fat is fed; but this effect is due to the choline. Danilewsky, 1895 and 1896, reported that feeding isolated lecithin stimulates growth, increases the red corpuscles and accelerates physical development, as compared with control animals; but others (Goldfarb, 1907; Yoshimoto, 1910) failed to obtain any results. The clinical data are even more unsatisfactory than the experimental.

Phosphorus in Nerve Tissue.—Nervous tissue is rich in phosphorus (⅓ per cent of moist; 1½ per cent of dry), but not more so than glandular organs. Its phosphatide content (27 per cent of dry) is three times or more that of glands; but the presence of phosphorus is not decreased even in severe nervous diseases (dementia praecox) (W. Koch, 1909).

Carcinoma.—Hypodermic injection retards the growth of rat carcinoma; oral administration is not effective, presumably because the lecithin is decomposed before absorption (Robertson and Burnett, 1916).

Action on Circulation.—Danilewsky, 1906, and Katznelson, 1910, state that the heart of frogs and rabbits is stimulated by dilute, depressed by concentrated solutions. Lifschitz, 1910, describes rise of blood pressure and cardiac stimulation. Lawrow and Woronzow, 1912, reported a marked antagonistic effect to cardiac poisons (chloral and other lipolytic narcotics). They attribute the effects partly to direct cardiac stimulation, partly to disintoxication of lipolytic poisons. Hauschmidt, 1913, confirms that intravenous injection is harmless and lessens the toxicity of the lipolytic narcotics and also of curare, strychnine and morphine; but that it increases the toxicity of ricin. G. K. Ashby, 1946, confirmed that intravenous injection of pure lecithin is not toxic to rabbits, but that it becomes so on exposure to air. Commercial samples were toxic.

Hemolysis.—Minute quantities of lecithin markedly accelerate some hemolytic poisons, but not others. This is due to contamination with free fatty acids and does not occur with pure lecithin (Roy and Chopra, 1941). Complex *antihemolytic* properties of lecithin and cholesterol are described by Lee and Tsai, 1942.

Role in Fat Assimilation.—Bloor, 1915 *et seq.*, found that the *lecithin content of the blood* increases 10 to 35 per cent during the absorption of fats, generally parallel to the increase of blood fat. The accumulation of lecithin is greatest in the corpuscles, which contain about twice as much as the plasma. The cholesterol content (which is about equal in the corpuscles and plasma) is not increased by feeding fats.

Lecithin on Cutaneous Absorption.—Borshim, 1912, claimed that small amounts, rubbed into the skin before the application of a potassium iodide solution, increase its absorption; while large amounts have the reverse effect. Glucose, salicylic acid and tetanus toxin were not absorbed.

Administration.—Commercial lecithin has been administered as pills, 0.1 to 0.5 Gm. per day. It has also been given hypodermically, 1 cc. of 5 per cent in oil; but in view of the impurities, this is not advisable. It is incompatible with alkalis.

◆

VITAMINS

In addition to the essential calories, amino acids and inorganic salts which are needed in considerable quantity to replace the ordinary daily wear, normal metabolism also requires the presence of minute amounts of various other elements, inorganic and organic, probably as essential parts of specialized enzyme systems. This holds true of all living organisms, the lowest plants—such as yeast—as well as of the higher animals.

Small quantities of such substances are often sufficient. "Biotin," for instance, acts on the growth of yeast in a dilution of $1:4x10^{11}$ (F. Kogl, 1937). Yeasts, molds and bacteria are specific in their nutritive requirements, so that they are utilized for the assay of vitamins and amino acids (references, J.A.M.A., 1944, *124:*578, 649). The *intestinal bacteria* synthesize a number of vitamins, particularly B and K. Interference with the intestinal flora by effective intestinal antiseptics, such as sulfaguanidine and succinyl sulfathiazole, hinders the growth of rats (C. A. Elvehjem, 1944). The needs of *insects* appear even more specialized than those of man, perhaps because their power of synthesis is more limited (review, C. M. McCay, 1938).

The term "*vitamin*" was introduced by Casimir Funk, 1911, for these indispensable "accessory food substances" (Gowland Hopkins, 1912) which vertebrates can not synthesize for themselves, at least in adequate quantity, and which they must obtain from food. They are definite organic substances, generally non-nitrogenous hydrocarbons, belonging to various chemical groups. Some have been isolated as pure crystals and prepared synthetically, and these have identical actions. They are rather unevenly distributed among various animal and vegetable foodstuffs, so that deficiencies are liable to occur with one-sided diets, although varied diets generally furnish adequate supplies, even to the poorer families. Deficiencies may arise from digestive disturbances which interfere with proper absorption, and sometimes from unusual demands (McCollum and Simmonds, 1929; "vitamin deficiency by interference," N. Jolliffe, 1943). *Starvation* in itself automatically cuts off the supply of vitamins, so that vitamin deficiency becomes a part of malnutrition generally, in chronic diseases, marasmus, chronic intoxications and drug addictions. The *restricted diets* in the treatment of obesity, allergy, infections, convalescence, peptic ulcer and infant feeding generally require supplemental administration of vitamin mixtures. The *time of development* of the deficiency varies for each substance and differs for various animals, according to their need for the particular vitamin, the amount stored in the tissues, and their ability to synthesize. The store of thiamine is exhausted in a week or two; that of ascorbic acid lasts for several months.

Suboptimal Diets.—From an investigation of Americat dietaries, Borsook and Halverson, 1939, concluded than practically all families spending $2.08 per week per person on food were eating adequately, and some with $1.50. In families with yearly incomes of less than $3000, practically all consumed enough vitamin C, ⅔ were deficient in vitamin B, practically all did not consume enough vitamin A, and half not enough Ca. Practically all had sufficient Fe.

Deficiency in the supply of a specific vitamin results in the specific syndrome of the "vitamin deficiency disease," such as rickets, scurvy, beriberi, polyneuritis, xerophthalmia, pellagra, which are characteristic for each vitamin; and in nonspecific general impairment of appetite, nutrition, growth, fertility, general health and resistance to infections. It is through these deficiencies, and their prevention and cure by certain foods, that the existence of the various vitamins was recognized. Before the vitamins were isolated, they were distinguished by the letters of the alphabet: (A) for the antixerophthalmic vitamin; (B_1) for the antineuritic thiamine chloride; (B_2) for the antipellagric nicotinic acid; (C) for the antiscorbutic ascorbic acid; (D) for the antirachitic vitamin; and so on. These designations continue to be used as synonyms of the pure chemicals or of the groups of related chemicals which share the actions. A tabulation of the symptoms and treatment of vitamin deficiencies is published by the Committee on Foods and Nutrition, 1946, J.A.M.A., *131*:666.

The *nonspecific effects* are chiefly manifestations of disturbed nutrition, which necessarily interfere with *growth* and general resistance, so that the organism is more susceptible to *infections*. Even the dermatoses are merely conspicuous instances of what occurs in other cells (R. J. Williams, 1942). The general impairment of nutrition probably accounts for decreased fat absorption when A, B or D vitamins are notably deficient (review, A. C. Frazer, 1940). Deficiencies of vitamins lower resistance to the progress of rat leprosy (Badger *et al.*, 1940).

The mode of action of vitamins is generally that of coenzymes, the simpler parts of special enzyme systems (review, C. A. Baumann and Stare, 1939). Thiamine pyrophosphate is cocarboxylase. Nicotinic acid amide and riboflavin "lubricate" oxidative processes. Riboflavin phosphoric acid is the prothetic group of flavoprotein, the "yellow enzyme" which is an essential part of many dehydrogenation systems (review, Baumann and Stare, 1939, "Respiratory Enzymes").

Vitamin deficiency by substitution may be produced by chemicals so closely related to a specific vitamin that they compete with it in its enzyme relations without producing its specific reactions. Administration of glucoascorbic acid produces scurvy; pyrithiamine produces all the phenomena of thiamine deficiency; dicoumarin those of K vitamin deficiency; phenazine of riboflavin deficiency; beta acetylpyridine of nicotinic acid deficiency (review, D. W. Wolley, 1944).

The tissue changes in vitamin deficiencies are reviewed by Wolbach and Bessey, 1942.

Multiple Factors.—Unsuitable diets are likely to be deficient in more than one factor, so that clinical vitamin deficiencies are usually more complicated than the experimental. Pellagra generally involves deficiency of nicotinic acid, thiamine chloride, riboflavin and others. Each contributes to the syndrome, which is not completely curable until each of these has been met.

Single deficiencies occur clinically in rickets and in infantile scurvy.

Vitamin mixtures should represent simple multiples of the normal requirements. The U.S.P. provides a series of *official multiple-vitamin preparations* under the name of "*Triasin B*" capsules, tablets and injections containing thiamine, riboflavin and nicotinamide; and "*Hexavitamin*" tablets and capsules containing A and D vitamin, ascorbic acid, thiamine, riboflavin and nicotinic amide.

The composition of these is shown in the following table, along with the daily normal income recommended by the National Research Council, and the *Minimum Daily Income* recognized by the Food and Drug Administration.

	Minimum Daily Requirement (F.D.A.)	Recommended Total Daily Income (NRC)	Hexavitamin Capsules and Tablets	Triasyn B Capsules and Tablets
Vitamin A	4000 units	5000 units	5000 units	———
Vitamin D	400 units	400 to 800 units	400 units	———
Thiamine hydrochloride	1 mg.	2 mg.	2 mg.	2 mg.
Riboflavin	2 mg.	3 mg.	3 mg.	3 mg.
Nicotinic acid amide	10 mg. (?)	20 mg.	20 mg.	20 mg.
Ascorbic acid	30 mg.	75 mg.	75 mg.	———

Supernormal income of vitamins, as additions to the usual American diet, produces no recognizable effect on resistance, energy, "vim" or anything else except the imagination (Ruffin and Cayer, 1944). There is no satisfactory evidence that it improves the output of factory workers (A.M.A. Committee on Foods, 1942, J.A.M.A., *118*:618). The incidence of colds is not reduced by multiple vitamins (Cowan *et al.*, 1942). The vast sums expended on vitamins by the public are largely wasted.

The healing of wounds is not improved by topical applications of any or all of the vitamins; or of sulfonamides (rats; Williams and Bissell, 1944).

Excessive vitamin income appears capable of increasing the virulence of certain *virus infections* (report, Council on Pharmacy and Chemistry, 1945, J.A.M.A., *129*:211). *Deficiency of vitamin income* increases the normal resistance of mice to inoculation of poliomyelitis virus (C. Foster *et al.*, 1942). Undernourished chickens are practically immune to the Rous sarcoma virus (Rous, 1911). Caution is indicated in transfering these results to man. The relation of vitamins and hormones to cancer are reviewed by D. Burk and Winzler, 1944.

Absorption.—All vitamins are absorbable from the *alimentary tract* under normal contions; but mineral fats interfere with the absorption of the fat soluble vitamins, especially A and carotene. Bile is essential for the absorption of vitamin K. The *skin* absorbs the lipid-soluble vitamins A, D and K; D sufficiently to produce curative and even fatal effects; but the absorption is inexact and uneconomical. It is doubtful whether the water-soluble B and C vitamins are absorbed through the skin (reviews, H. A. Calvery *et al.*, 1946; Eller and Wolff, 1940).

Administration. — Vitamin deficiencies should be prevented and corrected by suitable diet. Concentrates or isolated principles, however, make it possible to introduce additional quantities when they are especially needed, as in infant feeding, or to meet acute symptoms, or when absorption is impaired. The dosage of the pure principles should be prescribed as milligrams; the impure preparations as U.S.P. units.

Quantitative determinations of the vitamins generally require biological methods, the prevention or cure of experimental deficiencies. The potency may be expressed in arbitrary units. Comparison standards for A, B, C and D are furnished by the Health Organization of the League of Nations and designated as *International Units.* The U.S.P. units conform to these.

ASCORBIC ACID

This constitutes the *Vitamin C* or *antiscorbutic vitamin* (*cevitamic acid*). It occurs widely distributed in plants and animal tissues, and therefore in fresh food, but is easily destroyed by oxidation and is therefore likely to be deficient in preserved foods. It is a dietary essential for man, primates and guinea pigs, but most other animals synthesize it in adequate quantity. It is a fairly simple carbohydrate, related to the sugar sorbose, which occurs abundantly in fresh fruits and vegetables, and to a less extent in meats. It is also prepared synthetically. Its deficiency leads to the symptoms of scurvy, with hemorrhages from the gums and in other situations, changes in tooth and bone formation, suspension of growth and other phenomena; these are promptly corrected by its administration. The condition is not infrequent in improperly fed infants. Cows' milk contains only a fourth as much as human milk. Severe scurvy was common on ships in the days of long sailing voyages. It is now rare in adults, because these have considerable of the substances stored in their tissues so that the disease develops only after a deprivation of some four months, for which there is not often occasion. Partial deficiency of ascorbic acid may lead to a variety of "prescorbutic" phenomena, including dental caries, pyorrhea and gum infections; but these are not characteristic and may arise from other causes. Various forms of clinical gingivitis are not improved by administering ascorbic acid (Stamm *et al.*, 1944). The daily requirement of ascorbic acid is not definitely known, but it increases in pregnancy and lactation, and with heightened metabolic activity such as heavy manual labor, and in fever, especially in tuberculosis.

Historical.—The first successful antiscorbutic treatment is ascribed to Jacques Cartier, 1536, who employed an infusion of pine needles in an expedition on the St. Lawrence River. The real knowledge of scurvy protection dates from Lind, 1747, a British naval surgeon, who demonstrated the efficacy of lemon juice. Experimental investigation was made possible when Holst and Fröblich, 1907, found that scurvy could be induced in guinea pigs by a diet devoid of green food. C. G. King and Waugh, 1932, first isolated crystalline hexuronic acid from lemons and identified it as the antiscorbutic active principle. Two weeks later, Svirbely and Szent-Györgyi announced that they had isolated an active hexuronic acid from adrenal glands. Waugh and King then showed that the active hexuronic acid from the two sources is identical. The hexuronic acid had been prepared by Szent-Györgyi in 1928 from several sources, but without his knowing its relation to scurvy (C. G. King, 1938). Karrer *et al.*, 1933. and Haworth, 1933, established the correct formula by synthesis. It is a levorotatory lactone of tetraoxyketocapronic acid. It was named "ascorbic-acid" by Haworth and Szent-Györgyi, 1933.

Related Compounds.—Dextro-ascorbic acid has no antiscorbutic action. Its aqueous solution oxidizes more rapidly than the levo form and therefore tends to protect the latter from oxidation (Yourga *et al.*, 1944). Levo-rhamno-ascorbic acid has about a fifth of the potency of ascorbic acid; none of the other derivatives ranks higher than a tenth (Zilva, 1935).

The assay methods are reviewed by Bessey, 1938. The *chemical assay* of ascorbic acid by titration of its reducing action, under specified conditions, with 2.6 dichlorophenol indophenol as indicator, is more rapid and accurate, although less specific than the biological methods. The *international unit* is 0.05 mg. of ascorbic acid, the amount usually present in 0.1 cc. of lemon juice. Fresh orange juice contains about 1000 units (50 mg.) per 100 cc. The *bio-assays* include the preventive method of Sherman *et al.*, which is probably the most useful; the curative method of L. J. Harris *et al.*; and the dental method of Höjer.

Ascorbic acid is synthetized by most animals, but not by man, the primates and the guinea pig, either adult or embryo. These derive their supply entirely from the food. Dogs, cows, rabbits, rats, mice, prairie dogs, pigeons and chickens are able to supply their own needs without extraneous addition; dogs, indeed, form it considerably in excess of their needs. Mannose is the most effective precursor (S. S. Ray, 1934), but mice and rats use dextrose (Widenbauer and Korschorreckt, 1937). Rats require adequate intake of *thiamine and riboflavin* for their ascorbic synthesis (Sure *et al.*, 1943). Dogs on thiamine-deficient diets develop oral scorbutic lesions which are prevented and promptly cured by thiamine administration (Govier and Greig, 1943). Adrenalectomy has no effect on the synthesis. Chick embryos synthesize early (King, 1938, review). *Ether anesthesia* increases the synthesis by ten to fifteen times in dogs, considerably in rats, but not in guinea pigs (D. E. Bowman, 1932).

The formation of ascorbic acid in plants is apparently associated with growth, for it is abundant in the actively growing parts of all green plants, including algae and perhaps bacteria. It is considerably more abundant in green leaves than in colorless leaves or roots, suggesting a relation to chlorophyll. It is often associated with carotene, but not necessarily. Unripe seeds, such as green peas, contain large amounts, which decrease as ripening advances. Dry seeds contain neither ascorbic acid nor its oxidation product, dehydro-ascorbic acid; but when they are moistened and warmed, ascorbic acid appears in a few hours in the area of sprouting (reviews, C. G. King, 1936, 1938).

Absorption.—Ascorbic acid is readily absorbed from the intestinal tract in the amounts in which it is administered. It is subject to bacterial decomposition in the intestines, and it is conceivable that abnormal decomposition may account for some cases of deficiency. It is protected by even small amounts of dextrose (A. I. Kendall and Chinn, 1938).

Fate.—The absorbed ascorbic acid is partly distributed and stored in the tissues, partly excreted unchanged, especially in the urine. and a considerable part is destroyed, it is not known where or how. The loss is greater during rapid growth, in both plants and animals (M. E. Reid, 1943). The retention depends on the need of the organism and the degree of saturation of the storage depots. The *quantity destroyed* corresponds to the difference between the income and excretion, and, when these are in equilibirum ("saturation balance"), amounts to 25 to 50 mg. per day in man (King, 1938).

Oxidation.—With *p*H below 7.6, aqueous solutions are not oxidized in the air unless a catalyst is added. The solutions are therefore not auto-oxidizable within the normal *p*H range of animal or plant tissues (Barron *et al.*, 1936), but in plants ascorbic acid occurs associated with specific *ascorbic oxidase*, which catalyzes its oxidation. It may also be oxidized by phenol oxidases, by peroxidases, by hemochromogen and by traces of copper (review, Lipton, 1942). Its role in *cell oxidation* is obscure, although it is presumably concerned in respiration. It is conceivable that activated reactions occur to enable ascorbic acid to act as a hydrogen transport agent and respiratory catalyst, and as a reversible oxidation-reduction system with its immediate oxidation product, dehydroascorbic acid VII; but this has not been demonstrated (King, 1938). For instance, liver and kidney tissue of C-depleted guinea pigs does not show any decrease of respiratory capacity, nor is it increased by adding ascorbic acid (Stotz *et al.*, 1937). It appears to be essential only for the metabolism of phenylalanine, phenylpyricoic acid and l-tyrosine (Basinski and Sealock, 1946). Glutathione protects ascorbic acid against oxidation, and ascorbic acid protects epinephrine. Certain acids and potassium *thiocyanate* and *iodide* protect ascorbic acid solutions against oxidation, by forming addition or condensation products. Ascorbic acid *detoxicates* cyanide and phenol analogous to glycouronic acid (Leibowitz and Guggenheim, 1938).

The excretion of ascorbic acid occurs chiefly in the urine. In man, this ordinarily contains about 35 mg. per day. A daily output of less than 10 to 15 mg. indicates deficiency. Scorbutic children excrete less than the normal (Harris and Ray, 1935), reflecting their subnormal income. If an additional quantity is ingested, the concentration in the urine rises, reaching a maximum in three to six hours, up to eight or ten times the normal (L. J. Harris *et al.*, 1933).

If it is administered daily in graded doses over long periods, the urinary concentration is fairly proportionate to the intake, and nearly identical for different individuals; but if only a few doses are given, different individuals vary in the amount excreted. The urinary excretion after a single adult dose of 600 mg. is used as a clinical test of the repletion or depletion of the ascorbic acid store; excretion of less than 30 per cent in twenty-four hours is below normal (Harris and Ray, 1935).

The fecal excretion is slight, normally less than 6 or 10 mg. per day in man, even when large amounts are ingested. It is increased in diarrhea (Farmer and Chinn, 1938).

Conditions other than storage also affect the output. Fever, for instance, causes it to drop, and additional income is required. *Acetylsalicylic acid* in therapeutic dosage increases the ascorbic acid excretion of children to two or three times (A. L. Daniels and Everson, 1939). This effect occurs in rats and guinea pigs, also with sodium salicylate, but not with neocinchophen, caffeine, salyrgan or sodium bicarbonate (L. T. Samuels *et al.*, 1939). The marked increase after ether anesthesia of dogs and rats is due to increased synthesis. Many terpenes and sesquiterpenes, including camphor, carvone, menthol and thujone, increase ascorbic acid in rats, apparently by increasing synthesis (Longenecker *et al.*, 1939), perhaps to detoxicate these by conjugation.

The blood concentration of ascorbic acid is an index both of its availability and of its storage. In human serum it ranges ordinarily between 0.6 and 2 mg. per 100 cc., averaging about 1.2 mg. in normal, 0.8 in prescorbutic and 0.5 in clinical scurvy (King, 1938). It is inverse to the amount required to produce saturation, as reflected in the urine excretion (Smith, 1938). With a *diet free from ascorbic acid*, the plasma level of man falls to practically nothing in about forty-two days. Symptoms of scurvy appear in five months and become severe in six months (Lund and Crandon, 1941). The plasma level of ascorbic acid is reported to be decreased by administration of neoarsphenamine, and more markedly by iron; bismuth has no effect (Farmer *et al.*, 1940). It is significantly changed by inducing *hyperpyrexia* in normal human subjects (S. L. Osborne and Farmer, 1942).

Storage in Organs.—Ascorbic acid occurs in all tissues and fluids. The amount varies with individuals (King, 1934), but the relative order is the same in all vertebrates, whether they synthesize the substance or obtain it from the food. The total amount is probably highest in the liver (Zilva, 1936); but the concentration is generally highest in the tissues with the highest metabolic rate. The pituitary gland is especially high (2.6 mg. per Gm. in the pars intermedia); then generally, in descending order, in the corpus luteum, adrenal cortex, young thymus, liver, brain, testes, ovaries, spleen, thyroid, pancreas, salivary glands, lung, kidneys, intestines, heart muscle, spinal fluid and blood; the concentration in the heart is about a twelfth of that in the adrenals (Yavorsky *et al.*, 1934). Active tumor tissue ranks high, decreasing with necrosis. The organs of the newborn have a high concentration which gradually decreases while on *milk income*, faster on diluted cows' milk than for the breastfed. The daily excretion of breastfed infants in early lactation is 40 to 50 mg. of ascorbic acid. Human milk contains 4 to 8 mg. per 100 cc., raw cows' milk 1 to 2.6 mg., pasteurized milk 0.1 to 1 mg. (King, 1938, review).

The deficiency phenomena have been explained as inability of the mesenchymal supporting tissues to form and maintain their characteristic intercellular substance (in contrast to vitamin A, which acts on ectodermal and endodermal cells). The defect involves the collagen of the fibrous tissue, the matrix of bone, dentine and cartilage, and all nonepithelial cement substance, including that of the vascular endothelium. This leads to structural weakness, to hemorrhage in regions of stress and trauma, to failure to form osteoid tissue, to loosening of the teeth, to delay of wound healing, and the like. The calcium metabolism is not affected directly, but in advanced scurvy calcium is liberated by the osteoporosis. The proliferative power of the cells is not impaired, and the osteoblasts undergo their normal morphologic changes. Connective tissue cells continue to manufacture an imperfect and often liquid substance, but this does not form fibrils. Administration of ascorbic acid rapidly converts the liquid into the normal intercellular jell. Improvement is demonstrable within twenty-four hours. The ascorbic acid is evidently involved in some obscure manner in the synthesis of collagen and reticulin. Tissue culture experiments have given conflicting results (Wolbach and Howe, 1926; Dalldorf, 1938; Wolbach and Bessey, 1942; M. E. Reid, 1943).

D. L. Maclean *et al.*, 1939, do not believe that organs other than the teeth and bones show sufficient change to justify a general gelation defect theory, but that there is primary degeneration of the odontoblasts and osteoblasts.

Capillary vulnerability is the most obvious symptom of scurvy. If the teeth are erupted, the *gums* become swollen, boggy, hyperemic, bleed easily, ulcerate and necrose. The capillary bleeding is probably due to weakness either in the endothelial cement substance or in the support of the collagen fibrils. (The *effect of dietary deficiencies on oral structures* is reviewed by Schour and Massler, 1945.) The *skin* also shows early perifollicular or petechial hemorrhages, especially in the lower extremities and where it is exposed to pressure. The earliest indication of incipient scurvy is the "capillary resistance test," the production of petechial hemorrhages by venous stasis (Göthlin, 1933, 1937; Dalldorf, 1933). Severe scurvy interferes with the healing of wounds (Lund and Crandon, 1941). Ascorbic acid is not effective against hemorrhagic conditions other than scurvy (review, Witts, 1937). *The dental effects of scurvy* have been studied extensively on the growing teeth of guinea pigs. Ascorbic acid deficiency arrests the formation of dentine by the odontoblasts and the separation of the pulp. This is the basis of one of the bio-assays. There are no corresponding data, however, for human infants; and it would not affect teeth that have erupted (Wolbach). The assertion that *dental caries* is a manifestation of latent scurvy (M. T. Hanke, 1930) is not supported by good evidence; nor is there convincing proof of its causation by deficiency of vitamins A and D. The original studies of Howe *et al.* on tooth changes were erroneous (Wolbach and Bessey, 1942). *Bone formation* ceases in the diaphyses of the long bones, and the existing bone becomes rarefied. The epiphyses are generally not affected. The periosteum shows abnormal connective tissue with tendency to subperiosteal hemorrhages (Dalldorf). Ascorbic acid combines readily with *calcium* and with protein, the latter much more readily if calcium is present (Ruskin and Jonnard, 1938). Josephson, 1935, reported that ascorbic acid tends to clear up clinical *cataracts*, especially those following dinitrophenol administration, and also dinitrophenol neuritis. Hawley and Pearson, 1938, find the ascorbic acid content lower in cataract lens, although the blood level is generally normal. They suggest that the lowered content of the lens may be the result rather than the cause of the cataract. Marked acceleration of the growth of implanted *carcinoma* in mice has been reported to follow administration of the ascorbic acid (Fodor and Kunos, 1934).

Metabolism, Nutrition and Growth.—Ascorbic acid is a potent stimulus to the growth of plant embryos that have been separated from the reserve food supply of the seeds. It is quite probable that it enters directly into the metabolism of animals, but the evidence is meager. Deficiency interferes with growth, but this could be explained by its effect on bones, connective tissue and capillaries. Sigal and King, 1936, reported that the ability of guinea pigs to assimilate dextrose orally is gradually impaired by ascorbic deficiency. Intravenous injection of large doses does not change the blood sugar level, however, nor that of cholesterol, calcium or phosphate; nor does the oral administration of large doses, to 6 Gm. daily, alter the cystine excretion in cystinuric subjects (J C. Andrews *et al.*, 1938). Ascorbic acid administration to rats increases the diabetogenic action of alloxan, under certain conditions (S. Levey and Suter, 1946). *Anemia* by deficient hematopoiesis is common in scurvy, but may be due to other concurrent dietary deficiencies, especially iron (Abt and Farmer, 1938). Ascorbic acid administration prevents the *hyperpyrexia* of dinitrophenol, thyroxin and external heat, but not that of tetrahydronaphthylamine or protein injection (H. T. A. Haas, 1939).

Adrenal Cortex.—Although this contains a rather high concentration of ascorbic acid, there is no evidence of any functional relation. Depletion of ascorbic acid does not shorten, nor its administration prolong, survival after excision of the adrenals (Firor and Grollman, 1934). It has been reported that its administration decreases *skin pigmentation* of Addison's disease, and that large doses produce mottled depigmentation of Negroes, and this has been linked with the observation that it prevents blackening of skin sections by dioxyphenylalanine ("Dopa"); but further experience is needed (Abt and Farmer).

Thyroid administration to guinea pigs raises their requirements of ascorbic acid (Demole and Ippen, 1935). Administration of ascorbic acid protects guinea pigs against thyroid hypertrophy when pituitary thyrotropic factor is injected (Marine *et al.*, 1934).

Resistance to Infection.—A. F. Hess, 1917, pointed out the high incidence of infection in scurvy, which was confirmed experimentally on guinea pigs by G. M. Findlay, 1923. Conversely, infections bring out latent scurvy (Mettier *et al.*, 1930). Wound healing is also impeded by ascorbic deficiency (Lanman and Ingalls, 1937), but the average person has sufficient ascorbic acid income, and further increase does not have a significant effect (Bartlett *et al.*, 1942). These defects are in part common to all nutritional disturbances and in part to the special lesions of scurvy. They are reinforced by the greater need of ascorbic acid when metabolic demands are increased. In active tuberculosis, for instance, the daily human requirement is raised from the normal of 15 to 30 mg. per day to 55 to 140 or even 200 mg. (Heise and Martin, 1936). Low blood values of ascorbic acid have been reported for achlorhydria (Alt *et al.*, 1937) and peptic ulcer; but this may be due to the restricted diet. *Tetanus toxin* is inactivated by ascorbic acid *in vitro*, but apparently not in living animals (Jungeblut, 1937). King *et al.*, 1935 and 1938, reported protection of guinea pigs. It occurs by direct interaction, probably through peroxide produced in the auto-oxidation of ascorbic acid, and is limited to relatively small doses of the toxin (C. W. Jungeblut, 1941). Additional ascorbic acid does not confer protection against *trinitrotoluene* (von Oettingen *et al.*, 1944).

The hemolytic complement activity of serum increases with its content of ascorbic acid to an optimum of about 1 mg. per 100 cc. This holds true for all animals tested, including man, and for variation produced by administration or depletion, including clinical scurvy, or by etherization. The effect occurs also on the addition of ascorbic acid to serum *in vitro*, and is due to the protection of the complement against oxidation: Complement is inactivated by a variety of oxidizing agents, iodine, peroxide, quinone or oxygen, and restored by reducing agents, such as ascorbic acid, hydrogen sulfide, glutathione, sodium hydrosulfite or cyanide. Iodoacetate also inactivates complement and is reversed by ascorbic acid and glutathione, but not by hydrogen sulfide or by cyanide (Ecker *et al.*, 1938, 1939). Ascorbic acid protects *epinephrine* against oxidation and in this way potentiates its pressor action (Reiser, 1938).

Large doses of ascorbic acid are somewhat *diuretic* (W. Evans, 1938), resulting clinically in slowly progressing dehydration (Abbasy, 1937), but with ordinary doses the diuresis is slight and does not appear practically important (C. F. Shaffer, 1944). Several writers have reported *vagotonic symptoms* in children and infants on large doses of ascorbic acid, but these effects do not occur regularly. *Intravenous injection* of 2.3 to 33 mg. per Kg. into chloralosed dogs generally causes prolonged contraction of the spleen, with little or no change in blood pressure (Cioglia and Frada, 1938). In cats, 50 mg. per Kg. lowers the blood pressure more than an equivalent amount of acetic acid (Kreitmair).

Perfusion of the *isolated frog heart* with levo ascorbic acid, 1:10,000, increases the height of contraction, and terminates in systolic arrest after one or two hours. This is not a direct effect, but may be attributed to the cardiac action of hydrogen peroxide which is formed in the oxidation of ascorbic acid, since it is not observed if the oxidation is prevented (Krayer *et al.*, 1943).

Ascorbic acid has been advised clinically for *prophylaxis against poisoning* by metals, organic solvents, aniline derivatives, phenol, cyanides and other poisons. The evidence is unsatisfactory (report, Council on Foods, 1942, J.A.M.A., *118*:620). It has no definite effect on *arsenical dermatitis* (McDonald and Johnson, 1941). It is reported to protect guinea pigs against *liver damage from hydrazine* (K. H. Beyer, 1942). Large doses lower the methemoglobin concentration in *congenital idiopathic methemoglobinuria* by substituting for the deficiency in the natural reducing system (R. F. Sievers and Ryon, 1945).

The clinical toxicity is low: no deleterious effects have been noted with doses of 1 to 6 Gm. in adults, even intravenously, or with plasma concentrations of 5 to 22 mg. per 100 cc. (Abt and Farmer, 1938).

The human requirements of ascorbic acid are not definitely known, nor how they vary for different ages, conditions and individuals. The criteria range from what is indispensable for normal capillary resistance, to saturation of the tissues by various test methods. According to the present imperfect data, they lie within 8 to 50 mg. daily for infants, 22 to 100 mg. or more for children, and 28 to 100 or more for adults. Adequate incomes, but with little margin of safety, are probably 20 mg. for infants, 40 for children and 60 for adults (S. L. Smith, 1938).

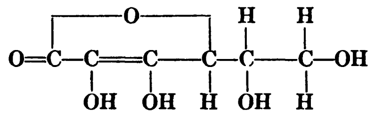
For adults, Pijoan and Lozner, 1944, found 18 to 25 mg. per day the minimum income to protect against scurvy; 80 to 100 mg. per day produced saturation, as judged by urinary excretion. The adequate intake should be somewhere between these figures. Daily excretion of less than 10 to 15 mg. indicates deficiency (Abbasy *et al.*, 1935). Ralli *et al.*, 1939, found that 100 to 135 mg. daily are required to maintain the plasma concentration above 1 mg. per 100 cc. Schultzer, 1937, found 40 mg. intravenously curative for moderate *scurvy. For infants,* 30 to 50 mg. daily are generally curative for acute scurvy, and 10 to 15 mg. prevent active symptoms. Breastfed infants obtain 40 to 50 mg. (Selleg and King, 1936); but cows' milk averages only about half that of the human (Whitnah and Riddell, 1936), and feeding formulas may furnish only a tenth as much as breast milk (Wachholder, 1936), so that they should be supplemented by orange juice.

Natural Sources of Ascorbic Acid.—Fresh orange or lemon juice contains about 1000 international units or 50 mg. of ascorbic acid per 100 cc. (60 to 70 mg., Harris and Ray, 1935). They have been used for prevention of scurvy in the ships of the East India Company since 1601 (E. L. Kennaway, 1942). Lime juice is effective when fresh, but deteriorates more rapidly than lemon juice (Hassan and Basili, 1932). A half pint of orange juice (240 cc.) contains more than 100 mg., and is therefore more than enough for all requirements from infancy to old age; but these may be supplied more cheaply by vegetables; in low-cost diets by potatoes, properly prepared.

Among the richest natural sources of ascorbic acid are the citrous fruits, tomatoes, green peppers and raw cabbage. The commercial canned orange juices contain 30 to 56 mg. per 100 cc.; tomato juice 13 to 29; pineapple juice 10 to 18 (E. M. Bailey, 1938). Rose hips are forty times more potent than orange juice. Half a hip meets the daily requirement of an adult (C. F. Wang, 1944). Practically none is contained in dry cereals and legumes, or in butter, eggs and cheese, and not much in milk. A tabulation of the ascorbic acid content of foods is given in the review of Bessey, 1938. A food should not be considered as a valuable source of ascorbic acid unless it provides a daily intake of at least 12.5 mg. (250 units) of ascorbic acid. The ascorbic acid of vegetables is oxidized and destroyed in ordinary drying, but may be preserved by rapid desiccation and exclusion of air (A. F. Hess, 1921).

Ascorbic acid as such is administered as tablets of 0.01 Gm. (equivalent to 20 or 30 cc. of orange juice). This is the daily protective dose for infants; for treatment, 0.06 Gm.; for adults, 0.05 to 0.1 Gm. per day. For parenteral administration, hypodermic or intravenous, in gastro-intestinal disturbance, 50 to 150 mg. per day, freshly neutralized by half its weight of sodium bicarbonate to prevent acid-necrosis and hemolysis (B. H. Fisher and Leake, 1934; H. H. Anderson and Leake, 1935).

***Ascorbic acid,** U.S.P., is prepared commercially from vegetable sources, from adrenal glands, and by synthesis.



It occurs as white, odorless crystalline powder, freely sol. in water, sol. in alc., insol. in ether. Stable if pure, but in impure preparations and in many natural products it oxidizes on exposure to light and air, and is incompatible with iron and other oxidizing agents. These also destroy it in fruit juices. *Dose,* 10 to 100 mg. per day; 50 mg. (¾ grain) daily, U.S.P.

Ascorbic Acid Tablets, U.S.P., are usually available as 25, 50 and 100 mg. *Sodium Ascorbate Injection,* U.S.P., in water for injection. The usual sizes are equivalent to 0.1 Gm. of ascorbic acid in 2 cc., 0.5 Gm. in 2 cc., in 5 cc., and in 10 cc., and 1 Gm. in 5 cc.

Vitamin P.—Szent-Györgyi *et al.,* 1936, found that paprika and lemon juice contain another substance than ascorbic acid, apparently a flavone which controls hemorrhage in various conditions, especially in clinical cases of increased capillary vulnerability (Scarborough, 1939; Kugelmass, 1940), in retinal hemorrhage and apoplexy. Isolated as crystals from lemon juice, the substance was named *citrin* and was found to consist of a mixture to two related flavone glucosides, *hesperidin* and *eriodictyol* (Szent-Györgyi, 1938). It is apparently identical with *rutin,* present in many plants, prepared from tobacco and most economically from buckwheat leaves (J. F. Couch *et al.,* 1946). This appears sometimes to decrease capillary fragility (J. Q. Griffith *et al.,* 1944), but further experience is needed (Report of Council on Pharmacy and Chemistry, J.A.M.A., *131:*743, 1946; R. L. Shanno, 1946).

VITAMIN A: THE ANTIXEROPHTHALMIC VITAMIN AND CAROTENE

Deficiency of this vitamin causes night-blindness, and excessive keratinization of surface epithelium, manifested especially as xerophthalmia. It is a primary alcohol of the benzene series ($C_{20}H_{29}OH$), consisting essentially of a half molecule of beta carotene ($C_{40}H_{56}$). It is not synthesized in animals, but is formed in the liver by the cleavage of certain vegetable carotenes and cryptoxanthin, which have been termed "provitamin A." These form its chief source in food. It may be administered as carotene, but is generally given as vitamin A, in the form of cod liver oil or other fish liver oils, or concentrates consisting of their nonsaponifiable lipoid fractions. These are more readily absorbed than is carotene, and they also contain the anti-rachitic vitamin D. Vitamin A is rather readily destroyed by oxidation, especially if dissolved in warmed fat, but in natural foods it is not materially weakened by ordinary cooking and careful canning (reviews: L. B. Mendel, 1933; Wilbur and Eusterman, 1933).

Other Questionable Therapeutic Uses.—The Council on Pharmacy and Chemistry reports that there is no adequate evidence for the usefulness of vitamin A in protection against colds, in prevention of renal calculi in man, or for treating hyperthyroidism, anemia, degenerative conditions of the nervous system and ulcerative conditions of the skin.

Historical.—About 1913, several American investigators discovered that butter fat contains some ingredient necessary for growth and nutrition, which is lacking in lard. As the chemical composition of the two fats is similar, they assumed some accompanying substance, which they named "fat-soluble vitamin A." They found that its deficiency could be supplied by cod liver oil, egg yolk and many vegetables. It was later shown that plants do not contain the vitamin, but owe their effect to the carotenes and related substances, which do not act as such but are transformed into the vitamin in the liver. The connection between carotene and vitamin A activity of vegetable foods was noted in the earlier investigations, but the experiments with feeding isolated carotene were then unsuccessful, because it had been oxidized in the isolation. Later work (von Euler, T. Moore) showed that pure carotene is highly effective, 0.003 mg. per day sufficing for the vitamin A need of rats. Carotene had been discovered in carrots by Wackenroder in 1831, and isolated as crystals by Willstaetter, 1910. Its constitution has been determined chiefly by P. Karrer, 1933, who also prepared the vitamin A synthetically. Biologically active preparations have been synthesized by N. A. Milas, 1946. The natural vitamin A was isolated and crystallized from fish oils by H. N. Holmes and Corbet, 1937.

Carotene (Provitamin A) is a lipoid-soluble yellow pigment (lipochrome) occurring in many plants. It is a strongly unsaturated aromatic terpene, $C_{40}H_{56}$. The crystals are readily oxidized with total loss of physiologic activity, so that special precautions are necessary for their conservation. It occurs in three isomeric modifications, the optically inactive betacarotene being by far the most widely distributed. It is twice as effective biologically as the dextrorotatory alpha-carotene, or the gamma form. The more important sources of carotene are carrots, sweet potatoes and yellow corn. Some of the carotene exists as such in animals, especially in eggs, butter, corpus luteum, blood, fat and most of the viscera, probably derived entirely from the food (von Euler, von Euler and Hellstrom, 1928). It is increased by the administration of carotene. Some 30 or more related *carotenoids* are known, but only one of these, cryptoxanthin, is converted into vitamin A in life, in addition to the three carotenes. *Lycopene,* the red pigment of ripe tomatoes, is isomeric with carotene. *Xanthophyls,* the yellow lipochromes of leaves, also belong to the carotenoid pigments, but are not converted into vitamin A. Carotene, lycopene, xanthophyl and capsanthene (red pepper pigment) occur in human fat to the total of 1 to 3.5 mg. per Kg. (Zechmeister and Tuzson, 1935). Many species of bacteria synthesize carotenoids and some carotene itself (Baumann, Steenbock and Ingraham, 1933). The function of carotene in plants is not known. It usually appears concurrent with active growth and closely associated with chlorophyll. Etiolated shoots contain little, suggesting that light is concerned, but once formed it does not disappear on yellowing in the dark (Bessey and Wolbach, 1938). The yellow color of *egg yolk* is due to carotenoid pigments, chiefly xanthophyls, ingested in the food (L. S. Palmer, 1915).

Conversion.—Vertebrate animals are not known to synthesize any carotenoid; but probably all can convert certain carotenoids into vitamin A, although the efficiency of the conversion may differ with the species. The transformation occurs in the liver, presumably by an enzyme. It is stored almost exclusively in the liver fat (Thomas Moore, 1931; Oleatt and McCann, 1931). Vitamin A is formed only from the four carotenoids which possess the beta-ionone ring structure. The conversion has also been accomplished by chemical means (review, L. S. Palmer, 1938). Hypodermic or intravenous injection of carotene does not secure nearly so good utilization as does oral administration, but if it is solubilized by polyethylene gluccol ("Tween 80") it is effectively converted into vitamin A on intramuscular injection (R. M. Tomarelli *et al.*, 1946). In rats, parenteral administration of carotene secures its deposition in the liver, but this is not effective against vitamin A deficiency, as is oral administration, suggesting that the transformation of carotene into vitamin A does not occur in the liver, but in the intestinal epithelium (E. L. Sexton, 1946). Further investigation is needed.

Absorption.—Vitamin A is readily absorbed from the intestinal tract under normal conditions; the absorption of carotene is variable and much more subject to interference with adverse conditions. Fats and oils promote, and mineral oils greatly impede, the absorption. Emulsion of liquid petrolatum interferes with carotene absorption quite as much as does the unemulsified (A. C. Curtis and Balmer, 1939). Absence of bile prevents the absorption of carotene, and probably interferes with that of the vitamin (Drummond *et al.*, 1935; Dutcher *et al.*, 1934; R. W. Jackson, 1934; Altschul, 1935; Greaves and Schmidt, 1935). Vitamin A is also absorbed fairly readily from hypodermic injection. Vitamin A itself is utilized equally well with injection and with oral administration. A colloidal suspension of carotene may be injected by vein, but its therapeutic efficiency is only 1 to 10 per cent of the oral administration, since the colloidal vitamin deposits largely in organs other than the liver (Lease *et al.*, 1942).

In a patient with a fistula of the thoracic duct, Drummond *et al.*, 1935, recovered from the chyle about 90 per cent of the vitamin A that was administered by mouth. It was present chiefly as esters of fatty acids. The absorption of carotene amounted only to 5 or 10 per cent. Virtanen and Kreula, 1941, report that only 3 per cent of the carotene of cooked carrots, and 2 per cent of ground raw carrots, are absorbed in man. Van Eekelen *et al.*, 1938, found that two healthy adults absorbed only 1 to 6 per cent of the carotene of carrots and spinach, but up to 60 per cent of isolated carotene dissolved in oil. Vitamin A in oil solution is absorbed most effectively from the upper and middle thirds of the small intestines. The absorption is promoted by physostigmine, retarded by atropine (Popper and Volk, 1944; Inglefinger *et al.*, 1943). Bile salts render carotene diffusible through colloidal membranes (von Euler and Klussmann, 1933).

Storage.—The vitamin A store normally varies with the carotene content of the diet. About 95 per cent of the total body store is in the liver, the remainder chiefly in the kidneys, lungs and suprarenals. The Kupffer cells appear primarily concerned in its storage and destruction (Domagk and Dobeneck, 1933; Young and Weld, 1935). It can be recognized microscopically by its fluorescence, as droplets in the epithelium and Kupffer cells of the liver, and in the adrenal cortex (Popper, 1940). When it is absent from the liver, it is also absent from the other organs. The store is small in the newborn, and increases rapidly through the milk nutrition, more rapidly by augmenting the vitamin A in the diet of the mother (Baumann, Riising and Steenbock, 1934). In adult animals, the liver store begins to increase within a few hours after administration of a large dose of the vitamin A; over 70 per cent of the quantity administered may be thus stored. A rat can store enough from one feeding of cod liver oil or carotene to supply its requirements for more than two months (McCoord and Luce-Clausen, 1934; C. A. Baumann *et al.*, 1934).

The vitamin A concentration of human livers averages 200 international units (0.1 mg.) per Gm. of moist tissue for adults, 130 units for children, 17 units for infants; but there is considerable variation in normal livers (J. B. Ellison and Moore, 1937). Fish livers run much higher, suggesting that fishes can synthesize the vitamin without carotene.

The vitamin A concentration of the blood depends on the dietary income. Severe hepatic damage is also associated with low A concentrations in the blood, correlating with the clinical course and function tests (D. Adlersberg *et al.*, 1945). Consistently low blood levels indicate depletion. It does not correlate well with biophotometric data (Steininger *et al.*, 1939). S. W. Clausen *et al.*, 1940, report that administration of *ethyl alcohol* to dogs mobilizes vitamin A from the tissues so as to increase its concentration in the blood; and L. B. Pett, 1940, claims improved biophotometric readings on the day after ingestion of alcohol.

Carotene is normally converted into vitamin A and stored in the liver, especially in the Kupffer cells, except a small amount which circulates in the blood and tissues. The blood serum contains normally about 0.11 mg. per 100 cc., and this is doubled or tripled in diabetes, presumably owing to diminished convertive capacity of the liver (Ralli *et al.*, 1936; Stueck *et al.*, 1937). At these upper levels, the carotene causes a visible yellow tint of the palms of the hands, soles of the feet and subconjunctival fat. Such carotenemia may also be produced by excessive medicinal administration of carotene. The conversion into vitamin A is also inhibited by other hepatic disease.

The phenomena of vitamin A deficiency are manifested clinically by night blindness and by excessive keratinization of the epithelium of the skin and mucous membranes, especially of the cornea and conjunctiva (xerophthalmia or keratomalacia), and also of the tongue, mouth, respiratory and urinogenital tract. This favors penetration of bacteria and therefore infection. There is no convincing evidence that systemic resistance to infection is lowered, except in the extreme degrees of deficiency which may be produced experimentally in animals and lead to malnutrition, inhibition of growth and cachexia. The phenomena are similar in man and all mammals and birds that have been studied. The requirement of vitamin A is small, at most a few milligrams daily for the largest mammals. Recovery from deficiency is rapid when the vitamin is again supplied, so that the change in the epithelium may be demonstrated in a few days (review, Bessey and Wolbach, 1938). The curative action is not local but systemic, for if oil with vitamin A is dropped on the conjunctiva of one eye of a keratomalacious rat, both eyes improve at the same rate (de Rötth, 1940). Ordinary diets evidently contain enough vitamin A to prevent conspicuous deficiency phenomena, although the margin is probably not wide. Close observation of low income groups almost always shows conjunctival xerosis, which yields to vitamin A administration (H. D. Kruse, 1941). Subnormal nocturnal vision, with minor degrees of "night blindness," responding promptly (within two weeks) to the administration of vitamin A, is apparently common in children, and the prophylactic administration of vitamin A, along with the D of cod liver oil, is advised by pediatrists. The more severe deficiency phenomena are seen especially when the income and absorption of the vitamin are decreased by prolonged gastro-intestinal disturbance. Toxic effects from overdosage of vitamin A have not been well studied, but are not likely to occur with reasonable doses, since the storage would provide a wide margin of safety. Severe deficiency may lower resistance to bacterial infection, but moderate deficiency does not appear to do so, and additional vitamin A certainly does not diminish susceptibility, for instance, to colds.

Historical.—Xerophthalmia and its treatment by liver diet are described in the Egyptian papyrus of Ebers, about 1500 B.C. (Hess, 1929). Administration of liver in night blindness (hemeralopia) was advocated by Hippocrates. Magendie in 1820 described the occurrence of perforating corneal ulcers in dogs fed exclusively on sugar, olive oil or butter. Similar eye affections were recorded by Livingstone, 1857, when his expedition was on limited rations. Nutritional keratomalacia was described by Bitôt, 1863 (Wilbur and Eusterman, 1934). Eye disease was occasionally observed by Osborne and Mendel, 1913, in their rats on restricted diets.

Experimental Deficiency Phenomena.—Young animals respond promptly to vitamin A deficiency by arrested growth and xerophthalmia. In young *rats*, this may develop in two or three weeks. Deficient bone formation is manifested by delayed dentition and by rickets. In adults, the results may not be notable for several months, partly because adults usually start with a larger store of the vitamin, and partly because they do not need the vitamin for growth. The body weight gradually decreases, the fur roughens, the rats are less agile, the movements become incoordinated, the feet rough and scaly, the animals are untidy, the eyes less protruding, the voice is hoarse or suppressed. Xerophthalmia sets in about this point, with the eyes glued shut, then purulent. Rhinitis with profuse discharge is frequent. Priapism occurs in a third of the males. The resistance to infections is lowered, and the intestinal bacteria invade the blood stream. Anemia does not appear to be a feature, but the blood platelets are said to be diminished (Cramer, 1925; Falconer, 1925). Female rats with insufficient vitamin A or carotene have only few offspring, and these are born with malformation defects of the eyes (Warkany and Schraffenberger, 1944). Sterility develops; indeed, a diet adequate for growth may not contain enough for reproduction (reviews, Mendel, 1933; Orten *et al.*, 1938).

Monkeys on a diet deficient in "A" lose appetite and weight, develop fatal colitis and die, without xerophthalmia, sinusitis or tongue abscess. Epithelial changes may be observed in the respiratory and genito-urinary tract. The animals probably succumb to the gastroenteritis before the keratomalacia has time to become prominent (E. B. Tilden and Miller, 1930; Turner and Loeb, 1932).

Night blindness (nutritional nyctalopia or hemeralopia) is one of the earliest clinical symptoms of vitamin A deficiency. It has no relation to xerophthalmia, the external eye disease following more severe deficiency, but depends on interference with the regeneration of visual purple which is essential to vision under faint illumination. It is most marked after exposure to strong light, which depletes the purple. This type of night blindness responds promptly to vitamin A therapy, improvement being demonstrable two hours after treatment starts. Cases that do not respond are due to congenital defects or other causes (review, Wilbur and Eusterman, 1934).

Incidence.—Nutritional night blindness is not uncommon in the Orient and in some European states. Few if any pronounced cases have been authenticated in the United States, but mild degrees are demonstrable by photometric reading in 26 to 75 per cent of children, the percentage being inverse to the presumptive carotene income of each group; all are promptly cured by the daily administration of 3000 units of vitamin A (Jeans *et al.*, 1937). Jeghers, 1937, found the condition in 10 to 50 per cent of adults, correctable by 30,000 units of vitamin A or carotene daily for three weeks. The minimal daily income for prevention is 4000 units. Experimental reduction to 200 units produced low photometric readings in six days, and subjective symptoms in five weeks. Failures to pass the night glare test of the Army are generally due to vitamin A deficiency and are remedied by its administration (Hutter and Dieter, 1943). Different individuals vary greatly in their response to vitamin A deprivation, to the administration of a single large dose, and to the resumption of a normal diet (Mandelbaum and Hecht, 1940).

Visual purple of the retinal cones is a carotenoid protein, formed continuously in the retina by the union of vitamin A and a carotenoid, "retinene," with protein. Light changes the visual purple to visual yellow. Darkness reverses the reaction and restores the purple and vitamin A (G. Wald, 1935). Fridericia and Hohn, 1925, showed that vitamin A deficiency delays or hinders regeneration of visual purple; Yudkin *et al.*, 1931, found that the retina contains a large amount of the vitamin. This appears also to be a precursor of the visual violet of the rods, for their threshold changes like those of the cones, for instance in alcoholic hepatic cirrhosis (C. Haig *et al.*, 1938).

Keratinization.—Aside from the chemical relation of vitamin A to visual purple, its primary action is on epithelial structures, its deficiency resulting in keratinizing metaplasia, with atrophy of the normal epithelium and substitution of a stratified keratinized epithelium, identical in all locations, and arising from proliferation of the basal cells, which undermine and replace the original epithelium. The swelling leads to occlusion of duct structures and retention cysts, which have been mistaken for abscesses. In man, the trachea and bronchi are the earliest and most common location of the metaplasia; then comes the renal pelvis. Xerophthalmia is rather late. Tooth formation especially of the enamel is deranged. Repair occurs rapidly when the deficiency is met, unless tissue was destroyed (Wolbach and Bessey, 1942).

The changes involve all epithelia that are replaced from basal cells; not those that divide directly, as in the liver, kidney tubules, gastric and intestinal mucosae. The effects begin with atrophy of the epithelium, reparative proliferation of the basal cells, development of the new cells into stratified keratinized epithelium. In *recovery*, the keratinized cells are shed, and the new cells formed in the stratum germinativum differentiate into the new epithelium characteristic for the location (Wolbach and Bessey).—The effect of vitamin A deficiency appears somewhat analogous to the action of estrogenic hormone on the *vaginal epithelium*. This cornification is the basis of the Evans and Bishop, 1922, test for vitamin A. It is possible, however, that the effect is partly indirect, through the ovary (C. A. Baumann and Steenbock, 1932). Vitamin A deficiency also interferes with fertilization and implantation of the ovum. *Xerophthalmia* (*keratomalacia*), keratinization of the epithelium of the cornea and conjunctiva, is a relatively late manifestation, and therefore is rarely seen in man in the United States; but it is a characteristic feature of the more severe deficiency in rats and other animals. It begins with dryness of the cornea and proceeds rapidly to irritation, suppuration and perforating ulcer of the cornea. Young animals develop xerophthalmia more rapidly (V. S. Nelson and Lamb, 1920; clinical, Pillat, 1929; Mendel, 1931). *Keratoconus* succeeds the acute xerophthalmia in rats. The shape of the cornea is restored in a few weeks by administering vitamin A, but corneal nebulae and myopia persist (J. R. Mutch and Richards, 1939). *Skin changes* are among the earliest manifestations and include dry skin, and papules from follicular hyperkeratosis, with lowered resistance to minor skin infections (MacKay, 1934; Jeghers, 1937). In rats, the *tongue* is involved early, beginning with the sublingual glands. *Dental changes* are striking in the incisor teeth of rats and guinea pigs and have also been observed in the toothgerm of a human infant (P. E. Boyle, 1933). They consist of atrophy and keratinization of the enamel organ and disappearance of the odontoblasts. These regenerate from connective tissue cells when the deficiency is supplied. The changes are radically different from those of scurvy (Wolbach and Howe, 1933). The endochondrial formation of bone is retarded, but this may be partly a result of inanition (review, Wolbach and Bessey, 1942).

Urinary Calculi.—In rats and guinea pigs, prolonged severe deficiency of vitamin A is apt to induce calcareous deposits and calculi of the urinary system from the tubules to the bladder, chiefly around large plaques of desquamated epithelial cells (Steiner *et al.*, 1939). Alkalinization of the urine favors the deposition. The bladder calculi were reported to disintegrate when the vitamin is administered. It is doubtful whether vitamin A deficiency has any relation to urinary calculi in man. Such relation is not supported by the dietary history of the patients, keratinization of the urinary tract is unusual (Kayser), and therapeutic results are not at all convincing. However, urinary calculism has become rare in children since the modern emphasis on dietary vitamins (references, H. L. Kretschmer and Brown, 1939).

Degeneration of the myelin sheath of peripheral nerves, especially the sciatic, and of scattered tracts in the spinal cord begins several days before other signs of deficiency appear in rats and increases to death, with muscular weakness, incoordination, and finally paralysis of the hind legs. Its progress can be arrested by supplying the deficiency (E. Mellanby, 1929, 1931; Satterfield and Sutton, 1935; Zimmerman and Cowgill, 1936). Disproportionate growth of the bone and nervous system may lead to mechanical damage and result in paralysis and nerve degeneration. *Testicular epithelium* undergoes atrophy analogous to other epithelial changes (review, Wolbach and Bessey, 1942).

Resistance to Infection.—If a vitamin A deficiency is so extreme as to produce keratinization, this furnishes less protection against bacterial invasion. There is no evidence, however, that susceptibility is increased in the milder grades of deficiency, and increase of vitamin A above the ordinary certainly does not increase resistance. Its characterization as "anti-infective vitamin" is misleading.

The critical control experiments of G. S. Shibley and Spies, 1934, show that the incidence of *respiratory infections* was not altered by the administration of vitamin A for over a year to normal adults on ordinary diets. Sutherland, 1934, found that the administration of cod liver oil concentrate during six months had no significant effect on infections of control groups of school children. J. M. Lewis and Barenberg, 1938, found essentially the same incidence of infection in a group of children kept for six to eight months on a fourth of the normal A income as in another group with four to eight times the normal income. The livers of children dying of acute infectious diseases generally have a considerable store of vitamin A. *Severe deficiency* lowers the resistance of rats to intraperitoneal injection of virulent bacteria (Boynton and Bradford, 1931). Evidence that marked deficiency may lower resistance in man has also been reported (C. E. Bloch, 1931). Lack of both A and D vitamins does not impair the production of antibodies (Wakeman, 1923). *Growth* is retarded by deficiency of vitamin A, but the effect is analogous to that of deficiency in any other essential food constituent and not specific (Mendel, 1933). Administration of the vitamin beyond the normal income does not increase the growth or nutritional state of infants (Sutherland, 1934; J. M. Lewis and Barenberg, 1938). It has no striking effect on *blood formation*. *Thyroxin* and vitamin A appear to be mutually antagonistic: Abelin *et al.*, 1926, reported that diets rich in cod liver oil or egg yolk decrease the toxic effects of thyroid feeding in rats; von Euler and Klussmann, 1932, reported similar results with carotene, and Eufinger and Gottlieb, 1933, claimed that vitamin A counteracts the effect of thyroxin on the metamorphosis of tadpoles. There is no convincing evidence, however, that vitamin A administration diminishes clinical hyperthyroidism. Conversely, Farold and Peters, 1933, found that thyroxin counteracts toxic overdosage of vitamin A. Abelin, 1933, found that thyroxin administration to guinea pigs decreases the vitamin A content of their livers; and Farold and Heidemann, 1933, reported that excision of the thyroid from goats interferes with the conversion of carotene into vitamin A (review, Clausen, 1938). The *oxygen consumption* of rats is not appreciably affected by vitamin A deficiency (Törnblom, 1935).

Toxic effects from overdosage of vitamin A have not been well studied, but they are not likely to occur with any reasonable dosage, since the storage provides a wide margin of safety.

Decalcification and multiple fractures of bones, cachexia, catarrh of the mucosae, damage to the kidneys and other viscera, trophic changes of the skin, and exophthalmos have been obtained by feeding excessive doses of fish oil to animals (Harris and Moore; von Drigalski and Laubmann, 1933). Profuse internal and subcutaneous hemorrhages occur by *decrease of prothrombin*. Administration of vitamin K prevents this, but not the other effects (Light *et al.*, 1944). Large amounts of *pure crystallized vitamin A* produce the bone changes but no significant visceral alterations (Collazo and Rodriguez, 1933). Noetzel, 1939, administering 40,000 units or more to rats, reports marked changes in the liver (fatty degeneration of the Kupffer cells, decrease of glycogen, loss of weight), and fat deposition in the reticulo-endothelial cells of the spleen, bone marrow and kidneys. Cod liver oil, 0.7 Gm. per Kg. daily, shortened the life span of rabbits, and 2 Gm. per Kg. had this effect on calves (W. A. Turner *et al.*, 1936).

Carotene appears to be practically nontoxic on intraperitoneal or intradermic injection (H. G. Wells and Hedenburg, 1916; J. T. Lewis and Reti, 1935); but upon intraperitoneal injection, pure carotene reacts as a foreign body, and produces granulomatous lesions (C. L. Conner, 1928). No carotene appeared in the blood or urine after large amounts. Intravenous injection produced no effect on rabbits. In man, especially in diabetes, excessive administration of carotene produces a yellow coloration of the skin, but no harmful effects. Extractives are said to be more toxic than pure carotene to rats (Lewis and Reti). Hess and Myers described a clinical carotenemia which occurred in infants receiving carrots in the diet, but on discontinuance of the carrots in the affected cases, pigmentation slowly disappeared, Pigmentation did not occur in the absence of carrots (review, R. Kuhn, 1933).

Unit and Assay.—The international unit for vitamin A is 0.6 microgram (0.0006 milligram) of beta carotene. This is also the unit of the current U.S.P.

It corresponds approximately to ⅔ of the obsolete unit of the older U.S.P., Sherman and A.D.M.A. The U.S.P. XII assay is made on the growth of young rats depleted of vitamin A by a special diet. It may also be estimated by a vaginal smear test on rats; or spectrographically (review, Munsell, 1938); and by the "*Carr-Price reaction*," a blue color which appears when antimonyl chloride solution is added to a chloroform solution of vitamin A. This gives consistent results when properly made; but carotene also gives the reaction, developing more slowly (Popper and Steigmann, 1943). Vitamin A differs from its precursors by having no absorption band in the visible spectrum, but a rather broad band in the ultraviolet. In common with all substances of the polyene structure, it gives *color reactions* with numerous agents, including antimonyl trichloride (blue violet for vitamin A, intense blue for carotene).

The daily requirements of vitamin A for man are not accurately known. They appear to increase with the weight and to decrease with age, and the two factors balance each other fairly closely so that there is probably not much difference in the gross needs of infants and adults. The League of Nations Committee advises 6000 to 8000 units for the diet of infants, and at least 5000 for pregnant and nursing women. A daily income of 10,000 units is certainly more than adequate (review, Booker, 1938).

In animals the level of vitamin A or carotene intake required for growth and for prevention of night blindness amounts to 25 to 30 units per Kg. of body weight per day, for all vertebrates (Guilbert *et al.*, 1937). This would come to 1750 to 2100 units for a 70 Kg. man; 3000 units would allow a 50 per cent margin for incomplete absorption. *Cockroaches* do not need vitamin A in their diet throughout their life cycle (Bowers and McKay, 1940).

Dietary Income.—Normal *infants* grow on 24 ounces of breast milk, representing somewhat less than 1500 units. The average diet for children in American hospitals contains 5000 to 6000 units per day and seems to be adequate. The addition of a quart of milk or a teaspoon of cod liver oil would raise this by 1000 or 3000 units. (Skimmed milk is of course poor in vitamin A.) A study of adult dietaries of American families for 1935 to 1936 (H. K. Stiebeling) averaged 2200 to 6200 units in cities, 3000 to 7200 units on farms, varying with the geographical location and the food cost. This would indicate that many of the lower income group have little or no margin. Jeghers, 1937, concluded that clinical deficiency symptoms appear in *adults* when the dietary income is below 4000 units.

Food Sources.—The foods which may serve as sources of vitamin A, directly or through carotene, may be classed as: *Excellent:* Butter (about 20 units per gram), cream, milk, carrots (raw), cod liver oil, eggs (yolk), spinach and water cress. *Good:* Cooked vegetables, bran, whole wheat, cheese, liver, fruits and tomatoes.

Milk contains both vitamin A and carotene; either may predominate. The vitamin A level, 1000 to 2000 units per quart, tends to be constant for a given animal, regardless of the income. Human milk contains more than cows' milk. *Egg yolk* contains vitamin A, not carotene. Its color is due to zeaxanthin and xanthophyl, which are not convertible into vitamin A. *Spinach* is reported to be considerably more effective against night blindness in very young children than the corresponding units of cod liver oil (Friderichsen and Edmund, 1937). Varying results have been obtained on adults. H. E. C. Wilson, 1937, found the absorption of carotene from *raw carrots* or cooked spinach to be 80 to 90 per cent if the diet contains moderate amounts of fat, 50 per cent if it does not.

Administration.—Routine administration of vitamin A is advisable for children under two years, especially those on artificial food; otherwise it need only be administered when real deficiency is present. It is usually given as cod liver oil or its concentrates, which also furnishes antirachitic vitamin. It is even more abundant in the liver oil of other marine fishes of the percomorph group. Halibut liver oil may be a hundred times more potent than that of the cod liver; and others may be still richer, but the potency varies greatly in different catches (Bills *et al.*, 1935).

Carotene has no advantage over vitamin A, and its variable absorption and greater instability make it less desirable. It may be administered in oil, adjusting the dosage to correspond to vitamin A units.

If the income of vitamin A is adequate, neither the absence nor the addition of carotene produces any demonstrable effects. It is, therefore, possible to obtain normal growth, maturity and reproduction in the absence of carotene (Palmer and Kimpster, 1919). If vitamin A is deficient, substitution of carotene in sufficient dosage (0.003 mg. per day for rats) corrects the deficiency completely, as concerns growth and fertility (Steenbock *et al.*, 1921; T. Moore, 1930).

Deterioration and Incompatibilities.—Vitamin A is destroyed by direct sunlight, by heating in the presence of air, and by rancidity (A. D. Holmes and Pigott, 1926); but if these are avoided, oily solutions are fairly stable and the use of artificial stabilizers, such as hydroquinone, is not necessary or advisable (J.A.M.A., 1937, *109:* 1454). Iron salts and other oxidizing agents hasten the destruction. Porous adsorbents are also destructive (H. N. Holmes and Corbet, 1939). The nature of the oil diluent has considerable effect on the absorption (Dyer *et al.*, 1934). *Mineral oil* interferes with the absorption of vitamin A, especially of carotene, but not of vitamin D (R. W. Jackson, 1934; Dutcher, Harris *et al.*, 1934).

Clinical Dosage.—The prophylactic dose of cod liver oil is 2 teaspoons per day, regardless of age. This corresponds to about 6500 units of vitamin A, with the minimal content of the U.S.P., 850 units per Gm. It also furnishes a minimum of about 650 units of vitamin D, on the basis of 85 units per Gm. In starting treatment of an actual deficiency, a larger quantity, up to 4 teaspoonfuls of cod liver oil, would be administered temporarily to speed the cure. Doses larger than 15 cc. daily are not more effective (Spence). The dosage of other fish oils, concentrates and carotene would be adjusted to furnish equivalent units.

Parenteral Administration.—Vitamins A and D are absorbed and effectively utilized if concentrates are injected hypodermically or intraperitoneally; but cod liver oil should not be so injected, as its fat is poorly absorbed and causes local irritation (Koene and Mendel, 1929). Davson, 1936, described marked phagocytosis, fibroblasts and young capillaries.

COD LIVER OIL AND OTHER FISH LIVER OILS

The oils expressed from the liver of cod and other marine fishes are convenient means of administering simultaneously vitamins A and D. These oils are the most concentrated natural source of A vitamin, which was discussed in detail in the preceding section. Vitamin D will be discussed with viosterol (see Index). Both vitamins are contained in the unsaponifiable lipoid; they are, however, quite distinct. Active concentrates are marketed. The official cod liver oil contains at least six hundred times as much A as does butter, so that a teaspoonful of the cod liver oil would represent 6 pounds of butter or 9 gallons of milk. Liver oils that are far richer still in A, without corresponding increase of D, are obtained from halibut and other marine fishes. These make it possible to reduce the dose of oil, the D vitamin being added by blending with other fish oils, or as viosterol. The exclusive milk diet of infants is apt to be deficient in both vitamins A and D; cod liver oil is therefore probably a better prophylactic against rickets than viosterol alone. Later, when the diet is more varied, the artificial introduction of vitamin A is less important, and viosterol is preferred, partly because it avoids the fishy taste. Cod liver oil has been advertised to protect against infections, because deficiency of vitamin A lowers resistance. There is no critical evidence, however, that increase of A income beyond that in normal diet has any additional protective value. The oil may be of some use if the diet is restricted in amount or variety, for instance, with the capricious appetite of phthisical patients.

Historical.—F. W. Headland ("Actions of Medicines," 1856) states that "it appears that the oil from livers of fishes was used as a remedy among the Hindoos and Burmese in very ancient times." "Since time immemorial" cod liver oil was collected for use in the arts, especially in the manufacture of leather; and like everything else, it was used as a folk medicine in the maritime districts of the countries bordering on the North Sea and the Baltic, where the fish are caught, in Scandinavia, Germany, Holland and Great Britain; especially against chronic rheumatism and rickets (which was described by Francis Glisson in 1650), scrofula and phthisis. The first known mention of its professional use is by T. Percival, 1771, from the Manchester Infirmary, where it was introduced, probably about 1766, against chronic rheumatism. Little attention was paid to it until the publication of a paper by Schenck, 1822, in Hufeland's Journal, on its use especially in sciatica and lumbago. This was followed by numerous commendatory papers, extending to scrofula and tuberculosis; including the "Treatise on Oleum Jecoris Aselli" (1841) of J. Hughes Bennett of Edinburgh. The first definite record of its professional use in rickets is in a paper by Schuette, 1824 (Headland, 1856, l. c.; George B. Wood's Therapeutics, 1856; A. Hess, "Rickets," etc., 1929; R. A. Guy, 1923). The use of the oil had periodic waves of popularity and distrust, until the efficacy in rickets was definitely confirmed by roentgenology, and animal experimentation permitted proper control. Before the recognition of vitamins, the activity of cod liver oil was attributed either to its caloric value as an easily emulsified (Buchheim, 1874) and assimilated, unsaturated fat (Motram, 1915), or to traces of compounds of iodine, phosphorus, amine bases (Gautier and Mourgues, 1888).

Assay.—Medicinal cod liver oil is now assayed on rats for both vitamins. Color tests have been proposed, but they are not altogether reliable (Y. Takada, 1927; E. R. Norris and Danielson, 1929).

Administration.—Buchheim remarked in his "Arzneimittellehre" (1853 to 1856): "Because of the nauseating odor, it is well to hold the nose while taking the dose." Infants do not object to it; with older children and adults, the dislike usually decreases on continued use. Some prefer emulsions, or peppermint or wintergreen flavor; others do not care for perfume with fish. The taste is best minimized by careful preparation of the oil and by cooling on ice; or by administering the concentrate in capsules. The oil is perhaps best given as a single dose, once a day, before breakfast; or two hours after a meal. It may produce eructations and diarrhea, especially in the summer; and indigestion and fever are contraindications. Both the A and the D effects can be secured by parenteral administration (Koene and Mendel, 1929), but this is not convenient.

The administration as prophylactic against rickets should begin two to four weeks after birth, increase in dosage to the fourth month, and be continued to two years. A daily dosage of 625 D units probably suffices for adequate protection. This is furnished by three daily doses of 2.5 cc. of cod liver oil of minimal U.S.P. and B.P. potency. Negro infants probably require somewhat more, 4 to 5 teaspoonfuls per day. Large doses may be given temporarily in starting the treatment.

Local Action on Wounds.—The application of cod liver oil dressings or ointment (33 per cent in petrolatum) to burns, ulcers and infected superficial wounds was reported to accelerate healing and decrease infection; but better controlled observations failed to show superiority over other ointments (review, Council on Pharmacy and Chemistry, J.A.M.A., 1943, *121*:759).

Beneficial results were reported by H. Lücke, 1933 and 1935; von Drigalski, 1934; and J. P. Steel, 1935. Lauber and Rocholl, 1935, attributed the effect to the epithelial action of vitamin A. Löhr and Unger, 1937, report that not only A, but also the D and the glycerides of the unsaturated fatty acids of cod liver oil accelerate healing, and that vitamin concentrates above those in cod liver oil retard healing. H. R. Getz, 1938, reported cure of *tuberculous ulcers* in guinea pigs by the topical application of cod liver oil; but that the potency is not parallel to the vitamin A content, although it resides in the nonsaponifiable fraction. *Sodium Morrhuate* has been tried *hypodermically*, like sodium gynocardate, against *tuberculosis and leprosy*. B. Rogers, 1918, claimed good results, but these lack adequate confirmation.

Sodium Morrhuate as Sclerosing Agent.—Intravenous injection of $\frac{1}{2}$ to 1 cc. of five per cent solution of this cod liver oil soap causes sclerosis, thrombosis and obliteration of the veins, which is utilized in the treatment of varicose veins.

PREPARATIONS.—***Cod Liver Oil,** U.S.P. (Oleum Morrhuae; Ol. Jecoris Aselli), is the partially destearinated fixed oil from fresh livers of Gadus Morrhua and other species of the family Gadidae. It occurs as a pale yellow thin oil, having a peculiar fishy but not rancid odor, and a bland fishy taste. It thickens on exposure to air. The U.S.P. requires that each Gm. of oil shall contain at least 850 units of vitamin A and 85 units of vitamin D. Most medicinal brands contain at least 100 units of D, chiefly 7-dehydrocholesterol, the same as is formed in the skin. When materially more than the U.S.P. requirements is contained in cod liver oil it should be given in proportionately lower dose. One "United States Pharmacopoeia Unit of Vitamin A" is equal, in growth-promoting and antiophthalmic activities for the rat, to one International Unit of Vit. A as defined and adopted by the Conference of Vitamin Standards of the Permanent Commission on Biological Standardization of the League of Nations in June of 1934; one "United States Pharmacopoeia Unit of Vitamin D" is equal, in antirachitic potency for the rat, to one International Unit of Vit. D (see Index under Vitamin D). The average *dose* for infants and adults, 8 cc., 2 drachms, corresponds to 6800 units of A and 680 units of D. Flavoring may be added. *Cod Liver Oil Emulsion,* U.S.P. (Emuls. Olei Morrhuae), contains 50 per cent oil and is sweetened and flavored acacia emulsion. Dose, infants and adults, 15 cc., 4 drachms. *Burbot liver oil* is similar to cod liver oil. It is adjusted to a potency of not less than 4480 units of vitamin A and not less than 640 units of vitamin D, per gram (N.N.R.).

Cod Liver Oil Concentrate (Liquid), N.N.R., is a concentrate of the nonsaponifiable fraction of cod liver oil, dissolved in a neutral oil. The vitamin A potency must be between 50,000 and 65,000 units, the D potency between 5000 and 6500 units per gram. It may be dispensed in *capsules* of not less than 5000 A and 500 D units, and in *tablets* of not less than 3120 A and 312 D units. The prophylactic *dose* is 6 to 12 drops, or 1 to 2 capsules, or 2 to 6 tablets daily.

Oleovitamin A, U.S.P. (Natural Vitamin A in Oil), is fish liver oil or concentrate diluted with vegetable oil so that each gram contains about 50,000 units of vitamin A and not more than 1000 units of vitamin D. Average prophylactic *dose* for adults or infants, 0.1 cc. daily. It may be dispensed as *Oleovitamin A Capsules,* U.S.P., containing either 5000 or 25,000 units per capsule.

Oleovitamin A and D, U.S.P., is adjusted to contain, per gram, about 925 units of vitamin A and 92.5 units of D. It may be flavored. The average *dose* for adults and infants is 8 cc. daily.

Concentrated Oleovitamin A and D, U.S.P., an oily liquid, contains, per gram, about 57,500 units of A and 11,500 of D vitamin. The average prophylactic *dose* for adults and infants is 0.1 cc. daily. It is available as *Capsules,* U.S.P., each containing 5000 units of A and 1000 of D.

***Halibut Liver Oil,** U.S.P. (Oleum Hypoglossi), is a fixed oil obtained from halibut livers. It contains, per gram, not less than 60,000 units of vitamin A and not less than 600 units of vitamin D. Flavors may be added. The average prophylactic *dose* for infants and adults is 0.1 cc. daily. It may be dispensed as *Capsules,* U.S.P., each containing 5000 or 25,000 units of vitamin A.

Percomorph Liver Oil, N.N.R., is a blend of oils obtained from various percomorph fishes, assayed and adjusted to a potency of not less than 60,000 units of vitamin A and 8500 units of vitamin D per gram.

Shark Liver Oil is adjusted to 16,500 units of vitamin A and 40 units of D per gram. It is marketed as capsules of 0.3 cc., containing not less than 5000 units of vitamin A.

Carotene in Oil is a solution in cottonseed oil, assayed to a potency of 7500 vitamin A units (4.5 mg. of beta carotene) per Gm.

THE VITAMIN B COMPLEX

Plants of all kinds contain water-soluble vitamins which promote nutrition. Diets that are deficient in these lead to arrest of growth, loss of appetite and weight, anemia, nervous and circulatory disturbances, skin lesions and progressive inanition which terminates in death by starvation. The phenomena are promptly corrected when food or watery extracts containing these vitamins are added to the diet. These events are complex resultants of the deficiency of a number of soluble substances, which generally occur together and which were therefore originally considered as one and designated as "*water-soluble growth vitamin*" or "*vitamin B,*" and now as the *vitamin B complex*. They are especially abundant in yeast, liver and bran (rice polishings); and these are the usual source of the complex. They are apparently essential constituents of enzyme systems that control certain oxidation-reduction reactions of carbohydrate metabolism in living cells. The antineuritic factor was the first to be differentiated as "B_1," from the growth factors "B_2" or "G" or "P-P" (pellagra preventive), and the complex has been resolved by special solvents and adsorbents into ten or more entities, characterized by specific deficiency symptoms, nutritional, dermal or paralytic, often confined to definite species of animals, rats, chicks or pigeons. Only three of these are definitely known to be connected with deficiency symptoms in man: thiamine with the polyneuritis of beriberi; nicotinic acid amide with the skin and nervous changes of pellagra; and riboflavin with certain dermatoses. These have been isolated, identified and synthesized, as has also a fourth principle, "B_6" or "Pyridoxine," which is connected with dermatosis in rats and apparently with some clinical conditions. Others are known only by their effects.

The B-complex vitamins *protect the liver* against functional and structural impairment by a variety of toxic agents. Deficiency of B-complex income impairs the liver so that it fails to inactivate estrogenic hormones, resulting in menorrhagia (M. S. Biskind and Biskind, 1942). Vitamin B complex *increases the inactivation of estrogen* (not of testosterone), and good results have been reported from its administration in menorrhagia and other forms of menstrual hyperactivity (M. S. Biskind *et al.*, 1944).

Vitamin Complex Preparations.—Since these vitamins occur together, deficiencies generally include more or less of the whole "complex," so that it may be advantageous to administer preparations containing all the potent components.

The *average American diet* before the enrichment of bread contained less of the B-complex vitamins than is now considered desirable: Thiamine, 0.8 mg. per 2500 calories instead of 1.6 as recommended; riboflavin, 1.4 mg. per day instead of 2.2 mg.; nicotinic acid, 11 mg. per 2500 calories instead of 15 mg. (editorial, J.A.M.A., 1945, *127*:160).

The following *groups of preparations* are recognized in N.N.R.:

(1) Mixtures of pure thiamine, 1 mg.; riboflavin, 2 mg.; nicotinic acid, 10 mg.; in daily dose or simple multiples.

(2) Dried brewers' yeast, assayed as such, or (3) fortified with thiamine and riboflavin; or (4) as a concentrate; or (5) fortified with riboflavin and nicotinic acid.

(6) A concentrate from liver with not less than 0.25 mg. of riboflavin per Gm.

(7) A concentrate from rice polishings, fortified with riboflavin and nicotinic acid.

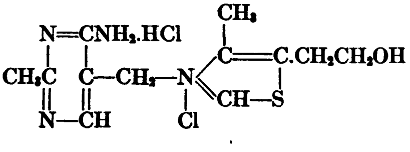
U.S.P. Vitamin Complex Preparations include *Yeast* (see Index) and *Rice polishings* (Perpolitiones Oryzae), *U.S.P.;* Rice Bran, Tiki Tiki.—*Extract of Rice Polishings,* U.S.P., is assayed to contain 20 units of thiamine per cubic centimeter. It is a viscous liquid. Average dose, 8 cc.

THIAMINE

This is the "antineuritic vitamin" or "B_1," deficiency of which results in polyneuritis and the clinical disease beriberi. Its chemical constitution has been established as a basic compound of pyrimidine and thiazole, and it is manufactured synthetically and marketed as the hydrochloride. It occurs in probably all animals and plants, both free and as thiamine pyrophosphate or cocarboxylase, which functions in living cells as co-enzyme in intermediate carbohydrate metabolism reactions, some oxidizing, some decarboxylizing. It plays a conspicuous role in the growth of all living organisms, from the lowest to the highest plants and animals. The normal human income is 1 to 2 mg. per day, and this probably does not leave a wide margin. It is apparently nontoxic in considerably larger doses. Its administration prevents and relieves the deficiency phenomena. Its usefulness has been demonstrated in beriberi, in some anorexias of dietary origin; and to insure optimal growth of infants and children. It may have a considerably wider scope, but this has not been established. (The subject is discussed in detail in the book of R. R. Williams and T. D. Spies, "Vitamin B_1 (thiamin) and Its Use in Medicine"; MacMillan, 1938.)

Historical.—Beriberi, an endemic peripheral polyneuritis with nutritional disturbances, spread rapidly in the Orient about the middle of the nineteenth century, when hulled rice was introduced. Admiral Takaki in 1884 demonstrated that the disease in the Japanese navy was due to this rice diet. In 1897 Christian Eijkmann, at that time stationed in Java, chanced to notice that chickens fed on the cooked rice discarded at the hospital developed polyneuritis. He recognized its similarity to beriberi, and found that it could be averted and promptly cured by feeding rice hulls or extracts from these. Yeast extracts are also effective. Casimir Funk, 1911, obtained crystals from rice hulls; but when purified, these proved to be nicotinic acid (Drummond and Funk, 1914), which is ineffective against the deficiency neuritis. Highly active concentrates were obtained by special adsorbents and differential solvents (A. Seidell, 1926), and the crystallized active principle was finally isolated by Jansen and Donath, 1926, who named it "aneurin"; and on a practical scale, as the hydrochloride, by R. R. Williams, Waterman and Keresztesy, 1934. The structural formula was determined and its synthesis accomplished by Williams and Kline, 1926, and Williams proposed the name thiamine.

Chemistry.—Thiamine hydrochloride has the *structural formula:*



This structure is chemically unique. The ring to the left is pyrimidine, to the right is derived from thiazole, . The latter is otherwise unknown in nature, and thiamine is the only vitamin known to contain sulfur. The position of the alkyl in the pyrimidine is also peculiar; and the N forms a quaternary base. The dry substance is stable in air, but neutral and alkaline solutions are rapidly destroyed, especially on heating, by hydrolytic cleavage into the constituent pyrimidine and thiazole ring. Acid solutions can be boiled over half an hour. The activity is rapidly destroyed by sulfite. The oxidation product, *thiochrome*, probably a dehydroderivative (Bergel *et al.*, 1935), is not antineuritic (Kuhn and Vetter, 1935). The oxidation is not reversible. The loss of activity in the cooking of foods is quite small, perhaps by the formation of stable esters with pyrophosphoric acid; but it disappears gradually from stored foods. The activity remains when yeast is autolyzed at 35° C. for 24 hours (Cooper, 1914).

Thiamine pyrophosphate, cocarboxylase, is widely distributed in nature, in animals chiefly in the liver and kidneys, along with thiamine. They are probably in dynamic equilibrium, with the pyrophosphate generally predominant (M. A. Lipschitz *et al.*, 1938).

Synthesis in Vivo.—Animals, including insects, can not synthesize thiamine even from its cleavage products, and must therefore obtain it fully formed from plants, directly or indirectly. It is manufactured by intestinal bacteria.

Plants synthesize it chiefly in the leaves. It is stored in the seeds for the needs of the embryo. Roots and lower plants require an extraneous supply, but can often utilize the intermediates, thiazole and pyrimidine, for the synthesis. Although yeast appears to be able to synthesize thiamine, its content generally depends on the amount of preformed thiamine in the cultural medium; it is therefore richer if grown on grain than on molasses media. Isolated roots also require nicotinic acid, pyridoxine and other vitamins which are normally synthesized in the leaves of intact plants (W. J. Robbins and Bartley, 1937).

Food Sources.—Thiamine occurs in all natural foods, in concentrations of 0.1 to 4 micrograms per Gm.

In plants, the average of 1 to 2 micrograms (about ½ unit) is exceeded only by seeds, especially the hulls and embryos, and by yeast grown in thiamine-rich media. "Wheat germ" or embryo, a by-product in the mills of the flour, contains it in much higher concentration than the endosperm. In animals, the liver, heart and kidney contain about 3 micrograms. Pork muscle is outstanding with 10 micrograms (all ratios are per Gm. of fresh food) (review, Munsell, 1938).

Fate and Storage.—Thiamine is readily absorbed from the normal digestive tract, but persistent diarrhea may lead to deficiency. The urinary excretion is small, the fecal still smaller. The greater part is temporarily stored in the various tissues, especially the liver and muscles, which contain more than half of the total store; but the storage capacity is limited, the thiamine is rapidly destroyed and any excess is merely wasted. If the income stops, deficiency symptoms appear in a week with pigeons (Pilcher and Sollmann, 1925), in ten days with rats, in three to four weeks with dogs (review, Cowgill, 1938). The organs are not devoid of thiamine when polyneuritis sets in. The liver loses ⅔ of its store in a week, then more slowly. The brain content is normally rather low, but is held more tenaciously than that of other organs.

The urinary excretion of thiamine in man amounts normally to 0.03 to 0.2 mg. per day, equivalent to 5 to 35 per cent of the amount ingested. The excretion after subarachnoid injection is less rapid than with oral, intramuscular or intravenous injection. A fifth to a fourth of the orally ingested thiamine may escape absorption and be eliminated by the feces (Siclounoff).

Human sweat excretes about 5 per cent of the normal intake of thiamine, about 3 per cent each of the riboflavin and pantothenic acid, and about 0.5 per cent of nicotinic acid (Cornbleet *et al.*, 1943).

The deficiency phenomena produced experimentally from synthetic diets approach those of *clinical beriberi* resulting from diets restricted too exclusively to hulled rice or white wheat flour. After about ninety days of such diets, the symptoms begin with fatigue, numbness and stiffness, tenderness and tingling of the legs, followed by their more or less complete paralysis, due to degeneration of the myelin sheaths of the peripheral nerves. Other situations may also become involved; for instance, the larynx. Parallel with these is loss of appetite and inanition, with or without edema (the "wet" and "dry" forms). Cardiac hypertrophy develops in man, and results in sudden death by acute cardiac dilatation. Animals generally die of inanition (review, Vedder, 1937).

Experimental thiamine deficiency in man, induced by eighty-six days of diet containing less than 0.15 mg. per day, but adequate in other respects, results in some of the neurotic symptoms of beriberi, but lacks the edema and cardiac dilatation. Clinical beriberi probably involves also other deficiencies (R. D. Williams, Mason *et al.,* 1940).

Vitamin B Deficiency on Work Output.—Decreasing the B-complex income of trained human subjects to about a third of the recommended daily requirement is reported to result in diminished work output by producing easy fatigue, muscular pain, irritability, anorexia and lowered pyruvic acid level of the blood. These effects disappear in a few days if the dietary deficiency is met (Barborka *et al.,* 1943). In rats, also, dietary thiamine deficiency produces rapid decrease of work performance as measured by swimming; with restoration on replacing the thiamine; but administration of thiamine to nondeficient animals does not improve their normal performance (Kniazuk and Molitar, 1944).

Rice Disease in Birds.—The phenomena, which have been studied especially in pigeons and chickens, are essentially identical with those in man. Pigeons fed exclusively on hulled ("polished") rice promptly lose their appetite, with almost parallel loss of weight, anemia, lassitude, weakness, diminished heat production, fall of body temperature and depressed respiration. Death occurs in about three to five weeks, when the body weight has fallen by 35 to 55 per cent, as in ordinary starvation. The nutritional disturbances are the most constant feature of the rice disease. Polyneuritis, characterized by muscular paralysis, occurs in less than half of the birds, after two to five weeks, usually in three. It is possible that it would develop also in others if they lived long enough (Eijkman, 1890 to 1897; Casimir Funk, 1911 to 1913). The malnutrition is also quite variable. The previous diet plays a rather minor part; if it was rich in vitamin, the malnutrition is delayed by about a week, corresponding to the limit of vitamin storage; if the diet was so poor in vitamin that the animals start with subnormal weight, the starvation proceeds more rapidly (Pilcher and Sollmann, 1925). Young animals are more susceptible than the full grown; with young rats, growth is arrested in two to three weeks. Pregnant and diseased animals are also more susceptible. McCarrison claims that partial vitamin B deficiency produces loss of appetite, diarrhea, atrophy of the lymphoid tissue of the intestines, especially of Peyer's patches, and sterility. The inanition is accompanied by *degenerative changes in the viscera* (McCarrison, 1919), essentially identical with those of simple inanition. This includes atrophy of the intestinal villi, leading to bacteremia. The *blood changes* are also identical with those of simple inanition; the total corpuscles decrease somewhat more than the body weight, and there is also hydremic plethora (Barlow and Biskind, 1928). These changes usually precede the degenerative lesions of the peripheral nerves and later of the spinal cord.

Beriberi in Mammals.—Typical beriberi polyneuritis has been produced in cats and dogs by an exclusive diet of lean meat, heated for three hours at 120° C. with sodium carbonate solution. Different animals require different periods to develop the disease. The pathology and the response to treatment are the same as for beriberi (Voegtlin and Lake, 1919). The condition, however, is complicated by other deficiencies. Rats on a hulled rice diet died from inanition, with relatively little anemia and no polyneuritis; the condition is completely relieved by the same agents as beriberi (Whitehead, 1930). Increased spontaneous activity and hyperexcitability are early indications of deficiency in rats (Bloomfield and Tainter, 1943). The acute deficiency phenomena in cats include impairment of reflexes involving synaptic centers in the midbrain (G. M. Everett, 1944).

Nervous phenomena begin with fatty degeneration of the myelin sheath of the peripheral nerve fibers, and then involve the axis cylinder, similar to the changes of nerve section, presumably by inability of the neurons to utilize carbohydrates (Wolbach and Bessey, 1942). There are also degenerative changes in the ganglion cells throughout the central nervous system. "Multiple neuropathy" describes the condition more accurately than "multiple neuritis," as the process is degenerative and not inflammatory. Similar changes are found in chronic alcoholism and lead poisoning, diphtheria toxin and starvation (Wechsler, 1938). They appear rather late in thiamine deficiency, and are probably secondary to the nutritional disturbance, but the point of attack appears to be different from that of simple starvation, for the latter is not affected by the administration of thiamine, which relieves the functional phenomena of thiamine deficiency in five or six hours (review, Wolbach, 1937). *Thujone convulsions* are not significantly influenced by thiamine deficiency or administration (Molitar and Sampson, 1937). *Striated Muscle* is not affected directly by thiamine; concentrations above 1:3,000,000 depress acetylcholine contracture. It increases potassium contracture (Torda and Wolff, 1944). It inhibits the muscle response to nicotine; this is not counteracted by physostigmine (Unna and Pick, 1944). It contracts physostigminized *leech* muscle (Byer and Harpuder, 1940).

Diminished food consumption and absorption is a basic phenomenon of thiamine deficiency, and many of the deficiency symptoms occur in control animals which receive similarly limited quantites of food with adequate thiamine (Cowgill, 1938). The marked *anorexia* of thiamine deficiency is the result of incapacity to digest, propel and assimilate food, and forced feeding results merely in stagnation of undigested food in the alimentary tract (Cowgill *et al.,* 1925). Symptomatic treatment of the digestive derangements by laxatives (Barlow and Biskind, 1928) or histamine (Danysz-Michel and Koskowski, 1922) is partly effective while atropine, epinephrine and pilocarpine accelerate the starvation (Arloing and Dufourt, 1923). Adsorbents (kaolin, charcoal, etc.) diminish the effect of thiamine (Masserli, 1922) by decreasing its absorption. Thiamine deficiency inhibits the *normal secretory and motor functions* of the stomach and probably of the intestinal tract (Uhlmann, 1918; McCarrison). *Excised intestinal segments* from such animals also show decreased motility and resistance (B. A. Plummer, 1927), and are less sensitive to acetylcholine. The addition of thiamine restores the susceptibility, although it does not increase the response of normal intestines (Abderhalden and Abderhalden, 1938). (Thiamine inhibits choline esterase, but only with concentrations much higher than those that occur in animals; Glick and Antopol, 1939.) The movements of normal excised intestines are not affected by the addition of thiamine, 1:1000 (Hecht and Weeve, 1937; Molitor and Sampson, 1936); nor has administration of thiamine any material effect on the appetite or the digestive functions of intact normal animals (Cowgill and Mendel, 1921). It sensitizes rat intestine to acetylcholine, but does not sensitize many of the other parasympathetic innervations (Byer and Harpuder, 1940). In 1:10,000 it inhibits the actions of nicotine on rabbits' isolated intestines, but has no effect on the response to ortho- and parasympathetic drugs (Unna and Pick, 1944). The failure of thiamine to affect gastro-intestinal functions directly indicates that the digestive depression is the result rather than the cause of the nutritional disturbance. The *intestinal bacterial flora* is modified and increased by the digestive stasis. The resistance of the intestines is lowered (W. B. Rose, 1928) and the blood is invaded with the ordinary intestinal bacteria (McCarrison, 1919; Barlow, 1927 to 1929). It has not been proved whether these have any special relation to the symptoms. The anemia, at least, appears to be chiefly a part of the general consumption of the tissues in the inanition (Moore and Barlow, 1931). The anemia changes present similarities to those of pernicious anemia (Dhar, 1925; Gildea *et al.*, 1930). A specific beriberi bacillus was claimed by Matsumura and Kakinuma, 1929. Thiamine deficiency shortens the incubation period of *rat leprosy* (Badger, Masumaga and Wolf, 1940).

Growth is checked or arrested by the malnutrition of thiamine deficiency, and is promoted when this is met by thiamine administration; but excess income does not increase growth beyond the normal rate or degree.

Metabolism.—The need for thiamine is greater if metabolism is increased, as in *thyroid poisoning*, and conversely, thiamine has a protective action against the toxic effects of thyroxin (Sure and Buchanan, 1913; Drill and Sherwood, 1938). *High carbohydrate consumption* increases the thiamine need (Funk, 1914) and introduction of carbohydrates into the crop of thiamine-deficient birds is toxic.

Thiamine administration diminishes the metabolic response to *thyroid* (R. D. Williams and Kendall, 1943). The thiamine level of the blood is generally subnormal in thyrotoxic patients (R. H. Williams, Egana *et al.*, 1943).

Fatty diet tends to spare thiamine and to cure spastic polyneuritis in rats, glyceryl caprylate being the most effective (H. M. Evans *et al.*, 1934). Conversely, thiamine appears to be necessary for the deposition of fat (Best and McHenry, 1937). Rats with deficient thiamine income show marked craving for fatty soaps. Deficiency of A, B or D vitamins decreases the rate of intestinal absorption of fat, probably in consequence of the impaired nutrition (review, A. C. Frazer, 1940). *Glycogen storage and the blood sugar level* are often deranged in thiamine deficiency, but not always, and the disturbance could be secondary to the inanition (Reader and Drummond, 1926). Abderhalden and Wertheimer, 1933, reported rise of blood sugar and of liver glycogen. Enlargement of the islands of Langerhans has been reported (Wolbach, 1937). *Changes in tissue respiration* had been described: Hess, 1921; Abderhalden, 1922; Mattill, 1923; C. J. Farmer and Redenbaugh, 1925; but Fleming, 1923, did not find any significant peculiarities in the metabolism of beriberi patients.

Co-Enzyme Function in Intermediate Carbohydrate Metabolism.—The pyrophosphoric ester of thiamine has been identified as *cocarboxylase* (1-4), the prothetic group for enzymes concerned with the oxidation, carboxylation, descarboxylation, dismutation and condensation of pyruvic acid (R. A. Peters, 1936; R. R. Williams, 1938). The latter is an obligatory intermediate in the normal carbohydrate breakdown, and probably in the interconversion of proteins, fats and carbohydrates. High pyruvic acid content of the blood is clinical evidence of thiamine deficiency.

Ingestion of dextrose by normal individuals increases the blood pyruvate. In thiamine deficiency the pyruvate curve rises higher and persists longer (Bueding *et al.*, 1941).

The thiamine of yeast is probably entirely in the form of its pyrophosphate ester; in rice hulls it is probably free. Both forms are antineuritic, but it is possible that the biologic utilization of thiamine is preceded by its conversion into the pyrophosphate. Hexose diphosphate, adenosine triphosphate and phosphopyruvic acid have been suggested as phosphate donors. On bacteria it has been shown that thiamine must be phosphorylated before becoming part of the pyruvic oxidizing system (Barron and Lyman, 1938). Iodoacetic acid inhibits the enzymatic synthesis, fluoride does not. Riboflavin forms a similar system. The wide distribution of thiamine, ascorbic acid, nicotinic amide and riboflavin indicates that they are essential for most if not all living cells, presumably as links of enzyme reactions that effect cellular metabolism. *Co-enzymes* are generally nucleotides connected with nucleoproteins and the cell nucleus. Many vitamins and some of the hormones of animals act as "*nutrilites*" to promote the growth of plants and lower organisms.

The chief metabolic reactions in which the cooperation of thiamine has been definitely demonstrated are the decarboxylization of pyruvic acid, and indirectly the oxidation of lactic acid, in nervous tissue, yeast and bacteria.

The involvement of the nervous system in thiamine deficiency is presumably connected with its dependence on the oxidation of carbohydrates (review, Wolbach and Bessey, 1942). Deficiency of nicotinic acid, riboflavin, pantothenic acid and pyrodoxine also results in degenerative changes of the central nervous system; but A, C, D and E vitamins affect nervous structures only indirectly (H. E. Himwich, 1943).

Brain tissue removed from thiamine-deficient pigeons shows an abnormally low oxygen uptake when suspended in Ringer-phosphate, in the presence of dextrose, lactate or pyruvate. The addition of thiamine to the suspension restores the normal oxygen consumption, apparently by the removal of the pyruvate which is present in increased amount in the thiamine-deficient brains. This is designated as the "*catatorulin effect.*" With brain, the pyrophosphoric ester has only a tenth of the potency of free thiamine. The addition of thiamine has no effect on suspensions of normal brain (Passmore, Peters and Sinclair, 1933; review, Quastel, 1939). *Methylglyoxal* occurs in considerable amount in the blood in thiamine deficiency (Arakawa, 1930; Uga, 1935). *Glutathione* is diminished, especially in the muscles. *Yeast fermentation* requires the presence of the thiamine pyrophosphoric ester (cocarboxylase), which is contained in the yeast, plus a specific yeast protein, carboxylase, the two together decarboxylizing pyruvic acid into acetaldehyde: $CH_3COCOOH \rightarrow CH_3CHO + CO_2$. Free thiamine does not produce this effect (Lohmann and Schuster). *Plants in general* probably require thiamine for their metabolism, but most are able to synthesize what they need, except some parasitical and saprophytic forms. Some of these can synthesize it if supplied with pyrimidine and thiazole, some with one or the other, and some can not form it even when both these intermediates are supplied. Thiamine or thiazole enables excised tomato roots to grow without tops, in dilutions as high as $1:10_9$ (W. J. Robbins, 1939).

Circulation.—The plasma volume is markedly decreased by the digestive disturbance, and this also results in *anemia. Cardiac hypertrophy* is a prominent feature in clinical beriberi. It is responsible for the dilatation of the right heart, pulmonary edema and congestion of the portal and splanchnic viscera. Its causation is not clear, but it may disappear promptly when thiamine is administered (review, Strauss, 1938).

Deficiency of thiamine, riboflavin and the other components of the vitamin B complex does not produce vasomotor changes in human subjects (G. M. Roth *et al.*, 1943). Thiamine administration is reported to increase the resistance of dogs to hemorrhage *shock* (Govier and Greer, 1941). In rats and pigeons, thiamine deficiency causes *bradycardia*, progressing to heartblock, appearing somewhat earlier than the polyneuritis (Drury. 1930; C. W. Carter, 1930). This constitutes one of the assay methods (Birch and Harris, 1934), but the results are not quantitatively consistent (Munsell, 1938). If there is no thiamine deficiency, its administration has no effect on the heart, nor does a 1:1000 solution affect the excised frog heart (Hecht and Weese; Molitor and Sampson). It does diminish vagus stimulation by acetylcholine (P. Kaiser, 1939). On the other hand, vitamin B augments the action of acetylcholine on denervated muscle of leech, on isolated intestine and on the circulation of cats (Agid *et al.*, 1937; Abderhalden and Abderhalden, 1938). It does not act as antiesterase (B. Minz, 1938).

The toxicity of thiamine is generally low. Rats have been raised on 5 mg. per day for three generations. It has been administered clinically in doses of 500 mg. daily for months, without producing any detectable effect after the deficiency symptoms were met. In other cases, however, ordinary full therapeutic doses, 17 to 40 mg. per day, may produce symptoms similar to thyroid hyperactivity, such as tremors, tachycardia and nervous irritability (C. A. Mills, 1941). *Sensitization* by repeated intravenous injection has been reported, with phenomena similar to serum anaphylaxis, including acute collapse (C. L. Laws, 1941; L. Schiff, 1941). *Sudden death*, with collapse symptoms, has followed intravenous injection of 100 mg. (Reingold and Webb, 1946).

The *lethal dose* for intravenous injection has been determined as 125 mg. per Kg. for mice, 250 for rats, 300 for rabbits and 350 for dogs. Death occurs by failure of respiration, preceded by shock, muscle twitching, clonic spasm, dyspnea. The heart and blood pressure remain good until the respiration fails. The fatal dose with hypodermic injection is about six times, and with oral administration about forty times that by vein. This would make the oral fatal dose for man about a kilogram (Molitor and Sampson, 1936; Hecht and Weese, 1937). Repeated intravenous injections of large doses (100 mg. per Kg.) into rabbits do not produce anaphylactic sensitization, but rather lower the toxicity (T. J. Harey and Flesher, 1946).

Unit and Assay.—The International Unit is 3 micrograms of thiamine hydrochloride, and this is taken as a standard of comparison for foods and pharmaceutical preparations. Other units are obsolete.

Some twenty methods of assay are currently used and advocated, but none seems to be altogether satisfactory. Those based on the prevention and cure of the deficiency polyneuritis deserve preference as being most specific, and the curative dose is the most reliable. The U.S.P. assay is based on the cure of rat polyneuritis induced by a deficient diet. R. R. Williams *et al.*, 1934 and 1935, showed that 0.001 to 0.002 mg. of the pure principle protects pigeons and rats fully against B_1 deficiency. To secure full growth requires a considerably larger dosage than that which suffices to prevent the neuritic changes. Other methods are based on the growth rate and on bradycardia (C. W. Carter, 1930). Chemical methods have not been developed sufficiently and the micro-organisms are not specific (Munsell, 1938).

The minimal requirements are generally estimated as normally 50 to 75 units (0.15 to 0.23 mg.) of thiamine hydrochloride for infants, and 200 to 300 units (0.6 to 0.9 mg.) for adults, daily, by mouth. (R. D. Williams, Mason *et al.*, found 0.95 mg. per day required to prevent marked deficiency symptoms; with further benefit by 2 mg. per day.) The minimal requirement can be expressed more significantly as 0.35 mg. per 1000 calories; 0.6 mg. per 1000 calories gives a liberal margin to offset possible losses in cooking (Melnick, 1944). *The requirements are raised when metabolism is increased.* These *requirements are increased* up to ten times with high carbohydrate consumption (Vorhaus *et al.*, 1935), forced exercise, thyroid administration or hyperthyroidism (Cowgill), and during fever, gestation and lactation. *Ordinary diets* contain 1 to 2 mg. The average American diet contains 0.32 mg. per 1000 calories (Lane *et al.*) and is therefore adequate, but the margin is not wide and the success of vitamin therapy in various clinical conditions indicates that deficiency is more common than was realized. If the thiamine income is adequate (1 mg. per day, or 0.5 mg. per 1000 calories), some is promptly excreted, so that there is no retention. If it is inadequate, the greater part is retained until the normal tissue concentration is reached (Melnick, 1942).

The richest sources in ordinary foods are the bran coat and the embryo of grains and legumes, and lean pork. The content in human milk depends primarily on the quantity ingested by the mother, so that infantile beriberi was common in the rice countries. Modern wheat flour contains only an eleventh as much thiamine as stoneground flour of olden times (G. R. Cowgill, 1939). A. Z. Baker, Wright and Drummond, 1937, estimate that the daily thiamine income of the indigent of London was 600 to 1100 units, almost twice that of the London highest income groups in 1937 (450 to 550 units). *Raw fish diet* destroys thiamine and so tends to produce deficiency (in foxes; R. G. Green *et al.*, 1941).

Dosage.—This should maintain the daily income at least at the normal minimum, 0.35 mg. of thiamine hydrochloride per 1000 calories of food; 1 mg. daily for adults, 0.25 mg. for infants; and preferably raise it to two or three times this quantity. There is no objection to adding this amount to the ordinary diet, but there is no advantage in raising the prophylactic dosage above 3 mg. for adults or 0.5 mg. for infants. In treating deficiency phenomena, however, it is advisable to administer 10, 20 or even 50 mg. daily, until the symptoms are corrected. These higher doses secure much better results in alcoholic neuritis (Goodhart and Jolliffe, 1938).

The treatment of *severe neuritis* may begin with 50 to 100 mg. per day, parenterally, divided into doses of 10 to 20 mg. If no response is obtained in a week, it is useless to continue. If the response is favorable, the administration may be changed to oral (Aring *et al.*, 1939).

Therapeutic Uses.—Administration of thiamine is indicated whenever the income is insufficient, and not otherwise. The outstanding example of its effective use is in the prevention and treatment of beriberi. The degree of deficiency represented by this disease is not likely to occur with American and European dietaries, however, except perhaps in penal institutions and insane asylums; but deficiency sufficient to produce neuritis occurs in the anorexia of alcoholism and forms a part of the picture of delirium tremens and pellagra. The toxic polyneurites of pregnancy, diabetes, gastric disorders and postinfective conditions have also been attributed to thiamine deficiency (Youmans, 1937). Minor deficiencies, manifested by anorexia and malnutrition, and miscellaneous neurites are difficult to diagnose as such except by their history and by the response to thiamine administration. The increased thiamine needs of pregnancy and lactation, hyperthyroidism and fever may justify its prophylactic administration, especially if digestive disturbance hinders the absorption. This may require parenteral administration. All deficiency phenomena respond promptly and completely to the administration of thiamine or preparations of yeast or rice hulls ("tiki tiki") which contain it. The improvement begins in a few days and "cure" is completed in a few weeks, except that regeneration of injured nerves requires longer; and if the degeneration and inanition are too far advanced, the progress is merely delayed and decline proceeds to death (review, Strauss, 1938).

Alcoholic neuritis does not develop, even with large consumption of alcohol, if the diet is adequate. Jolliffe and Joffe, 1935, found that patients with this condition always had gross dietary insufficiency for at least twenty-two days. If no thiamine at all is consumed, about twenty days elapse before the first neuritic symptoms, and the final stages are reached in a few weeks. In partial deficiency, the neuritis may remain stationary for a long time. *Pellagra neuritis* is promptly relieved by intravenous injection of thiamine hydrochloride, but this has no effect on the stomatitis. Nicotinic acid relieves the latter and not the neuritis (T. D. Spies and Aring, 1938). *The acute neuritis of leprosy* is markedly relieved, often in one to three days, by thiamine injection (Badger and Patrick, 1938). Thiamine is *not analgetic* against the severe pain of cancer, neuralgia or spinal cord tumors, even when 100 mg. per day are injected intravenously for ten days (Aring *et al.*, 1939).

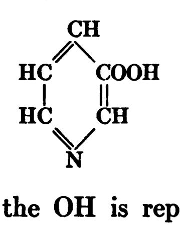
PREPARATIONS: ***Thiamine Hydrochloride, U.S.P.**, thiamine chloride, crystalline vitamin B_1 hydrochloride, aneurine hydrochloride, occurs as white crystalline powder, absorbing water on exposure to air, very soluble in water, the 5 per cent solution having a *p*H of about 3.5. Dose (1 Gm. in about 1 cc.); generally 10 mg. daily. *Thiamine Hydrochloride Tablets*, U.S.P., usually available as 3, 5 and 10 mg. *Thiamine Hydrochloride Injection*, U.S.P., in water for injection; usual sizes, 5, 10 and 50 mg. in 1 cc.; 0.25, 0.5, 1 and 1.5 Gm. in 10 cc.

NICOTINIC ACID (NIACIN)

Most of the phenomena of pellagra in man and an analogous condition, "blacktongue" in dogs, are cured by the administration of nicotinic acid or its amide, and may be considered as due chiefly to deficiency of these dietary factors which form part of the "vitamin B complex," which was designated as "P-P" (pellagra preventive) before the compounds were isolated and identified. Pellagra may also involve additional deficiencies, notably of thiamine and riboflavin, and the symptoms due to these are not removed by nicotinic acid, but only by the addition of the lacking factors. The synonyms "niacin" and "niacinamide" were devised for the lay public to avoid misleading connotations of "nicotinic."

Historical.—The connection between pellagra and restricted diet had long been noted, and Goldberger *et al.*, 1925, and T. D. Spies, 1935, showed that it could be prevented and cured by the administration of yeast extracts containing the "P-P" factor, which also cured the canine "blacktongue," inflammatory and ulcerative changes of the skin and mucous membrane that developed in full grown dogs on restricted diets. Elvehjem *et al.*, 1937, identified nicotinic acid as the effective constituent (review, D. T. Smith and Gower, 1938; Elvehjem, 1939).

Chemistry.—Nicotinic acid is a fairly simple substance, pyridine-3-carboxylic acid:



In the *amide*, the OH is replaced by NH_2, and in coramine by $N(C_2H_5)_2$. Nicotinic acid was originally obtained (1867) by the oxidation of nicotine, and is manufactured synthetically.

Nicotinic acid occurs in rice polishings and yeast (Funk, 1911), and the amide has been isolated from liver. The amide is contained in the *cozymase* which plays an important role in fermentation, glycolysis and respiration. Nicotinic acid inhibits the oxidation of lactic acid in slices of brain; nicotinic amide is much less effective (Z. Baker *et al.*, 1938). Rats do not require nicotinic acid, as they can synthesize it freely (W. J. Dann, 1941), apparently from various simple nitrogen sources, such as amino acids, ammonium and choline (Huff and Perlzweig, 1942). They develop deficiency symptoms if deprived of pyridoxine (B_6), which is chemically somewhat related (S. A. Harris and Folkers, 1939). Rabbits also synthesize nicotinic acid rather freely (Swaminathan, 1942).

Fate.—*The nicotinic amide concentration in the blood* is 0.54 to 0.83 mg. per 100 cc. in normal adult males, 0.52 to 0.74 mg. in females; about 90 per cent of this is in the corpuscles. *The urinary excretion* depends on the concentration in the plasma, not in the whole blood. It amounts normally to 1.7 to 30 mg. per day, free and combined, and about 60 mg. additional as trigonelline after methylation. Oral administration of nicotinic acid results in prompt and marked increase of its urinary excretion, amounting to about 22 per cent of the ingested; about half of this as trigonelline, a third as nicotinuric acid, and an eighth as nicotinic acid or amide. Trigonelline and nicotinic acid, administered as such, are excreted fairly completely and unchanged (Melnick, Robinson and Field, 1940; Sarett *et al.*, 1942). Rats, in contrast to man, dog and rabbit, can destroy trigonelline and nicotinuric acid (Huff and Perlzweig, 1942).

Specificity.—As tested on canine "blacktongue," nicotinic acid, its amide and ethyl nicotinate are about equally potent. Most of the related pyridine derivatives are ineffective when tested against blacktongue of dogs. The only active derivatives are those that can be oxidized or hydrolyzed to nicotinic acid or its amide (Woolley *et al.*, 1938). *Quinolinic acid*, pyridine-2.3-dicarboxylic acid, is strongly antipellagric (Vilter and Spies, 1939).

Clinical Pellagra.—Oral administration of nicotinic acid or amide promptly cures or greatly improves the characteristic phenomenon, including the lesions of the mucous membranes (glossitis, stomatitis, vaginitis, urethritis and proctitis), the early dermal erythema, the mental changes, and the porphyrinuria, even though the diet which produced the disease remains otherwise unaltered; but in this case the lesions return when the nicotinic acid is discontinued (T. D. Spies *et al.*, 1938; D. T. Smith *et al.*, 1937). Nicotinic acid does not cure polyneuritis and cheilosis, which may be associated with pellagra if thiamine and riboflavin are also deficient (Spies and Aring, 1938); nor has nicotinic acid any effect on glossitis and dermatitis or the psychotic states (Cleckley *et al.*, 1939) unless these are due to the specific deficiency. Porphyrinuria, however, is benefited even when it is due to other causes, *f. i.*, lead poisoning (E. S. Gross *et al.*, 1938). Nicotinic acid also relieves specifically the syndrome formerly called "*alcoholic encephalopathy*," characterized by clouding of consciousness, cog-wheel rigidity and uncontrollable grasping and sucking reflex (K. M. Bowman *et al.*, 1940).

Dosage.—The optimal intake of nicotinic acid is not established with certainty, but is probably 15 to 20 mg. per day for adults. The therapeutic dose is up to 500 mg. per day, in ten doses of 50 mg. each, by mouth, or 50 to 80 mg. per day by vein. Oral administration is preferred. Smaller amounts may suffice, or it may be necessary to increase them (Spies *et al.*, 1938). The administration is continued for ten to fifteen days, until the condition is cured. Recurrence is prevented by 100 mg. per week (Elvehjem *et al.*, 1937).

Yeast is effective, but large doses are needed, 60 to 270 Gm. of dried yeast daily (Spies *et al.*, 1937). For *dietary prophylaxis*, milk, lean meat, liver, fish and legumes are considered especially effective (Sebrell, 1937). For *canine blacktongue*, 0.1 mg. of nicotinic acid per Kg. of body weight for ten days is ineffective, 0.2 mg. is slowly effective, 0.5 mg. rapidly, 10 mg. no more rapidly. Coramine requires larger doses, 5 to 10 mg. per Kg., but the results are more lasting (D. S. Smith *et al.*, 1938).

Nitritoid side actions, similar to the effects of histamine, may occur in man with 30 mg. of nicotinic acid and are constant with 100 mg. or higher, orally, or 10 mg. by vein. They are unpleasant but brief and harmless, and do not preclude further administration. Even at their peak, the blood pressure, temperature and respiration are not significantly altered (Spies, Cooper and Blankenhorn, 1938). Susceptibility varies considerably, probably by differences in absorption, for the effects always occur on intravenous injection of 10 mg. (Sebrell and Butler, 1938). They do not occur with nicotinic amide (Bean and Spies, 1940).

The symptoms consist of marked but transient flushing, itching, burning and tingling of the face and upper trunk. The blood pressure, pulse, respiration and temperature are not materially changed. The blood flow is generally increased in the arm, but little in the leg (D. I. Abramson *et al.*, 1940). The cutaneous vasodilatation is produced by nicotinic acid and other compounds containing the free pyridine radical, but not by their amides (Bean and Spies, 1940). Gastro-intestinal motility may be increased. Daily doses of 1 Gm. have been administered without further deleterious effect (Spies *et al.*, 1938; Sebrell and Butler, 1938). The peripheral vasodilatation can not be used for treating peripheral vascular disease, since it is too brief and uncomfortable, and it involves arterial constriction (Popkin, 1939). It often relieves severe idiopathic *headache*, migraine and the headache that follows spinal tapping. The effect appears proportional to the flushing; 100 mg. usually suffice, and produce no untoward effects except uncomfortable heat and brief throbbing (Goldzieher and Popkin, 1946). It has no effect on the course of *experimental hypertension* (H. Goldblatt, Kahn and Lewis, 1942), but is reported to relieve *rheumatoid arthritis*. The flush lasts about an hour after intravenous injection of 200 to 400 cc. of 0.05 per cent in saline. It may be administered orally, three doses of 50 mg. fifteen minutes apart, repeated three times daily, increased to 0.1 or 0.2 Gm. if necessary. No harm followed 5.4 Gm. per day (C. M. Kurtz *et al.*, 1945). There are also reports of marked and lasting relief of *angina pectoris* (F. J. Neuwohl, 1942) and of trigeminal neuralgia (W. E. Adams and Robinson, 1941: 50 to 75 mg. by mouth, two to four times daily). Nicotinic acid increases the acidity and volume of *gastric secretion*, but more slowly than histamine. It was not beneficial to achylia patients (Malaguzzi-Valeri and Paterno, 1939). *Nicotinic acid amide* (but not nicotinic acid) depresses the tonus of the uterus and intestines of guinea pigs, and of the stomach of frogs (L. Liaci, 1940).

The toxicity for animals is low. For rats and mice, hypodermic or oral administration of doses corresponding to 5 or 7.5 Gm. per Kg. are required to kill half of the animals. Dogs may be given 2 Gm. per Kg. orally per day without toxic symptoms. The growth of rats is not retarded by oral administration of 1 Gm. per Kg. daily for forty days, or 200 mg. per Kg. intraperitoneally for twenty-four days. *Intravenous* injection up to 1 Gm. per Kg. had no effect on the blood pressure or electrocardiogram in dogs (K. Unna, 1939; McCrea, 1938).

Addition of 1 per cent of nicotinic acid to a 10 per cent casein diet inhibits the *growth* of rats almost completely, probably because the trigonelline synthesis preempts methyl groups; this may be prevented by adding methionine, not by choline or betaine. The same amount of nicotinic acid has no effect on growth, but produces *fatty liver;* this is prevented by choline, and betaine, as well as by methionine (Handler and Dann, 1942). A *microbiologic assay* for nicotinic acid and nicotinamide, on cultures of Lactobacillus arabinosus, is described in the U.S.P.

PREPARATIONS.—***Nicotinic Acid, U.S.P.,** *Niacin*, occurs as white crystalline powder, sol. in 60 parts of water, freely soluble in alkaline carbonates. Average dose, 25 mg. *Nicotinic Acid Tablets*, U.S.P., usual sizes 25, 50 and 100 mg. *Ampuls* for intravenous injection are usually 1, 2 and 10 mg. per cubic centimeter.

Nicotinamide, U.S.P.; Nicotinic acid amide, niacinamide. White crystalline powder, bitter, odorless. Freely soluble in water (1:1); neutral to litmus. Average dose, oral, 25 mg.; parenteral, 100 mg.—*Tablets of Nicotinamide*, U.S.P., usual sizes 25 and 50 mg.—*Nicotinamide Injection*, in water for injection, usual sizes 100 mg. in 1 cc. and in 2 cc.

RIBOFLAVIN

This substance, also known as lactoflavin, Vitamin G or B_2, occurs widely distributed in living cells, and forms part of an important oxidation-reduction system. It is necessary for the growth of chicks and rats, and its deficiency in rats causes cataract. In man, deficiency phenomena consist in rather minor but specific inflammation and keratosis of the tongue, lips (cheilosis), face and sclera, and vascularization of the cornea. They are usually associated with other B complex deficiencies (review, E. M. Nelson, 1937; W. H. Sebrell, 1937; H. C. Sherman and Lanford, 1937).

Historical.—When the "B_1" of the B complex was destroyed by heating in an autoclave, the residue was found to retain the property of preventing the stunting of rats by certain limited diets, such as oats (Emmet and Luros, 1919; M. I. Smith and Hendrick, 1926). This second growth-promoting factor, which was designated as B_2 or *G*, was then identified with the flavins, a group of nitrogenous water-soluble yellow pigments, or "lyochromes," which occur also in animal fluids and organs, especially in the whey of milk, in eggs and in liver. Several have been isolated pure, as crystals, and these differ rather widely in growth-promoting activity (L. E. Booher, 1933; R. Kuhn, 1933; H. von Euler, Karrer, Adler and Helmberg, 1934; P. György, Kuhn and Wagner-Jauregg, 1934). P. György, 1935, and v. Euler *et al.*, 1935, showed that the synthetic and natural substances are biologically identical. The terms "B_2" and "G" have been applied successively to so many fractions of the complex that their use is confusing.

Chemical and Occurrence.—Riboflavin, dimethyl-ribityl-alloxazin, is a three ring compound with four nitrogens in the rings. It has been synthesized. It is rather heat-stable, especially in acid solution, but is very labile when exposed to light. It is polymeric, one form melting at 281.2°, the other at 293.6° C. (J. A. Means *et al.*, 1943). It is the yellow-green fluorescent pigment of whey, and was known as lactoflavin, ovoflavin and hepatoflavin, according to its source, but these are identical. It is obtainable from many other sources, animal and vegetable. It is formed primarily in green leaves and is most abundant there. The chief dietary sources are milk, cheese, ice cream, meat and fish (reviews, L. E. Booher, 1938; A. G. Hogan, 1938).

Riboflavin is a constituent of the enzyme xanthine oxidase (E. G. Ball, 1939). It occurs as riboflavin (alloxazine nucleotide), the prosthetic group of *flavoprotein*, the "*yellow oxidation enzyme*" of Warburg and Christian, which is present presumably in all living cells, as an essential part of many dehydrogenation systems. It has been suggested that, together with cytochrome, it is concerned in some phase of muscular contraction. A *microbiologic assay* for riboflavin, using Lactobacillus casei, is described in the U.S.P. The activity is confined to a limited range of structural derivatives.

Fate.—Riboflavin is absorbed from the digestive tract (P. György, 1936). It is *stored* in the organs, but the content is not materially increased by raising the income to ten times the normal (R. Kuhn *et al.*, 1935). On the other hand, the store is retained very tenaciously, and is at one-third to one-half of the normal even in rats that die of riboflavin starvation (Vivarico, 1935). When the income is adequate, the excess is excreted in the urine.

A partial supply of riboflavin is furnished by its *synthesis through bacterial action* in the gastro-intestinal tract. This is considerable in ruminants and rats: but man also may continue for months to excrete five to six times the amount of a low riboflavin income (Najjar *et al.*, 1944).

The deficiency syndrome in man is not completely differentiated. The most characteristic feature is cracking and erosion at the corner of the mouth (cheilosis) and roughing of the skin, especially over the nose, which occur in over half of the subjects exposed to the deficiency, and are cured in four to six days by the oral administration of 5 mg. of riboflavin daily (Sebrell and Butler, 1938; Spies *et al.*, 1939; Sydenstricker *et al.*, 1939). The skin changes are like those of pellagra, but riboflavin is not effective against nicotinic deficiency, nor against other nutritional dermatoses of rats and chicks (Sebrell *et al.*, 1937; E. M. Nelson, 1937). The two deficiencies are often concurrent, however, and riboflavin is sometimes a useful adjunct to nicotinic acid (Spies *et al.*, 1939). Its addition to vitamin A is also helpful in resistant cases of night blindness (M. S. Kimble and Gordon, 1939). *Superficial vascularization of the sclera (keratitis rosacea) and of the cornea* is also characteristic of riboflavin deficiency, in man and in animals, and is promptly benefited by riboflavin (Sydenstricker *et al.*, 1940; C. A. Conners *et al.*, 1943). The vascularization of the cornea is presumably a response to interference with its cell respiration (Wolbach and Bessey). *In adult dogs*, riboflavin deficiency causes decrease of appetite and activity, loss of weight, and, after some fifteen to twenty weeks, sudden collapse with bradycardia and arrhythmia, marked fall of temperature, slowed respiration, coma and death. Autopsy shows degenerative changes in the central nervous system and yellow mottling of the liver. Injection of riboflavin causes recovery in three to twenty-four hours, even in advanced cases (Sebrell and Onstott, 1938; Street and Cowgill, 1939; Potter *et al.*, 1942). Intravenous injection of 1 mg. per Kg. prevents anoxic depression of the linguo-maxillary reflex. It also inhibits anoxic depression of the smooth esophageal muscle of frogs (H. F. Hailman, 1944). It promotes hemoglobin regeneration after hemorrhage (György, Robscheidt-Robbins and Whipple, 1938).

Deficiency in rats slowly stunts the growth and lowers the general tone and resistance, with nonspecific dermatosis and loss of hair (von Drigalski, 1935). Diminished skin sensitivity disposes to pediculosis (P. György, 1938). The resistance to endemic murine typhoid is lowered (H. Pinkerton and Bessey, 1939). Keratitis and vascularization of the cornea are frequent. The latter is followed by infiltration with leukocytes, striking changes in the collagen, degeneration of the epithelium and ulceration. Riboflavin administration secures prompt improvement and repair (Bessey and Wolbach, 1939; R. E. Eckardt and Johnson, 1939). *Nutritional cataract* develops in about a tenth of the rats subjected to riboflavin deficiency, starting after about fifty days, as opacity of the fetal nucleus. Once started, it proceeds and involves the other eye, even though riboflavin is administered (P. L. Day *et al.*, 1931, 1938; P. György, 1935; R. E. Eckardt and Johnson, 1939). The normal lens contains two groups of fluorescent substances, flavin and dimethyl alloxazin. In cataract lens the flavin is absent and replaced by a photolytic product, lumiflavin (F. P. Fischer, 1935).

Rats may show partial paralysis of the legs, with degeneration of the myeline sheath and swelling of the axis cylinder in the sciatic and brachial plexus and spinal cord; marked atrophy of the testes and thymus, and structural changes of the thyroid and adrenals in severe cases (Shaw and Phillips, 1941). Riboflavin, like ascorbic acid, antagonizes the rise of temperature by dinitrophenol, thyroxin and external heat, but not that of tetrahydronaphthylamine or protein (H. T. A. Haas, 1939). In growing mice, riboflavin deficiency decreases the *rate of growth* and of ossification, and intensifies the degeneration of the cartilage (B. M. Levy and Silberberg, 1946). In *baby chicks* it produces a characteristic leg disorder and subnormal growth (Bethke *et al.*, 1937).

The *optimal daily intake* of riboflavin is probably about 1 mg. for children, 3 mg. for adults, somewhat higher during pregnancy and lactation. The *therapeutic dose* is 2 to 10 mg. per day, by mouth or, if necessary, by vein. No side effects occur from relatively large doses.

Mice are not injured by a thousand times their normal income (R. Kuhn and Boulanger, 1936). No toxic manifestations occur from long continued daily administration of 10 mg. to rats or 25 mg. to dogs (Unna and Greslin, 1942). On the other hand, restriction of the dietary income of six normal men to 0.31 mg. per 1000 calories for five months caused no deficiency symptoms (Keys *et al.*, 1944).

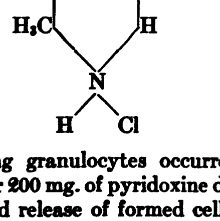
Preparations.—*Riboflavin*, U.S.P. (lactoflavin, vitamin B_2, vitamin G), occurs as clusters of fine orange-yellow needles. It is slightly soluble in water (1:10,000), very sol. in dilute alkalis, sol. in alc., insol. in ordinary lipoid solvents. It is stable toward heat, oxidizing agents and strong mineral acids, but sensitive to alkali. The watery solution has an intense yellow-green fluorescence, which is abolished by acids or alkalis. It deteriorates rapidly if it is exposed to light. Dose, 2 to 10 mg. per day. *Riboflavin Tablets*, U.S.P., 1 and 5 mg. *Riboflavin Injection*, U.S.P., in water for injection, dissolved with nicotinamide, urea or other harmless agents declared on the label. Usual sizes are 0.25 mg. in 1 cc., 1 mg. in 2 cc., 5 mg. in 2 cc.

MINOR COMPONENTS OF THE VITAMIN B COMPLEX

In addition to thiamine, nicotinic acid and riboflavin, which are needed by all organisms, the "complex" of yeast contains other dietary factors essential for some species, but less definitely for man. A *glossary* of the confusing synonyms is given by E. M. Nelson, 1937.

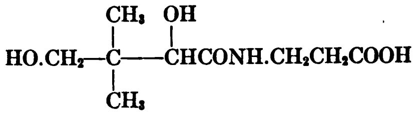
Pyridoxine, *vitamin "B_6" or "H,"* was recognized by P. György, 1934, and synthesized by S. A. Harris and Folkers in 1939; the identity of the synthetic was confirmed biologically by E. J. Reedman *et al.*, 1940. György found that its *deficiency* causes a florid dermatosis in young rats, which can be cured by 0.05 mg. of synthetic pyridoxine hydrochloride per day (Reedman *et al.*, 1940). Presumably other structures are also affected (Wolbach and Bessey, 1942). If the deficiency is prolonged over four months, the rats develop epileptoid attacks (H. Chick, Sadr and Worden, 1940). Chicks do not develop dermatitis, but respond by slow growth, convulsions and other nervous manifestations (Lepkovsky and Kratzer, 1942). Young ducklings show growth failure and severe microcytic anemia; older ducks develop paralyses and convulsions (Hegsted and Rao, 1945). Its toxicity is low; 3 Gm. per Kg. are required hypodermically to produce convulsions and death (K. Unna, 1940; Antopol and Tarlow, 1942).

Deficiency symptoms have not been conclusively demonstrated *in man*, but T. D. Spies, Ladisch and Bean, 1940, report that intravenous injections of 50 mg. of pyridoxine promptly cure residual pellagra symptoms which resist thiamine and riboflavin in some patients. Spies, 1940, believed that its deficiency produces rather ill defined clinical symptoms. He describes marked improvement in postencephalitic Parkinsonian syndrome, with striking relief of the tremor and rigidity in a few minutes after intravenous injection of pyridoxine hydrochloride. Jolliffe *et al.*, 1942, report benefit in persistent adolescent acne; R. S. Willis *et al.*, 1942, in hyperemesis gravidarum. Daily doses of 5 to 250 mg. have been used, usually 5 to 10 mg. of *pyridoxine hydrochloride*. Rapid and significant rise of circulating granulocytes occurred in thiouracil *granulopenia* after 200 mg. of pyridoxine daily; the prompt response indicated release of formed cells (Fishberg and Vorzimmer, 1945). *Roentgen sickness* is reported to be improved by oral administration of pyridoxine hydrochloride (R. J. Reeves, 1946).



Pyridoxal phosphate functions as co-enzyme of amino acid decarboxylase, and of glutamate-aspartate transaminase (H. C. Lichstein *et al.*, 1945).

Pantothenic acid is a growth-stimulating factor which occurs in liver and probably other tissues, in yeast and molds and probably other plants. It is a derivative of beta alanine and has been synthetized by R. J. Williams *et al.*, 1940, and E. T. Stiller *et al.*, 1940.



$$HO.CH_2{-}\underset{CH_3}{\overset{CH_3}{C}}{-}\overset{OH}{C}HCONH.CH_2CH_2COOH$$

Its value in human nutrition has not been clearly demonstrated. Deficiency symptoms in animals include dermatitis, keratitis, adrenal hemorrhage and atrophy, a characteristic depigmentation of hair, and arrest of growth (Woolley *et al.*, 1938; R. J. Williams, 1943; P. György and Poling, 1940; K. Una and Sampson, 1940; L. M. Henderson *et al.*, 1942). Its deficiency inhibits endochondrial ossification in growing mice (B. M. Levy and Silberberg, 1946). The most significant lesion is fatal hemorrhagic necrosis of the adrenal cortex (Wolbach and Bessey, 1942). The intestinal absorption of galactose is decreased by pantothenic deficiency (J. R. Leonards and Free, 1943).

Young *dogs* require about 0.1 mg. of pantothenic acid per Kg. per day. Weaning puppies, after four to six weeks of pantothenic deficient diet, suddenly develop a fatal complex with gastro-intestinal symptoms, prostration, coma and convulsions. Necropsy reveals fatty liver, mottled thymus, hemorrhagic renal degeneration, frequently gastritis, enteritis and intussusception. Intravenous calcium pantothenate and dextrose cures the condition (A. E. Schaefer *et al.*, 1942).

Achromotrichia, graying of the hair, may be produced in rats by deficiency of *paraminobenzoic acid* (Ansbacher). Others have failed to obtain this effect (Unna *et al.*, 1941; L. M. Henderson *et al.*, 1942). Paraminobenzoic acid is not effective against the pantothenic graying, or vice versa. Graying of rat hair resulting from exclusive milk diet is cured by adding Fe, Cu, and Mn to the food (A. H. Free, 1940). Continued ingestion of *phenylthiocarbamide* by black or hooded rats produces graying in four to seven weeks; black hair returns in about ten weeks after discontinuing (C. P. Richter and Clisby, 1942). The natural graying of human hair is not checked by administering pantothenic acid (R. R. Williams, 1940; Kerlan and Herwick, 1943). Brandaleone *et al.*, 1943, report some degree of restoration in exceptional cases under combined treatment with calcium pantothenate, paraminoacetic acid and brewers' yeast.

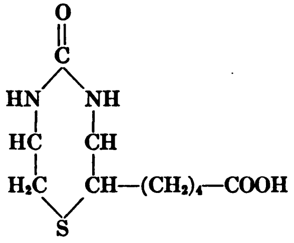
The *toxicity* of pantothenic acid is low; 0.8 to 10 Gm. per Kg. are required to cause death (by respiratory failure). Prolonged feeding with subtoxic doses does not cause any symptoms (K. Unna and Greslin, 1941).

Fate.—In rabbits the blood normally contains 0.05 to 0.07 mg. per 100 cc. It may rise to 9.3 mg. after hypodermic injection of 500 mg. From 50 to 75 per cent of the administered dosage is excreted by the urine within two hours. In man, the blood level is lower, 0.018 to 0.025 mg. per 100 cc., and less is recoverable from the urine (P. B. Pearson, 1941).

For *therapy* in man, Spies *et al.*, 1940, administered 100 mg. of calcium or sodium pantothenate intravenously.

"Folic Acid" (see Index), a "norite eluate of solubilized liver," classed as a B vitamin, plays a role in the production of blood cells.

Biotin, identical with vitamin H and "coenzyme R," has been isolated as a definite compound with its chemical structure (du Vigneaud, 1942) confirmed by synthesis (S. A. Harris *et al.*, 1943; review, K. Hofmann, 1943). It occurs in almost all cells, liver and yeast being especially rich. It is one of the factors in the "bios" of Wildiers (review, R. Hertz, 1946). It is highly potent, promoting the growth of a yeast strain in dilutions of $1:10^{11}$ (Kögl and Tönnis, 1936). It is also essential for the growth of certain bacteria and for strains of the legume-nodule organism Rizobium. Its toxicity is low; the fatal dose for mammals ranges from 0.8 to 10 Gm. per Kg. Death occurs by failure of respiration. Prolonged feeding with subtoxic doses produces no symptoms. It has no effect on the course of experimental hypertension (Kahn and Lewis, 1942).



"*Procarcinogenic*" *Effect.*—Tumor tissue is relatively rich in biotin. Administration of biotin to rats ingesting the dye "butter yellow," dimethyl amino azo benzene, increases the incidence of hepatic carcinoma, while riboflavin and casein confer marked protection (du Vigneaud *et al.*, 1942). Biotin does not increase the growth of transplanted sarcomas in mice.

Biotin is apparently not essential in human nutrition, but information is not adequate.

"Avidin," a specific basic protein constituent of raw egg white, binds biotin stoichiometrically to a nondialyzable compound so that it cannot be absorbed from the intestinal tract, or by yeast. This creates biotin deficiency, manifested in mammals, including man, and birds as "*egg white injury,*" nutritional disorders and especially eczematous dermatitis, curable by administering biotin (Eakin *et al.*, 1940, 1941). Avidin is destroyed by cooking and egg white injury is therefore not likely to occur spontaneously in man; but it may be induced by ingesting 200 Gm. of dehydrated egg white daily for several weeks. The symptoms are similar to those of thiamine deficiency, but are cured by parenteral administration of biotin (Sydenstricker *et al.*, 1942).

"Lysozyme," closely related to, if not identical with, biotin, produces lysis of susceptible bacteria by depolymerizing and hydrolyzing a mucoid of their membrane (K. Meyer, 1944).

Culture-Activating Substance "Bios."—The multiplication of yeasts, infusoria, bacteria and other organisms is more rapid in media on which the organisms have already been grown (within certain limits) than it is in fresh culture media. Wildiers, 1901, and F. B. Robertson ("Chemical Basis of Growth and Senescence," 1923) attributed this to the formation of an autocatalytic agent, "bios." The relation of this factor to the other yeast vitamins has not been worked out. It does not appear to be identified with the B complex (review, F. W. Tanner).

Auxin, a plant hormone (see Index) which stimulates the growth of the stem, the rooting of cuttings and the formation of the fruit from the ovary in higher plants, was isolated by Kögl and Haagen-Smit, 1931. It is part of a respiratory system, effective only when succinic or malic acid is present (Commoner and Thimann, 1941). The same action is possessed by a series of entirely different aromatic acids, indoleacetic, ciscinnamic, nephaleneacetic, phenylacetic, etc., their molar activity being nearly equal (review, F. W. Went, 1943; see Index).

YEAST

The ordinary bakers' and brewers' yeast, "*faex medicinalis,*" consists of the cells of *Saccharomyces cerevisiae,* filtered from their cultures, generally in extracts of malted grain; they are often mixed with starch to the proper consistency. The living cells have long been used as a bactericidal dressing for ulcers and boils, but are not effective (Schugt, 1921). The discovery of vitamin B in yeast (McCollum *et al.*, 1916) aroused fresh interest. The administration of living, dried and autolyzed yeast or extracts increases the thiamine and riboflavin content of the diet; but the thiamine of raw yeast is only 17 per cent utilized (M. Hochberg *et al.*, 1945); its availability is strikingly increased by boiling (H. T. Parsons *et al.*, 1945). Rather large doses of yeast are effective against human beriberi (although less active than rice-hull extract, Saleeby, 1919) and the polyneuritis and malnutrition of polished-rice disease, and in pellagra. Yeast has been widely advertised with exaggerated claims as a cure for digestive derangements, constipation, boils and as a general "tonic." Critical experiments are generally disappointing, and its use may cause considerable digestive disturbance.

Living and perhaps also dead yeast cells are *laxative* (F. A. Brown *et al.*, 1934), but it is questionable whether they should be preferred to the medicinal laxatives that are better understood. The administration of yeast is sometimes followed by the relief of *acne,* furunculosis, herpes, etc.; but the results are so inconstant that it is not possible to judge how far they are due to coincidence or to other factors, such as the catharsis, the high content of nucleic acid, etc. (Tsuru, 1909; Abraham, 1910). The dosage is from 1 to 20 Gm. of the "compressed yeast" per day. Yeast extracts resemble "meat extracts" in taste and may be used to flavor soups and bouillons. Yeast has been proposed as a *nitrogenous food;* but its protein value is not high, a large part escaping by the feces. Its high purine content tends to raise the uric acid of the blood (Funk, Lyle and McCaskey, 1916). Caution should be observed in administering yeast continuously; for Osborne and Mendel, 1919, frequently observed degeneration of the testicles, with consequent sterility, in rats on a yeast-containing diet.

Yeast and Vitamins on Carcinogenic Substances.—In rats exposed to dimethyl amino azobenzene, the incidence of liver cancer is decreased by supplementing the diet with yeast (Kinosita, 1937) or with riboflavin plus casein (Kensler *et al.*, 1941). Yeast feeding also protects against other carcinogenic substances (Maisin and Pourbaix, 1938). Intravenous injection of yeast plus pantothenic acid inhibits spontaneous mammary cancer in mice more effectively than either agent alone. The addition of other vitamins had no effect (Lewisohn *et al.*, 1941).

PREPARATIONS.—*Dried Yeast*, U.S.P., Saccharomyces Siccum, consists of the dry cells of S. cerevisiae, a by-product of the brewing of beer, "brewers' yeast"; or from culture media, "primary dried yeast." Each Gram must contain not less than 0.12 mg. of thiamine hydrochloride, 0.04 mg. of riboflavin, and 0.25 mg. of nicotinic acid. *Dried Yeast Tablets*, U.S.P., are usually available as 0.5 Gm.

NUCLEOTIDES

Injection of nucleic acid salts (derived from the nucleoproteins of nuclear material, usually prepared from yeast) produces temporary leukopenia, followed by marked leukocytosis, involving chiefly the polymorphous neutrophils. The leukocytosis is chiefly of peripheral origin; but there is also hyperplasia of the bone marrow. This may be maintained by repeated injections, at least for a time, without becoming either exhausted or excessive (literature in Doan, Zerfas *et al.*, 1928). The leukocytosis has been used to combat malignant neutropenia (Jackson, Parker and Taylor, 1932), with somewhat doubtful success.

Das Gupta considers that it has not been proved that pentnucleotide or liver extract accelerate the formation of white cells, and believes that the reported transient pentnucleotide leukocytosis is due mainly to redistribution of the leukocytes. He believes that colchicine is the only drug that stimulates the proliferation of cells in the bone marrow, and that its toxic effects outweigh this stimulation. Good clinical response, however, has been reported in neutropenia following benzene, and gold thiocyanate, poisoning (Rheinheimer and Smith, 1933), but not many cases are on record. In rats poisoned with benzene it quickened the restoration of either the red or white corpuscles (C. Reich and Reich, 1934). The clinical improvement of the blood picture may begin in twenty-four hours, but generally does not become marked till the third to sixth day of administration, regardless of the previous duration of the illness. It then progresses till the normal is reached, perhaps about the tenth day. The fever which accompanies malignant neutropenia falls within a day after a marked increase of neutrophils has become established. Severe cases respond as well as the mild, or better. The delay in the response may account for some of the failures. Sometimes the increase of neutrophils leads to suppurations, such as pyelitis, presumably by making possible a leukocytic response to a preexisting irritation (Jackson, Parker and Taylor, 1932). It has been suggested to increase the neutrophils above the normal to combat other infections (Chantemesse, 1907, tried this for tuberculosis), but the value has not been demonstrated. Rather crude extracts and digests of yeast were employed originally. Recently more refined preparations, especially *pentose nucleotides*, have come into use, with the advantage that the effects may be better controlled. Guanine nucleotides, adenine, and pure adenyl guanidic acids also produce considerable neutrophilia, but the preceding neutropenia requires a larger nucleic molecule (Doan, 1932).

Administration.—Pentnucleotide, N.N.R., is an 8 per cent solution (approximately) of the sodium salts of the pentose nucleotides (chiefly four) from the ribonucleic acid of yeast (*p*H 7.2). This is injected into the gluteal muscles, 10 cc. twice daily, till the white count has risen definitely, then once daily till the count has remained normal for three days. In desperately ill patients, these doses may be doubled. The upward trend of the white blood cells is usually recognizable about five days after starting the administration. Nucleins are not anaphylactic antigens (De Waele and van de Velde, 1932), but intradermal injection of nucleic acid, 0.008 mg., or its clearage products provokes a positive skin reaction in patients allergic to ragweed pollen, while normal individuals do not react to this dosage (Winkelwerder *et al.*, 1939). Intravenous injection of nuclein is not advised, since it causes considerable acute reaction (dyspnea, precordial distress, bradycardia and sweating). With intramuscular administration these reactions are absent or mild. *Adenine sulfate* has been used in neutropenia, with about equal success. It is administered by vein (0.5 to 1 Gm. per day) and therefore acts more promptly; perhaps with less colloidoclastic reaction than intravenous pentnucleotide.

Fate.—Nucleic acid passes the stomach unchanged. It is partly split in the intestines, with the liberation of phosphoric acid, but not of purines. A further part is presumably split during absorption (bibliography, Forbes and Keith, 1914). The *nucleins* are excreted as purine bases and uric acid; so that they are contraindicated in gouty and rheumatic conditions, etc. The phosphate elimination is also increased.

TOCOPHEROL (ANTISTERILITY VITAMIN E)

This substance is essential for the fertility of rats and mice in both males and females (Evans and Bishop, 1923), but apparently not for the larger domesticated animals (B. H. Thomas *et al.*, 1938) and probably not for man. J. C. Drummond, 1939, pointed out that the diet of the poorer people in England is notably deficient in this vitamin, but that they are prolific. Wheat germ oil, 0.25 to 6 cc. per day, has been reported effective against *habitual abortion*, menstrual disorders, failure of lactation, and vaginal pruritus, but the results lack convincing clinical evidence, and unfavorable effects, gastro-intestinal irritation and skin rashes sometimes follow the larger doses. They are rarely serious (review, S. W. Clausen, 1940). Tocopherol has also been employed in muscular *dystrophies and spinal cord lesions*, with doubtful results.

Chemistry.—The protective substance occurs in the oil of wheat germ and other seeds, fresh vegetables (lettuce), fruits and many other foods. It was isolated by H. M. Evans *et al.*, 1936. It was identified as an alcohol, $C_{29}H_{50}O_2$, and named tocopherol. It exists as three modifications, which occur together. The alpha form was synthesized by Karrer, 1938. One of its decomposition products, durohydroquinone and its ethers, produces the same effects (Evans *et al.*, 1938). The tocopherols are potent *antioxidants*, preventing rancidity of fats (Olcott and Mattill, 1941). Tocopherol appears to be stored tenaciously; a single large dose allows fertility for two gestations but not for three (Olcott and Mattill, 1934). Spectroscopic studies of rats fed with tocopherol show its presence in the leg muscles, with high doses also in the adipose tissue, but not in the liver (Culbertson, Ridgeway and Drummond, 1940). Continued oral administration in myopathies raises its concentration in the serum from about 0.65 mg. to 2 mg per cent (Wechsler *et al.*, 1943).

Tocopherol deficiency effects differ materially in various animals. The principle phenomena are failure of early embryonic development in rat and mouse; irreparable degeneration of germinal epithelium in male rat (Mattill and Stone, 1923); degeneration of skeletal muscle in most species; nutritional encephalopathies in chicks. Rats also show retarded growth, straddling gait, coarse hair (reviews, Wolbach and Bessey, 1942; A. M. Pappenheimer, 1943), and progressive loss of pigment from the incisors (Granados and Dam, 1945).

The death of the developing embryo in rats and mice is due to limited development of the placenta. The fetus dies with widespread hemorrhages when about two-thirds of the gestation is reached. Some discoloration and degeneration of the uterine muscles have been reported, and uterine fibrosis and fibromyomata may result if the deficiency is protracted (Barrie, 1938; Martin and Moore). *Eggs* laid by hens on an E-deficient diet also do not develop living embryos, but die about the tenth day (Mattill, review, 1938). They show excessive cell proliferation in the mesoderm, obstructing the blood vessels of the blastoderm (Adamstone, 1931).

Muscular dystrophy and spinal cord lesions, resembling amyotropic lateral sclerosis and tabes dorsalis, result in rats with vitamin E deficiency, and are cured by alpha tocopherol (M. Goettsch and Pappenheimer, 1931; G. C. Knowlton *et al.*, 1939). They occur also in other mammals. Tocopherol apparently plays an essential role in the metabolism of skeletal muscle. Deficiency produces extensive necrosis (H. S. Olcott, 1938), resembling the hyaline degeneration of infectious diseases. Cod liver oil increases the degeneration (C. G. Mackenzie *et al.*, 1941). Widespread degenerative changes in the central nervous system have been described (M. Lipschutz, 1936; Einarsen and Ringsted, 1938), but the evidence is not satisfactory. Smooth muscle is not affected (review, A. M. Pappenheimer, 1943). Administration of tocopherol and of wheat oil has been *tried clinically in neuromuscular disorders*, but the results are disappointing (A. J. Lubin, 1942). The "*encephalomalacia*" *of chicks*, resulting from E-deficient diet, involves cerebral ischemia associated with impairment of the blood vessels (A. J P. Martin and Moore, 1938).

Alpha tocopherol acetate quickly cures *capillary fragility* and purpura induced in dogs by stilbestrol. Human thrombocytopenic purpura is also benefited by 200 to 400 mg. daily, after one or two weeks, but its administration must be continued indefinitely (F. Skinner, Shute *et al.*, 1946).

Large doses of tocopherol orally are not toxic to animals (Demole, 1939); nor does long-continued administration produce *sarcoma* in rats (Dingemanse and van Eck, 1939; H. M. Evans and Emerson, 1939), as has been claimed.

Vitamin F.—This term was applied by Evans to unsaturated fatty acids of lard and butter, which appeared necessary for the continuance of gestation and for the prevention of sterility in males. The designation was then transferred to linoleic acid, in respect to its effects on the skin. It has been dropped.

Vitamin K is discussed in connection with blood coagulation (see Index).

CHAULMOOGRA OIL

This fat, which is expressed from the seeds of East Indian trees of the genus Taraktogenos and Hydnocarpus, consists of the glyceryl esters of a unique series of cyclic fatty acids. These possess a specific toxicity for acid-fast bacteria. It has been reported that the administration of these acids and their esters appears to stay the progress of clinical leprosy, producing recession of the nodular, macular and anesthetic lesions, and the degeneration and disappearance of the bacilli, so that a considerable proportion of the cases can be paroled as apparently cured. The disease tends to recur, however, and it is itself subject to temporary intermissions from a variety of causes, so that the effectiveness of the treatment is difficult to appraise and critical observers doubt whether the course is better than with patients who do not receive the drug (review, G. W. McCoy, 1942). The amenability decreases with the duration of the disease. The oil has been used in India against leprosy since antiquity; but the nauseating taste and the gastro-intestinal irritation render intensive medication by mouth difficult. Weekly intramuscular injection of the ethyl-esters of the fatty acids is better tolerated. The treatment must be continued for a considerable time. Chaulmoogra oil has also been suggested for the treatment of tuberculosis, but there is no convincing evidence of its clinical value, and the results of animal experiments were negative. Good results have been reported in lupus. It has been used as an anthelmintic in the Orient since antiquity, but is not employed for this purpose by modern physicians.

Composition.—F. B. Power *et al.*, 1904 to 1907, confirmed by A. L. Dean and Wrenshall, 1920, showed that true chaulmoogra oil consists principally (90 per cent) of the glycerides of a series of unsaturated fatty acids which are unique in that they contain a closed 5-carbon ring, are optically active, and have not been found in any other oils. The most abundant of these acids are *chaulmoogric acid*, and *hydnocarpic acid*, which contains 10 CH_2 in the side chain, instead of 12. The structural formula was established by Shriner and Adams, 1925, confirmed by synthesis, and various homologues prepared. Their actions on the leprosy bacillus are qualitatively similar, but the hydnocarpic is somewhat more active. There are also small quantities of other homologues. Roger Adams and his associates synthesized other cyclic fatty acids and found these more or less effective against the leprosy bacillus. C. D. Leake, Anderson and Emerson, 1934, tested a number of the esters on rat leprosy (the identity of which with clinical leprosy is not established), and compared this with the toxicity and local irritation, and the lethal action *in vitro*. The most effective contain the cyclopentyl group, are optically active and possess the highest degree of unsaturation. Ethyl chaulmoograte ranked high (Anderson, Emerson and Leake, 1934). The oil contains also small quantities of ordinary fats, which do not participate in the action. The oil of Gynocardia odorata, which has been confused with chaulmoogra oil, does not contain the cyclic fats, and is inactive (Schoebl, 1924).

Historical.—The first attempts to obviate the oral administration utilized the hypodermic or intramuscular injection of the oil, generally thinned by the addition of olive oil (for instance, V. G. Heiser, 1913). This produced severe local irritation. Leonard Rogers, 1916, used the sodium salt (soap) subcutaneously and intravenously; this also gave good response, but often led to obliteration of the vein. The ethyl esters were prepared by Hollmann and Dean, 1919, and applied by McDonald and Dean, 1920, at Honolulu. Although these are less irritant, they often produce febrile reactions and vein sclerosis. Further references can be consulted in Walker and Sweeney, 1920.

Clinical improvement is seen only in part of the patients. It is described as disappearance of the macules; initial swelling of the nodules, then softening, contraction, and complete cicatrization; improvement of sensation; decreased swelling of the nerves; healing of the ulcers; disappearance of the bacilli from the nasal mucus and the blood of the macules; improvement of general health. The response of early cases requires three months of energetic treatment; three to six months with moderately advanced cases. Old cases do not respond. Relapses tend to occur when treatment is stopped, even if it has been continued for years. Similar improvement may occur without chaulmoogra, but only exceptionally, according to those who are convinced of its value; in about the same ratio, according to the skeptical (comprehensive review, H. Schlossberger, 1937).

Renal Damage.—Toxic doses or hypodermic and intravenous injection of sodium hydnocarpate, and also of the ethyl esters, are reported to produce hemolytic anemia, nephritis, albuminuria, hematuria, fatty degeneration of the liver and emaciation in rabbits and dogs (B. E. Read, 1933). Repeated intravenous injections into rabbits resulted in parenchymatous degeneration of the kidneys and liver (C. N. Frazier, 1931)

Focal reactions, intensification and irritation of the local lesions, febrile symptoms, and sometimes anaphylactoid phenomena (F. L. McDaniel, 1924) may occur, and some observers consider them essential for therapeutic results (E. Muir *et al.*, 1923). Latent tuberculosis may be activated. Softening and resolution of the lesions is reported in rat leprosy, but they are not cured.

The *fatal dose* is fairly high, even with intramuscular injections. Intravenous injections kill with smaller doses by hemolysis.

Febrile Reaction.—With the modern intensive administration, about 10 per cent of the patients develop skin eruptions and fever, beginning one to three days after the injection and disappearing in two to three weeks. The reaction is not serious, but may require interruption and slowing of the treatment (McDonald, 1920). It is probably due to the liberation of toxins by the reaction of the bacteria and tissues.

Bactericidal Action in Vitro.—Chaulmoogra oil and the sodium salts of its fatty acids are about a hundred times more potent than is phenol against tubercle bacilli and other acid-fast bacteria, while other bacteria are not susceptible (Hernandez, 1918; Walker and Sweeney, 1920). The potency appears connected with the fatty and waxy nature of the acid-fast envelope, which is presumably altered by these acids. This again is connected with their cyclic structure and not with their unsaturated characters; for the soaps of linoleic acid and the cod liver oil lack the specific toxicity.

Dosage of the "Ethyl Chaulmoograte."—This consists really of the esters of the mixed acids. McDonald uses it in weekly injections into the upper and outer quadrant of the gluteal region, alternating the sides weekly. The first injection is of 1 cc., increased by 1 cc. every second and third injection, until the maximum of 3 to 5 cc. is reached. Resistant lesions may also be injected directly with the ester. The injection produces some pain and irritation, and sometimes necrosis, but much less than the oil (Voegtlin *et al.*, 1921). The irritation is due partly to impurities and decomposition products of the raw oil. Abscess is exceptional. There is generally no digestive disturbance.

Oral Administration of Ethyl Chaulmoograte.—The dose is increased gradually from 1 to 5 cc. per day, after meals, in warm milk or hot tea. It is tolerated much better than the oil, and over longer periods, since its taste and odor are not disagreeable and it does not disturb digestion.

Oral Administration of Chaulmoogra Oil.—The dosage begins with 0.3 cc. three times daily, and is increased to the point of tolerance. Various methods are described by B. E. Read, 1925. The emetic action is reflex and may decrease on continued administration. *Overdosage* may cause dyspnea, laryngeal spasm, renal irritation, weakness, and intensification of the lepra lesions.

Intramuscular administration of chaulmoogra oil is quite painful and seriously irritant, and easily produces necrosis at the site of injection (Voegtlin *et al.*, 1924; Cadbury, 1920). Absorption of the oil and esters is even slower than with ordinary oils, because of the inflammatory reaction (Valenti, 1917). The oil must be thinned by the addition of olive oil, and analgesics are usually added, as in the "Heiser Mixture," equal parts of chaulmoogra and camphor oil, with 3.6 per cent of resorcin. It is injected weekly, increasing from 2 to 10 cc. *Intravenous injection* of the esters is dangerous, as it may result in pulmonary embolism (Walker *et al.*).

Sodium Soap.—The intravenous injection, according to Rogers, 1917, produces temporary giddiness, headache and occasional occlusion of the vein, preventing its further use. According to Voegtlin *et al.*, 1921, this is due to the alkalinity of the soap, and is a serious objection. Rapid injection of the 2 per cent solution also produced embolism.

Tuberculosis.—The similarity of the bacilli suggested to Rogers, 1916, that chaulmoogra oil might be efficient in tuberculosis. The experiments of Voegtlin *et al.*, 1920, failed to reveal any effect on the weight, growth, lesions and mortality rate of a large series of tubercle-infected guinea pigs.

PREPARATIONS.—*Chaulmoogra Oil,* U.S.P., a fixed oil expressed from the ripe seeds of Taraktogenos or Hydnocarpus species. Average dose, 1 cc. *Ethyl Chaulmoograte,* U.S.P., insoluble in water, miscible with alcohol. Average dose, oral or intramuscular, 2 cc.

◆

EMOLLIENTS, DEMULCENTS AND PROTECTIVES

These are chemically indifferent substances that are used to cover and thus to protect surfaces against drying and other irritation. Oils, fats and glycerin, when so applied to the skin, also tend to soften the epidermis and are therefore termed emollients (*emollire,* to soften). When applied to mucous membranes or wounds, protectives are designated as demulcents (*demulcere,* to smooth down), since their main purpose is to soothe irritation. Viscid water-miscible solutions, for instance, of the gums, or glycerol, adhere to these moist surfaces better than does oil. This corresponds to the natural mechanisms for the protection of the body surfaces: While the skin is normally covered with a thin layer of emollient oil, the mucous membranes of the interior of the body are moistened with mucus, which is a gummy demulcent. Fine insoluble and adhesive powders, such as talcum, are also used as demulcents of the skin and mucous membranes. The protectives diminish the local action of chemical, mechanical or bacterial irritants, decreasing pain, reflexes, catarrh, spasm and other manifestations of irritation. They delay and diminish absorption from the stomach, intestine, subcutaneous tissue, etc. This diminishes the systemic effects of absorbable poisons and prolongs their local actions.

Mechanism of Action.—Colloids and fats are practically indifferent and unabsorbable for cells, so that they do not produce direct effects on them; but, through their adhesive character, they form a covering and hinder the access of irritant agents. Oils prevent the penetration of water-soluble substances; gums, that of fats and resins. Gums also diminish the effects of crystalloids by increasing the viscidity of the solution, thereby interfering with its transportation (von Tappeiner, 1902). Adsorption probably also plays a part, for dissolved substances are condensed on the surfaces of fine powders and thus removed from the solution.

Emollient drugs comprise the true fats and oils (glycerides of fatty acids), wool fat, petrolatum and glycerin. They are applied as a protective dressing to the skin, ulcers, burns and other superficial wounds; as vehicles (salves) for the application of medicaments to the skin or, more rarely, for systemic effects (mercurial inunctions). Internally, the true fats serve as nutrients. Larger amounts than can be digested stimulate peristalsis and act as intestinal lubricants and laxatives. For external use, the liquid or soft fats should be chosen when the preparation is to be rubbed into the skin glands, whilst protection and prolonged contact are secured by the harder and more adhesive ointments, wool fat and petrolatum mixtures, cerates and plasters. Petrolatum alone is not very adhesive. All the ointments and glycerol tend to soften the epidermis, by preventing drying. In this they aid the natural oil of the skin and prevent roughness and "cracks" from wind, cold weather, sunburn or skin diseases. On hairy areas or those subject to friction or sweating, greases may lead to folliculitis by blocking the follicles. In such locations it is preferable to apply drugs as lotion or "vanishing creams."

Penetration of the Skin.—Fats and oils are not absorbed by the epidermis, but they may be spread so thin over the surface that they become invisible, and a small quantity may be rubbed into the hair follicles and gland ducts, liquids more rapidly than solid fat (Eller and Wolff, 1939), and can eventually be demonstrated microscopically in the lymph channels. True fats are slowly oxidized and disappear; but the mineral fats remain indefinitely in the subcutaneous tissue and produce chronic irritation and fibrosis. Animal and vegetable fats therefore deserve preference when penetration is desired (Sobieranski, Juckuff, Meyer).

Absorption through the skin occurs almost entirely from the gland ducts and hair follicles. The dead, desiccated and cornified cells which constitute the stratum corneum are not easily penetrated, and are futhermore covered by a greasy layer of lipid, chiefly esters of cholesterol and fats (M. L. Higgins, 1943). The skin is relatively impermeable to electrolytes. It is generally permeable to gases, but carbon monoxide is an important exception. The maximal absorption of oxygen by the skin is only a hundredth of that by the lungs (G. Zuelzer, 1904).

Fats on Penetration.—Fats and oils protect the skin against the penetration of fat-soluble irritants, such as phenol, mustard oil or "mustard gas" (Sollmann, 1918, 1919). On the other hand, oiling of the skin hinders the access of watery solutions to the epithelium (Filehne and Biberfeld); but ointment may increase absorption by retaining the sweat and preventing the normal evaporation of water (S. Rothman, 1921), and so macerate the cornified cells as to increase their permeability. Application of fat solvents, however, generally increases absorption from watery solutions (strychnine, R. Winternitz, 1891; insulin, S. Hermann and Kassowitz, 1935).

Rancidity.—Fats turn "rancid" on keeping, especially if exposed to air, light and heat, or if they contain protein impurities. The change consists in oxidation with the development of free volatile fatty acids. Rancid fats are disagreeable and irritating. Petroleum products are free from this objection, but rancidity may be avoided with other ointments by keeping and dispensing them in air-tight "tin tubes."

Oil-Aspiration (Lipid) Pneumonia.—Oil "drops" instilled into the nose or nasopharynx may be aspirated into the trachea and lungs. This occurs also with laxative mineral oils, especially in infants and debilitated patients. It causes little, if any, immediate disturbance, but if it is often repeated it gives rise to chronic recurrent inflammation of the respiratory tract. This varies greatly in severity according to the kind and amount of the aspirated oil. Animal oils produce more severe lesions than mineral oils. Infants show interstitial proliferative inflammation and quite commonly exudative pneumonia, the "lipid pneumonia" of I. Graef, 1939, and eventually fibrosis. Organized granulomatous lesions are more frequent in adults (review, P. R. Cannon, 1940).

OLIVE OIL AND OTHER BLAND FATTY OILS (OLEA PINGUA)

The expressed oils of olive, cottonseed, almond, sesame, etc., are essentially similar. Olive oil is preferred for internal use because of its more agreeable flavor. These oils are employed externally to soften the skin and crusts in eczema and psoriasis; as dressing for burns; as vehicles for liniments, etc.; and by rectal injection, to soften fecal concretions (150 to 500 cc., 5 to 20 ounces, of the cheaper cottonseed oil, warmed. Hertz claims that oil is less effective than water for this purpose). Internally, olive oil is used as nutrient, laxative, and in hyperchlorhydria (15 to 50 cc., ½ to 2 ounces before meals). Kennedy and others claimed beneficial results in biliary colic, using large doses (150 to 500 cc. in four to eight portions within three hours). The concretions found in the feces when olive oil and Epsom salt are given are not gallstones, but soap (magnesium oleate). Fats are useful antidotes in corrosive poisoning. The protective action of oils against irritation and absorption was known and used by the Greek physicians. These oils are insoluble in water or glycerol, sparingly in alcohol, freely in chloroform, ether, volatile oils, or fats.

Influence on Digestion.—Neutral fats allay gastric peristalsis, diminish gastric secretion and acidity (Pavlov; Chiari, 1915), and lessen the pyloric tone. They leave the stomach slowly and in small portions; a fatty meal requires seven hours for complete passage into the duodenum. The digestibility of animal fats is discussed by Langworthy and Holmes, 1915. The length of gastric sojourn increases with the melting point of fat (Feyer, 1913). Clinical doses of olive oil do not affect the acidity or emptying time of the stomach (F. L. Apperly, 1943). In the duodenum, fats check the gastric discharge and stimulate the flow of pancreatic juice and the evacuation of the gallbladder (review, Ivy, 1934).

Subcutaneous injections of fats as nutrients were proposed by Leube, 1895, but the absorption of plain fats is too slow to be of practical value (Winternitz, 1903). Somewhat better results were obtained with fats emulsified by lecithin (Mills and Congdon, 1911). The injection of free fatty acids would be toxic. Fats are also oxidized when emulsions are injected into a vein (Murlin and Riche, 1915).

Oleic Acid Anemia.—Continued administration of large doses of oleic acid, by mouth or hypodermically, to animals produces hemolysis and severe anemia (Faust, 1906 and 1908; Adler, 1911). Similar effects produced by the injection of extracts of tapeworm (bothriocephalus) are also attributed to oleic acid-cholesterin esters (Faust). However, Klotz and Spencer, 1917, did not observe any changes in the number or structure of the blood corpuscles after two weeks of intravenous injection of suspensions of cholesterin in sodium oleate. The saturated higher fatty acids are also hemolytic (Shimazono, 1911). The hemolysin of bacterium putridum is oxydimethyl thiol-erucic acid, a typical unsaturated fatty acid (Burckhardt, 1910).

Atopic Reactions.—Asthmatic attacks in atopic individuals have been reported as the result of contact or ingestion of linseed oil (Taub and Zakon, 1935) and cottonseed oil (Coca).

PREPARATIONS.—***Olive Oil**, U.S.P. (Oleum Olivae; Sweet Oil), is a pale yellow or greenish-yellow fixed oil, expressed from the ripe fruit of Olea europoea. Dose, 30 cc., 1 ounce.

Oleic Acid, U.S.P. (Acid. Oleicum), is an oily liquid acid, chiefly $CH_3(CH_2)_7CH{:}CH(CH_2)_7.COOH$, obtained from tallow and other fats. Yellowish or brownish yellow; peculiar lardlike odor and taste, practically insol. in water; miscible with alcohol, chloroform, and with fixed and volatile oils. Used as solvent for metallic oxides and alkaloids intended to be absorbed from the skin.

Cottonseed Oil, U.S.P. (Ol. Gossypii Seminis), is a pale yellow fixed oil expressed from seeds of cultivated varieties of Gossypium. Slightly soluble in alc. On account of its cheapness, it is especially adapted for external use. It is inferior for internal administration; it can not be readily emulsified or saponified, since the free fatty acids have been removed in the process of purification. Feeding with "*cottonseed meal*" (not the oil) sometimes produces toxic effects. These are due to *gossypol*, a crystalline substance, $C_{30}H_{30}O_8$, first isolated by Marchlewski, 1899. It is insoluble in water, soluble in dilute alkali, in oils and in gasoline. It may be rendered harmless by autoclaving the cottonseed meal at 15 to 20 pounds for several hours and by various methods of oxidation, precipitation or extraction (Withers and Carruth, 1915). The *phenomena of cottonseed poisoning,* as observed in the slow poisoning by feeding farm or experimental animals (dogs, rabbits, cats, less typical in rats), consist of diarrhea, loss of appetite, emaciation, edema of the lungs and shortness of breath, edema of the anogenital region, neuritis and paralyses. The disturbance of digestion and nutrition is due to intestinal impaction and enteritis, which is severe and may be hemorrhagic. Injections of alkaline or oily solutions produce marked irritation and edema at the site of injection. Intravenous and intraperitoneal injections cause congestion and hemorrhages in the viscera, cardiac dilatation and death from pulmonary edema. Less characteristic direct effects on the heart and excised intestine have been described. Cottonroot bark, which also contains gossypol, has been used as abortifacient (see Index), but does not seem to be very effective (Schwartze and Alsberg, 1924; E. P. Clark, 1927). The toxic properties of *Tung nuts* were studied by Erickson and Brown, 1942.

Other Fatty Oils are Expressed Almond Oil (Ol. Amygdalae Expressum); Peanut Oil (Ol. Arachis); Linseed Oil (Ol. Lini); Corn Oil (Ol. Maydis); and Sesame Oil (Ol. Sesami; Teel Oil, Benne Oil); Persic Oil, expressed from the kernels of apricots or peaches.

Theobroma Oil, U.S.P. (Ol. Theobromatis; Cacao Butter), is a yellowish-white solid fat from the roasted seeds of Theobroma Cacao. It melts at the temperature of the body. It is used mainly for making suppositories, as a lubricant in massage, and for cracked nipples. It is not to be confused with *Oleum Cocos,* the expressed oil of the coconut, the fruit of the palm, Cocos nucifera. It is a whitish fat, soluble in alcohol, used especially in soap making.

SOFT ANIMAL FATS

These are employed as ointment bases. They have the inconvenience of rapidly turning rancid. This is delayed by antiseptics, as in Benzoinated Lard.

Preparations.—*Benzoinated Lard,* U.S.P. (Adeps Benzoinatus), is lard (the purified internal fat of the abdomen of the hog) impregnated with 1 per cent of Benzoin. It imparts to the lard a pleasant odor, the antiseptic and stimulant properties of the balsams, and increases its keeping qualities. Lard is insol. in water; slightly sol. in alc.; melts between 36° and 42° C.

Butter (Butyrum) and *Mutton Suet* (Sevum) are similar. *Other animals* also yield fats which are popularly supposed to have special advantages—dog fat, goose grease, etc. There appears to be no established reason for preferring them to the more easily obtainable lard.

WOOL FAT—LANOLIN

This differs chemically from ordinary fats in that the fatty acids are not united to glycerol but to cholesterol and isocholesterol and smaller quantities of other alcohols. Crude wool fat or suint was used by the ancients, but has a disagreeable odor. A purified hydrated product was introduced by Liebreich as "lanolin." Even this has a rather unpleasant odor and disagreeable sticky consistence, but it does not readily turn rancid. Since its composition resembles that of the natural skin fat, it was believed that it would be more readily absorbed; but this does not seem to be the case. Its chief advantage lies in the property of forming salvelike emulsions with up to two or three times its volume of water, so that watery solutions may be incorporated with it. In contrast to ordinary emulsions, the water is the dispersed and the lipid the continuous phase. Considerable quantities of true fats or petrolatum may be mixed with the wool fat without destroying this quality. Anhydrous wool fat melted with three parts of petrolatum can be mixed with at least twice its weight of water. Anhydrous wool fat is too "doughy" for ointments; it is employed after the admixture of 30 per cent of water (Hydrous Wool Fat), or better with the further addition of an equal weight of petrolatum or other fat. Ointments containing wool fat are more adhesive and coherent than ordinary fats, more suitable for prolonged effects, but less so for inunction.

Wool fat consists of a mixture of cholesterol esters and of alcohols of the fatty series, including ceryl alcohol. Its fatty acids are largely those of ordinary fats (E. Rohmann, 1916). Wool fat is *not absorbed* from the intestines (Bloor, 1913).

Preparations.—***Hydrous Wool Fat,** U.S.P. (Adeps Lanae Hydrosus; Lanolin), is the purified, fatlike substance from sheep's wool, containing 25 to 30 per cent water. It occurs as a yellowish-white ointment-like mass, having no more than a slight odor; is sparingly sol. in alc., insol. in water, but is miscible with about twice its weight of water. The Anhydrous *Wool Fat,* U.S.P. (Adeps Lanae; Anhydrous Lanolin), is a light yellow, tenacious, unctuous mass, melting between 36° and 42° C., insoluble in water but mixing with up to two parts of water without separation; sparingly sol. in alcohol.

COMPOUND OINTMENT BASES

These differ chiefly in consistence and miscibility. One of the most useful is the mixture of equal parts of hydrous wool fat and petrolatum, a water-in-oil emulsion that mixes both with fat and with moderate quantities of water. *White Ointment,* U.S.P., consists of white petrolatum with 5 per cent each of wool fat and white wax. It is also miscible with considerable water. "*Yellow Ointment,*" U.S.P., similarly contains 5 per cent each of wool fat and yellow beeswax, and 90 per cent yellow petrolatum. The U.S.P. authorizes adjustment of the proportions of the vehicle ingredients of its ointments to climatic conditions. *Cerates* are stiffer ointments containing sufficient wax so as not to melt at body temperature. *Simple Cerate* (Ceratum, U.S.P.) is composed of benzoinated lard and white wax. In *Rosin Cerate,* U.S.P. (Cerat. Resinae, Basilicon Ointment), lard is stiffened with yellow wax and rosin. *Toilet creams* are soft ointments used for protection and cleansing. *Cold Cream* (Ung. Aquae Rosae, U.S.P.) is a water-in-oil emulsion made with expressed almond oil stiffened with white wax and spermaceti (a fat from the skull cavity of the sperm whale, chiefly cetyl palmitate), emulsified with 0.5 per cent of borax, flavored with oil of rose. *Hydrophilic Ointment,* U.S.P., consists of white petrolatum and stearyl alcohol, 25 per cent of each, incorporated into water and glycerin by synthetic emulsifiers. It is cooling by the evaporation of its water. Many modifications exist; a typical formula was given by Galen.

Emollient creams are cold creams, generally with some wool fat. *Vanishing creams* (foundation creams) are emulsions of stearic acid in water, made with soap. They contain 70 to 90 per cent of water, which evaporates from the skin, leaving a very thin film of stearic acid, which serves as an adhesive surface on which to spread powders. *Cleansing creams* are maximally superfatted soaps (Fantus, 1936). *Protective films* used by mechanics and painters as "invisible gloves" against soiling with grease, paint or varnish, and as protection against chemical irritants, consist of paste of sodium silicate and soaps, often with casein. They prevent access of dirt and wash off easily.

WAXES AND WAXLIKE FATS

These are used in pharmacy mainly to stiffen ointments (as in cerates).

Preparations.—These include *Yellow Beeswax,* U.S.P. (Cera Flava); *White or Bleached Beeswax,* U.S.P. (Cera Alba); *Spermaceti,* U.S.P. (Cetaceum), a pearly-white, fatty substance obtained from the head of the sperm whale; *Stearic Acid,* U.S.P. (a mixture of fatty acids, chiefly stearic and palmitic, sol. in 20 parts of alcohol); *Stearyl Alcohol,* U.S.P., a mixture of solid alcohols, chiefly stearyl alcohol; *Sodium Stearate,* a mixture of varying proportions of sodium stearate and palmitate; *Rosin,* U.S.P. (Resina; Colophony), is the amber-colored residue left after distilling off the volatile oil from turpentine, the concrete oleoresin obtained from species of pine.

PETROLATUM AND OTHER PETROLEUM PRODUCTS

"Mineral fats" are mixtures of hydrocarbons obtained from petroleum by fractional distillation, chilling, purification by filtration through bone black, etc. They consist of hydrocarbons of the methane and related aliphatic series. According to the process of preparation, they occur in various consistencies, from the waxy "paraffin" (employed for hardening ointments), through the buttery "petrolatum" (a typical emollient), to the "liquid paraffin" (used especially for laxative and sprays). The color, from deep yellow to almost pure white, does not affect the action, except that dark red petrolatum protects the skin against *sunburn* (Luckiesh *et al.,* 1946). Notwithstanding the chemical difference, they resemble the fats in physical character and therapeutic application. They have the advantage that they are chemically indifferent, do not undergo deterioration, can not become rancid or irritant, and do not react with drugs, such as oxidizing or reducing agents. They are not so well adapted for inunction.

Liquid Petrolatum as Laxative.—Only minimal amounts of mineral oils are absorbed from the digestive tract (Channon and Collinson, 1929). By far the greater part is eliminated unchanged by the feces (Randolph, 1885; Hutchinson, 1899; Bloor, 1913). They can not, therefore, act as nutrients. By softening the feces, they are mildly laxative, and are used as such in intestinal stasis (A. D. Schmidt, 1905; Lane, 1913). Sometimes they do not mix well with the feces, the oil leaking from the anus. Occasionally they induce nausea and regurgitation (Bastedo, 1914). They interfere materially with the absorption of carotene, vitamins D and K, calcium and phosphate, so that continuous use is not advisable. There is no evidence that they are carcinogenic (Council of Foods, 1943, J.A.M.A., *123:*967). Any of the "liquid paraffins" (Petrolatum Liquidum Album) may be employed—there being no therapeutic difference between the light or heavy Russian or American oils (Bastedo, 1915). Their composition is perhaps also similar. The usual dosage is from 10 to 30 cc., one-half hour before meals; or a single dose of 30 to 60 cc. before retiring. The "light" oil is preferred for sprays (Wilbert, 1914); the more viscid oils for laxatives. All oily sprays and insufflations interfere with ciliary movement. Repeated aspiration of liquid petrolatum "nose drops" or laxatives gives rise to chronic hyperplastic bronchitis and *lipid pneumonia* (see Index); 100 to 120 cc. of oil were found in the lungs after 20 years' use of nose drops.

Composition of Liquid Petrolatums.—All crude petroleum oils are complex mixtures of hydrocarbons, the composition varying quantitatively according to their origin. The constituents likewise vary with the origin. In North America they are chiefly of the aliphatic series; in Borneo and Sumatra, of the aromatic series; and in Russia, both series. These differences are eliminated in refining, so that the composition of the thoroughly refined, colorless products is probably similar, whether the product is derived from Russian or from American oils. The liquid petrolatums consist mainly of naphthenes (C_nH_{n-2}) and polynaphthenes (C_nH_{2n-2} and C_nH_{2n-4}). They do not contain true paraffins (C_nH_{2n+2}); so that the term "Paraffin Oil" is a misnomer. The irritant olefin hydrocarbons and the benzenes of the crude oils are absent from the refined. Certain ingredients, which give the fluorescence and rancid taste, are more difficult to eliminate from some oils than from others (Brooks, 1916) The history and composition are discussed in the J.A.M.A., 1914, *62*:1740.

Absorption and Metabolism of Paraffin.—Histologic evidence shows that a small amount is absorbed from the intestines in man as well as in rabbits, rats and guinea pigs, especially if the oil is emulsified with particles smaller than 0.5 microns. It is demonstrable in the mesenteric lymph nodes, liver and spleen (W. A. Stryker, 1941; A. C. Frazer *et al.*, 1942). N-hexadecane tagged with deuterium and fed to rats is fairly well absorbed, partially deposited in the tissues, and oxidized to fatty acids, apparently in the liver (De W. Stetten, 1943).

Paraffin Treatment of Burns.—Paraffin of proper plasticity may be used as dressing for burns, roentgen ray burns, and pruritus. A thin film of melted or liquid paraffin is painted on the clean surface, covered by a thin layer of cotton, and this again by a heavier coat of melted paraffin; then cotton, bandages, etc. The treatment obtained notoriety in the form of a secret preparation ("Ambrine"), but simple "surgical" paraffin is fully as good. The addition of antiseptics is useless, since they are hermetically sealed in the solid paraffin (Sollmann, 1917). Simple petrolatum dressing gave the most prompt healing of minor industrial burns (R. D. McClure and Lam, 1943). Liquid petrolatum is probably the best agent for the removal of fuel oils from burns and wounds.

Melted paraffin may also be used as a protective surface coating for ordinary dressings. Fisher, 1916, suggested the impregnation of bandages with paraffin mixtures to avoid adherence to wounds. Gauze impregnated with liquid petrolatum is not easily clogged by secretion, and therefore facilitates absorption by the dressings (Sollmann, 1917). N. Burns, 1917, reported erysipeloid skin eruptions following the use of liquid petrolatum, when insufficiently purified, as wound dressing.

Sterilization.—H. Lyman, 1917, suggested paraffin for sterilization of instruments; ten minutes at 150° C. kills even anthrax spores. *Mineral oil treatment of bedding and floors* retains bacterial dust (Loosli, Wise *et al.*, 1946). The bacterial count of the air may be reduced by 97 per cent, but cross infections are not reduced (Hollaender, 1946).

Paraffin Prothesis.—The persistence of the mineral fats in the subcutaneous tissue has been utilized for the *correction of deformities* (*e. g.*, of the nose), by injecting subcutaneously a mixture of paraffins melting at about 40° C. There is some danger of embolism, and the results are not permanent, the paraffin being gradually replaced by scar tissue (Heidingfeld, 1910), which may become a starting point for neoplasms.

Paraffin "Wax" Dermatitis and Cancer.—Continuous handling of unpurified paraffin may lead to dermatitis (Joseph, 1896), acne and other eruptions, papillomas and carcinomas. Mice and rats are also susceptible. Refined mineral oils, however, are not carcinogenic, even when used over long periods; nor do they produce irritation, for the carcinogenic agents are destroyed by the sulfuric acid used in the purification and also by other oxidizing and reducing agents. American crude oils are generally slightly carcinogenic (F. C. Wood, 1930; review, J.A.M.A., 1934, *102:* 1702).

PREPARATIONS.—*Paraffin*, U.S.P., melts between 50° and 57° C. It corresponds closely to Hard Paraffin, B.P.

**Petrolatum*, U.S.P. (Soft Paraffin, B.P.; Petrolatum Jelly), is a yellowish to light amber-colored semisolid mixture of hydrocarbons melting between 38° and 54° C. *White Petrolatum*, Petrolatum Album, has been wholly or nearly decolorized. *Hydrophilic Petrolatum*, U.S.P., contains white petrolatum, 73 per cent; wool fat, 15 per cent; white wax, 8 per cent; stearyl alcohol, 3 per cent; cholesterol, 1 per cent.

Petroleum (*coal oil, kerosene*) is somewhat irritant and narcotic. The clinical symptoms include local irritation, drowsiness, collapse, muscular twitching and coma. Myocardial insufficiency, hepatic and renal damage, and pneumonia may occur if death is delayed for several days. Pulmonary injury may result in rabbits from kerosene carried in the blood (Deichmann *et al.*, 1944). Its toxicity is generally low, and recovery has occurred after swallowing as much as a liter; but if it is aspirated into the lungs, as is liable to occur especially in young children, it may cause irritation pneumonia, so that six patients died in a series of sixty-five (Nunn and Martin, 1934). It should be treated by emesis and gastric lavage with olive oil or perhaps better with warm water, until the odor of kerosene becomes nearly imperceptible.

Gasoline (*petroleum benzin, petroleum ether, petroleum naphtha*) is a mixture of petroleum hydrocarbons distilling from less than 100° to about 400° F.; it contains various paraffins, olefins, naphthenes and benzene derivatives differing according to origin. Inhalation of the vapors causes headache, nausea, giddiness, inebriation, unconsciousness, muscular tremors, convulsions, dyspnea, cyanosis and death (Buergi and Burgl; Wolf, 1911). The inebriation, the "naphtha jag" of rubber factories, shows restlessness and excitement similar to alcohol intoxication, some subjects becoming happy and hilarious; others morose and quarrelsome. The excitement is followed by the after-effects of an alcoholic debauch: lethargy, sick headache, restless night, and morning nausea and misery. Addiction has been reported by inhaling the gasoline from a handkerchief. *Chronic poisoning* results in dulness, pain in the limbs, trembling, muscular weakness and other nervous disturbances (Rambousek), and pulmonary hemorrhages (Jaffe, 1914). E. R. Hayhurst, 1936, describes manifold bizarre symptoms. Blood changes are rare and damage to the blood is much less than with benzene. The symptoms of acute and chronic poisoning, as they occur in industry, are described by R. T. Johnstone, 1941. *Concentrated vapors* cause purely paralytic symptoms in frogs, but in mammals they have only a weak anesthetic action. Concentrations above 1:100 are rapidly fatal to most animals. Susceptibility varies considerably and some tolerance is acquired. If they are inhaled to the exclusion of air, they will cause an asphyxial anesthesia. Before this sets in there are very characteristic convulsions (Sollmann, 1904; Haggard, 1920). The animal struggles violently, then falls on its side and claws the air with all fours, as if running. The pupils are widely dilated. Reflexes are absent. The spasms are intermittent, and between them the dog is perfectly limp, except that the toes, tail and eyelids continue to twitch. The respiration is first stimulated, then weakened. There is paralysis of the vagus, then depression of the cardiac muscle, and later of the vasomotor center. Either heart or respiration may stop first. Gasoline is, therefore, unsuitable as an anesthetic even for animals; although it has been tried with man (Felix, 1888). In cats whose sympathetic tonus has been raised by epinephrine injection or by decerebration, petroleum ether is likely to produce ventricular rhythm, but less so than benzene (Nahum *et al.*, 1936). The most frequent changes at autopsy are visceral congestions and petechial hemorrhages, particularly in the lungs (W. Machle, 1941).

If gasoline is swallowed, it may produce similar narcotic symptoms (restlessness, incoordination, cyanosis) and some local irritation: intense burning sensation in the mouth and esophagus, vomiting, loose stools, sometimes bloody. Recovery occurs after a few hours of depression, unless gasoline has been aspirated into the lungs, in which case hemorrhagic pneumonia develops, often fatal in two to eighteen hours, sometimes after recovery from the acute effects. Serious poisoning may result from 20 to 30 Gm., and with children 10 to 15 Gm. may be fatal. The usual fatal dose for man is about 500 cc.; recovery has followed 250 cc. Of seven children who had swallowed gasoline, two died (Nunn and Martin, 1934). The treatment would be lavage with olive oil. Gasoline is absorbed slowly from the alimentary tract, and excreted mainly by the lungs (Jaffe, 1914).

"Ethyl gasoline," containing lead tetra ethyl, produces dangerous acute lead poisoning, even when it is absorbed from the skin.

PREPARATIONS.—*Petroleum Benzin*, U.S.P. (petroleum ether): hydrocarbons of the methane series, distilling completely between 35° and 80° C.; highly inflammable; vapor explosive.

GLYCERIN

Glycerin or glycerol acts both as emollient and demulcent. It is used to soften the skin, to prevent chapping, and internally against coughs. Concentrated glycerin abstracts water, so that the soothing action is preceded by smarting. It should therefore be diluted with two or three volumes of water (rose water for lotions). This, or a half volume of 70 per cent alcohol, also decreases its excessive viscosity so that it is more easily applied. Glycerin does not abstract water from the *intact* skin, because of the impermeability of the stratum corneum. Its absorption from the intact skin is negligible. On the *conjunctiva* 25 to 50 per cent glycerin causes brief smarting, followed by active hyperemia, lasting several hours. It is used in trachoma and cataract. Undiluted glycerin injected into the rectum causes evacuation in a few minutes, without pain if there are no abrasions (5 to 10 cc., 1 to 2 ʒ; of the official suppository). Similarly, it provokes uterine contractions if introduced into the cervical canal. Large doses (100 to 150 Gm. per day, in divided portions) have been employed to kill intestinal trichinae. Glycerin is used in pharmacy as a vehicle and solvent for salts; as a sweetening agent; to preserve ferments and vaccines; to keep pill masses or extracts moist, etc. As a sweetening agent in diabetes it has been displaced by saccharin.

Nutrient Value.—Glycerin is transformable into glycogen and sugar, after oxidation to 2,3-dihydroxypropanal (glycerylaldehyde); but its nutrient value is doubtful, since larger quantities diminish gastric secretion (L. Kast, 1910) and provoke diarrhea. Like other intestinal irritants, it produces increased elimination of uric acid (Abl, 1913); but with gross overdosage there may be acute damage to the liver, kidneys and lungs. Large oral doses injure the digestive tract. Diuresis is more pronounced with oral than with hypodermic administration.

The toxicity is low with oral administration. No deleterious effects were observed in man with 110 Gm. of glycerin per day for fifty days; indeed, the body weight increased. Normal growth and reproduction occurred in rats with 41 per cent of glycerin added to the food for forty weeks, in dogs with 35 per cent added for fifty weeks. No gross or microscopic changes of the viscera were seen after two years of high glycerol diet (V. Johnson *et al.* 1933).

Hypodermic injection of large doses causes convulsant and paralytic symptoms, presumably through direct action of glycerin on the central nervous system. The blood corpuscles are laked. This is probably an osmotic effect, the glycerin remaining for a time unabsorbed, and in high concentration at the place of injection, and the corpuscles being laked during their passage through this area (Filehne). Administration of ascorbic acid doubles the threshold dose of hemoglobinuria and lowers the mortality rate (Pfeiffer and Arnove, 1937). Intravenous injection of even small doses produces transient fall of blood pressure. Lethal amounts result in gradual failure of the circulation (review, Deichmann). On muscle-nerve preparations, glycerin acts like veratrine.

Antiseptic Action.—Concentrations of 25 per cent and higher are distinctly disinfectant, the efficiency increasing with the concentration. Undiluted glycerin destroys $\frac{8}{10}$ of the bacteria in three hours (Winslow and Holland, 1910). On the other hand, glycerin hinders the antiseptic efficiency of substances for which it is a better solvent than is protoplasm; for instance, thymol, phenol, mercuric chloride or boric acid.

Glycerin in Cigarettes.—Glycerin is added to cigarette tobacco as a hygroscopic agent. The irritant effects of cigarette smoke have been attributed to the acrolein produced by the combustion of the glycerol, and diethylene glycol has been substituted. Other observers, however, found no difference in carefully controlled tests (Haag, 1937; Holck and Carlson, 1937).

PREPARATIONS.—***Glycerin,** U.S.P., $CH_2OH.CHOH.CH_2OH$, obtained from the hydrolysis of fats, is a clear, colorless, thick, syrupy, sweet liquid; miscible with water or alc., insol. in ether, chloroform or oils. Dose, 4 cc., 1 drachm. *Glycerin Suppositories,* U.S.P., contain each 3 Gm. of glycerin for adults, 2 Gm. for infants, and are solidified by sodium stearate.

Glycerites are solutions of medicinal substances in glycerin.

GLYCERYL ACETATES

Mono-, di- and triacetyl esters of glyceryl are used as solvents in industry and pharmacy. The irritant action on the tissues, hemolysis and toxicity increase with the number of acetyl radicals (Li *et al.*, 1941). Technical triacetin contains all three esters. *Glyceryl Triacetate,* U.S.P. (triacetin), $(CH_3COO)_3C_3H_5$, is a colorless liquid, miscible with water and organic solvents.

GLYCOLS

These dihydric alcohols are related to glycerol in chemical and physical properties. They are better and more universal solvents and are widely used as such in industry, and as anti-freeze agents. Their use as medicinal solvents is limited by their toxicity, which culminated in the tragic mass poisoning by a diethylene glycol "elixir." This, and other glycols with an ether linkage of two glycol molecules, cause profound hydropic degeneration of the epithelium of the renal tubules and hepatic cords, leading to fatal uremia. Propylene glycol is the least toxic.

Glycol "mists" (finely divided sprays) have a decided *germicidal action* on air-carried bacteria, extending also to influenza virus (which is not susceptible to ordinary germicides, but is to ultraviolet light). Gaseous glycols are even more effective (O. H. Robertson *et al.*, 1941). Liquid glycol is a relatively feeble germicidal agent, requiring up to 75 per cent. In the form of mist, propylene glycol, 0.2 mg. per liter of air, kills micro-organisms immediately; triethylene glycol is effective as 0.005 mg. per liter of air. Even considerably lower concentrations are claimed to be effective clinically, but this has not been sufficiently controlled for cross infections (Hollaender, 1947). The action probably involves condensation on the bacteria, acting as nuclei. High humidity of the air almost completely inactivates the glycol mist (W. F. Wells and Zappasodi, 1942). The maximal efficiency for triethyleniglycol vapor requires air humidity of 45 to 50 per cent, but substantial effects are obtained at 18 to 32 per cent (M. Hamburger *et al.*, 1945). Propylene glycol mist is harmless in the amounts used (W. Henle and Zellat, 1941). However, *triethylene glycol vapor* is especially effective (1:100,000,000 of air); it is odorless and is claimed to be the least toxic glycol (Robertson *et al.*, 1943). Addition of 1 to 5 per cent to the diet of young rats for two years did not change their growth, but the mortality was greater. Some developed calcium oxalate bladder stones, and the renal tubules sometimes contained oxalate concretions (H. J. Morris *et al.*, 1942).

The general pharmacology of the ethylene glycols was studied by von Oettingen and Jirouch, 1931. They cause local irritation, produce hemolysis, and depress muscular and nervous tissues. The intensity of these actions parallels the surface tension of aqueous solutions, the precipitant action on proteins, and the solution partition-coefficient. The *local irritation* of the undiluted glycols is less than that of 70 per cent alcohol. Propylene glycol is the least irritant (Latven and Molitor, 1939).

The relative toxicity on oral or parenteral administration increases in the sequence: glycerol: propylene glycol: diethylene glycol: ethylene glycol: diethylene glycol monoethyl ether: dioxane: ethylene glycol monoethyl ether (Holck, 1937; Lang *et al.*, 1938). The United States Food and Drug Administration, 1943, classes ethylene glycol, diethylene glycol, polyethylene glycol, and carbitol as definitely toxic. The single dose mortality for rats and guinea pigs has been studied on sixty glycols and derivatives by H. F. Smyth *et al.*, 1941. The *hydropic necrosis* of the renal tubules, and sometimes of the liver parenchyma, is produced only by the compounds that have an ether linkage between the glycol molecules, by diethylene glycol and its methyl, ethyl and butyl esters, by dioxane, and by dipropylene glycol; not by ethylene glycol and its diacetate, though these may cause deposition of oxalate in the kidneys and mild renal insufficiency. Even large intravenous doses of propylene glycol produce only hemoglobinuria and casts (P. J. Hanzlik, Newman *et al.*, 1939; E. P. Lang, Calvery *et al.*, 1939).

Propylene glycol, N.N.R., is used as a solvent and diluent similar to glycerin. It is a viscous fluid, *Sp. G.* about 1.036, miscible with water, alcohol, chloroform and ether. It produces moderate *local irritation* on application to mucous membranes and on hypodermic or intramuscular injection. It is readily *absorbed,* and is oxidized in the body similarly to ethyl alcohol or glycerol, the rate of combustion being largely independent of the dose. A part is excreted unchanged by the urine, to 45 per cent in twenty-four hours, with large doses (A. J. Lehman and Newman, 1937). The rapid combustion and excretion help to explain its low toxicity, which is about the same as for glycerin. Addition of propylene glycol to the *drinking water* of rats, up to 5 per cent, has no effect on normal growth; and even 10 per cent causes only a temporary check. No lesions in the viscera are demonstrable after 100 days (Reid Hunt, 1932; Hanzlik *et al.*, 1933; Holck, 1937; Weatherby and Haag, 1938). When the basal diet of rats includes 30 per cent of propylene glycol, growth and reproduction are somewhat less than with the same percentage of glycerin (Whitlock *et al.*, 1944). The *minimal fatal dose* for oral administration is about 33.5 Gm. per Kg.; hypodermically, 14 Gm. per Kg.; intravenously, 6.8 Gm. per Kg. (Weatherby and Haag, 1938). Large doses are narcotic, its potency (and its toxicity) being about a third of that of ethyl alcohol. Hemoglobinuria does not occur after oral ingestion of 12 cc. per Kg. (Lehman and Newman, 1937).

Ethylene glycol is about twice as toxic as propylene glycol, and about half as toxic as diethylene glycol, but the ratio varies for different animals (Haag and Ambrose, 1937). Added to the drinking water of rats, 3 per cent ethylene glycol proved fatal in an average of eight days, 5 per cent diethylene glycol in about two weeks, 3.6 per cent propylene glycol did not kill in ten weeks (Holck, 1937). Reid Hunt, 1932, considered ethylene glycol as toxic as methyl alcohol, although less dangerous, because it is not as rapidly absorbed. Page, 1930, however, observed no toxic effects in dogs on administering 9 cc. per Kg., as 30 per cent solution; the undiluted caused emesis with 5 cc. per Kg. He swallowed 15 cc. of the 80 per cent glycol without any noticeable effect except a slight feeling of warmth as it was swallowed. Several instances of poisoning by drinking ethylene glycol as antifreeze fluid ("*prestone*") are on record with symptoms of vomiting, somnolence, prostration, stupor and coma. Death may occur in twelve hours by paralysis of respiration; or hemorrhagic nephrosis may set in (J.A.M.A., 1930; *94:* 1940; Hansen, 1930). Hunt attributed the toxicity of ethylene glycol to its *oxidation to oxalic acid;* but it appears that this involves only a small fraction, and can not account for the phenomena. Monoacetate of ethylene glycol also yields a small quantity of oxalic acid; dioxane, diethylether of ethylene glycol and ethanolamine do not (F. H. Wiley *et al.*, 1938).

Ethylene glycol monoethyl ether is used as a solvent, "*cellosolve.*" A single thorough application of a solution containing 40 per cent in dilute alcohol is reported effective against head lice (W. A. Davis, 1943). A case of industrial poisoning with encephalopathy, in which this played a part, was reported by Donley, 1936.

Diethylene glycol obtained much notoriety as the toxic agent of the Massengill "sulfanilamide elixir," which resulted in the death of at least seventy-six and possibly more than a hundred people before its sale could be stopped. The chief effect is a severe chemical nephrosis with an unusual type of intracellular edema of the epithelial cells of the involved tubule, resulting in their destruction by compression.

The clinical symptoms started in twenty-four to forty-eight hours, with nausea, abdominal cramps, dizziness, malaise, vomiting, occasional diarrhea, lumbar pains. The urine diminished, and in fatal cases anuria became complete in two to five days, with rapid rise of blood urea and creatinine. Drowsiness developed, and slight edema, sometimes slight jaundice, then stupor and coma, cyanosis, pulmonary edema, subnormal temperature, and death after two to seven days of anuria and uremic coma. The pathologic changes consist of generalized edema, hydropic degeneration of the renal tubules, peripheral necrosis of the liver, sometimes hemorrhages into the gastro-intestinal tract. Identical visceral changes result from the administration of diethylene glycol to animals (Geiling and Cannon, 1938). The mechanism of the intracellular edema is not known. It may be that the unusual solvent properties break down the osmotic resistance of the cell membrane. *Bladder stones and tumors,* generally fibro papillomas, developed in rats after prolonged feeding with a diet containing 4 per cent of diethylene glycol (A. A. Nelson *et al.*, 1945).

The acute fatal dose of diethylene glycol for rats is 5 cc per Kg. intravenously, 7 cc. intramuscularly and 15 cc. by mouth. Rabbits are killed by about half the dose, also in *subacute* poisoning. The latter is fatal with much smaller doses: rats are killed in two to five days with daily oral administration of 3 to 6 cc. per Kg., with terminal anuria and coma as in man, and with the same pathology. Dogs vomit, so that the dosage becomes indefinite (Haag and Ambrose, 1937; Geiling *et al.*, 1937; Holck, 1937; Lang *et al.*, 1939).

Fate.—About half (40 to 70 per cent) of the orally administered diethylene glycol is excreted unchanged in the urine; only traces escape unabsorbed in the feces. The oxalic acid excretion is not appreciably increased, and is no higher than with glycerol administration (Haag and Ambrose, 1937). It evidently has no part in the toxic effects.

Local Hypersusceptibility.—B. A. Newman, 1938, reported vesicular dermatitis from handling cigarettes moistened with diethylene glycol; and positive patch-test with 5 per cent solution.

Diethylene glycol heated to about 150° C. is a convenient medium for the *sterilization of surgical instruments* (Gurchot and Mellars, 1940), but it is dangerous, since it may flash and burn at 135° C. (L. B. Tuckerman, 1941), although it boils only at about 250° C.

Diethylene glycol monoethyl ether, "carbitol," is about twice as toxic as diethylene glycol in acute poisoning (Geiling and Cannon, 1938). Its local application to the conjunctiva and wounds is less irritating than corresponding concentrations of glycerin (Cranch *et al.*, 1942).

Dioxane, the anhydride of diethylene glycol, produces essentially identical toxic effects. H. Barber, 1934, reported five subacute deaths in factory workers, with uremia, hemorrhagic nephritis, central necrosis of the liver. Similar lesions occur in animals (de Navasquez, 1935). Dogs also show gastro-intestinal disturbance and weakness (Schrenk and Yant, 1936).

Triethylene glycol is considerably less toxic than diethylene glycol, with continued administration (O. G. Fitzhugh and Nelson, 1946).

◆

DEMULCENTS OR MUCILAGINOUS SUBSTANCES

These comprise gums and other colloid substances, which form viscid solutions with water and are insoluble in alcohol. They are used to emulsify oils; to suspend insoluble powders; to mitigate the taste and local effects and to delay the absorption of other drugs; and to ally inflammations of mucous membranes, especially in bronchitis, gastritis, enteritis and diarrhea. The effects are local, but in the respiratory passages they extend reflexly into the bronchi. Gums and proteins (raw eggs, milk, flour) are employed for their protective action against irritant poisons. They are also precipitant chemic antidotes for metals. Acacia or gelatin is added to saline injections, to prolong their sojourn in the circulation (see Index, "Saline Infusions"). Mucilages and similar drugs (salep, Irish and Iceland moss) were formerly considered carbohydrate nutrients; but it has been shown that they are imperfectly digested, and for the most part eliminated unchanged by the feces (Mendel, 1908; Swartz, 1911). Psyllium is used as a laxative.

Demulcents as Flavors.—Gums and similar substances diminish the characteristic taste of all substances, acid, salt and sweet, as well as bitter. They act by enveloping the substance and forming a protective layer over the mucous membrane, and in this way preventing the access of the substance to the taste organs, and in the case of acid, chiefly by adsorbing this on the colloidal surface in loose combination (Schoene, 1928), so that the taste, for instance, is much less sour. Colloid substances of this kind are present in fruits as pectin bodies, and have a marked influence upon their taste. The raspberry, for instance, actually contains more acid than the current and but little more sugar, its less sour taste being due to the greater amount of these pectin substances present in it.

Gastric mucin itself has been administered as antacid protective against gastric and duodenal ulcer, 2.5 Gm. of a purified preparation (N.N.R.), precipitated by alcohol from digested mucosa of hog stomach, in water every two hours if necessary (Fogelson, 1931, 1936; Ivy and Fauler, 1931). It is disagreeable to take. The "*plant mucin*" of *okra* is more pleasant, but less effective. Fantus advocated *karaya gum*, a teaspoonful of the coarsely granular powder, stirred into water; but several cases of atopic hypersensitivity have occurred, with nasal, bronchial, cutaneous and gastro-intestinal reactions (Figley, 1940). *Pectin* also has a prophylactic and curative effect on gastric ulcers induced by cinchophen (M. Winters *et al.*, 1939).

Anaphylactoid phenomena on intravenous injection of gums are described under Anaphylaxis—see Index.

Starch (Amylum, U.S.P., maize starch) is used as a dusting powder. By boiling with water, starch undergoes hydration and polymerization and becomes a hydrophilic colloid, starch-paste. This is used as an emollient, in the form of *Starch Glycerite*, U.S.P. (10 per cent of starch, 70 per cent of glycerine, 0.2 per cent of benzoic acid); in poultices; and to secure the retention of enemas (teaspoonful, rubbed smooth with a little cold water and poured into a cup of boiling water). It is a chemical antidote to iodine. Boiled starch, which is much more digestible than the raw, is employed as a nutrient, especially as "*arrowroot*," the starch of Maranta, which has a somewhat finer flavor than the official corn starch. *Barley water* is used as a demulcent decoction; and as a protective colloid in diluting cow's milk for infants, to prevent the precipitation of solid masses of casein in the stomach. It is prepared by boiling for twenty minutes ten parts of washed pearl barley with 150 parts of water, and straining.

***Acacia**, U.S.P. (Gum Arabic), is the dried gummy exudation from Acacia Senegal or of other African species of Acacia. It occurs as spheroidal tears, fragments or powder; whitish to light amber colored; nearly inodorous; insipid, mucilaginous taste. Insol. in alcohol and lipid solvents, slowly forms a slightly acid solution in twice its weight of water. Incompatible with strong alcoholic solutions, borax or metallic salts. The *Mucilage of Acacia*, U.S.P., contains 35 per cent acacia, with 0.2 per cent of benzoic acid as preservative. Average dose, 15 cc.

Tragacanth, U.S.P., is a dried gummy exudation from the stems of Astragalus species. Swells in water to a gelatinous mass, without dissolving. Used in pill excipients, emulsions, etc.; 0.5 per cent suspends insoluble powders in water; 2.5 per cent produces a jelly. *Mucilage of Tragacanth*, U.S.P., contains 6 per cent, with 18 per cent of glycerin and 0.2 per cent of benzoic acid.

Methylcellulose forms stable, viscous, colorless, clear solutions with cold water. They have a refractive index similar to the cornea, and appear to be promising as conjunctival demulcent (K. C. Swan, 1945).

Demulcent Teas.—Drugs containing mucilages are used as decoctions, *ad libitum*, mainly in folk medicine. They include Althea (Marshmallow Root), Cetraria (Iceland Moss, a lichen), Chondrus (Irish Moss, Carrageen, a seaweed), Cydonium (Quince Seed), Salep (tubers of an orchid), Sassafras Pith, Sweet Almonds (Amygdala Dulcis) and Ulmus (inner bark of Slippery Elm).

POULTICE MASSES

Poultices (cataplasms) are used to convey heat and to macerate the skin. Hot water bags, radiant heat and diathermy are now preferred for heating, as being less "messy." A variety of pasty materials may be employed. The most common are linseed, starch, bread and clay. *Linseed poultice* is prepared by stirring one part of ground linseed into three parts of boiling water, to which a little baking soda may be added, to render it fluffy and less irritant. *Clay or kaolin poultice* is much heavier, but can be sterilized if desired. The rate of cooling of different poultice masses has been investigated by Pilcher, 1908. They do not differ materially. Immersion in paraffin baths of low melting point may be used as a "*paraffin poultice.*" Whole linseed is made into a demulcent decoction against bronchitis.

INDIFFERENT DUSTING POWDERS—ADSORBENTS

Very fine ("impalpable") insoluble, nonirritant powders, such as talcum, chalk, starch, zinc stearate, lycopodium, etc., are used to cover and protect the skin and mucous membranes, ulcers and wounds. They prevent friction, absorb secretions by capillary action, and are therefore drying. The insoluble bismuth salts also act largely in this manner. The bismuth salts, chalk, kaolin (clay, bole), fuller's earth and charcoal are used internally for similar protective effects, against gastrointestinal irritation. Dusting powders also adsorb dissolved or suspended substances on their large surface, and diminish their concentration in the solution and their absorption. This weakens the action of chemical agents, including bacterial products. At the same time, the drying renders the medium unsuitable for bacterial growth and so diminishes infection. The chemical antiseptic potency of powders is much weaker when these are applied in a thin layer to the skin or mucous surfaces than when they are heaped on, as in the usual plating tests (J. H. Brewer, 1939).

Water-absorbent powders should not be used on extensive profusely secreting raw surfaces, as they tend to cake and form adherent crusts. Starch becomes doughy even from sweating, and requires the addition of an antiseptic (2 to 4 per cent of boric acid or 1 per cent of salicylic acid) to prevent fermentation. *Zinc stearate*, magnesium stearate and lycopodium have a fatty surface which adheres to the skin and is not wetted by water, so that they permit seepage and evaporation, and do not crust (Fantus). They prevent irritation of the skin of infants by urine.—The use of *talcum powder* about open wounds, even for dusting surgeons' gloves, should be avoided. The particles act as foreign bodies, producing tubercles and fibrosis; in the peritoneum they cause adhesions (E. J. McCormick and Ramsey, 1941).

Prepared chalk is less hazardous, but may produce granulomas before it is absorbed. Potassium bitartrate or starch gums may be used (Seeling *et al.*, 1943). *Lycopodium should not be used on wounds.* It consists of the spores of a clubmoss, which may act as foreign bodies to induce indolent chronic inflammatory reactions and granulomas that may necessitate operation (Antopol and Robbins, 1937). It is also likely to be allergic.

Water Absorbing Power.—Sollmann, 1919, found this to range from 70 to 80 per cent for fuller's earth, kaolin and starch; and from 53 to 65 per cent for chalk and talcum.

Adsorption of Toxins and Antitoxins.—Diphtheria toxin and antitoxin are both adsorbed by animal charcoal; not by kaolin, talcum, kieselguhr or wood charcoal. This does not apply to other toxins and antitoxins. Tetanus toxin is absorbed by all the above agents (Zunz, 1913). In general, gram-positive bacteria are adsorbed much more effectively than the gram-negative (Eisenberg, quoted from Clark).

Face Powders.—The application of indifferent powders protects the skin against the irritation of sun and wind. The usual ingredient of the light powders is starch; of the heavy powders, barium sulfate and talcum. Addition of stearates facilitates adhesion to the skin. They are usually indifferent, but they tend to obstruct the ducts of the skin glands, and so may themselves become irritants. Organic powders may be subject to allergy. Some powders contain zinc oxide, bismuth subcarbonate and even lead carbonate. The lead is directly harmful. The presence of aniline dyes and perfumes in powders and other cosmetic preparations is sometimes responsible for severe dermatitis (Cole, 1924; H. E. Miller and Taussig, 1925).

Adsorbents in Diarrhea.—Bolus alba (kaolin), fuller's earth, bone black (carbo animalis), and tripoli (silica) check watery diarrheas and dysentery. In acute bacterial dysentery, large doses are given, 30 to 45 Gm. three times daily, stirred into hot tea (after a preliminary cleansing by calomel). Smaller doses suffice in chronic dysentery (Stumpf, 1914; Stoerk, 1915). The anti-diarrheal effects are explained by the more solid consistence of the stools; by the checking of bacterial growth; and by adsorption of the irritant putrefactive products (Kraus and Barbara, 1915). Excessive and prolonged administration may lead to accumulation of the adsorbent in the intestines (Bungart, 1917), but serious trouble is exceptional.

Kaolin is also used against peptic ulcer. The acidity of the gastric juice forms some aluminum chloride and silicic acid (J. Friedenwald and Morrison, 1937). It has been reported that adsorbents restrain somewhat the activity of digestive ferments (Strauss, 1916; Peterson, 1917); but this is probably unimportant. Gastric carcinoma is reported to have followed long-continued use of a kaolin preparation (A. L. Cohn *et al.*, 1941).

Hydrous magnesium trisilicate is used as antacid and adsorbent in treating gastric hyperacidity and the pain of *peptic ulcer*. Mutch, 1936, finds that the antacid action is sustained for hours and results in the formation of hydrated silica, which is strongly adsorbent for food poisons and other substances, including pepsin, protecting the ulcer against digestion. Even large doses do not disturb gastro-intestinal motility, causing neither constipation nor diarrhea; but the magnesium chloride may be laxative. It can not reduce the reaction of the stomach materially below neutral and does not easily induce systemic alkalinization, as the excess is insoluble and is voided in the stools. The urinary silicate is increased (Page *et al.*, 1941). Hydrated Aluminum Oxide is used similarly (see Index).

Charcoal against Indigestion and Flatulence.—Freshly heated charcoal adsorbs gases. This presumably led to its use against flatulence and heartburn. It is unsuccessful, for charcoal can not adsorb material amounts of free gases when it is moistened.

Wood charcoal, which is generally used, is slightly alkaline. However, it would be a wasteful and inadequate means of introducing alkali, since 1 Gm. neutralizes only about 5.5 cc. of N/10 acid, and is therefore equivalent to about 42 mg. (⅔ grain) of sodium bicarbonate.

Charcoal as Antidote.—Many substances, including alkaloidal salts, are quite effectively adsorbed by charcoal. This may slow their adsorption sufficiently to prevent toxic effects (Wicshowiki). However, only active charcoal (bone black or mineral charcoal) can be successful, and this is not always available (Joachimoglu, 1922).

According to Leschke, 1 Gm. of animal charcoal binds 850 mg. of mercuric chloride, 580 mg. of strychnine, 40 mg. of phenol. The protective adsorption of alkaloids and organic bases was studied by Loffler and Spiro, 1920.

Colloidal carbon (caramel) is harmless, even on intravenous injection. It antagonizes alkaloids (strychnine) when mixed *in vitro*, and even somewhat when the strychnine is given by mouth, and the carbon by vein; but this antagonism is too uncertain for practical application (Sabbatani, 1913 and 1914).

Charcoal is used to *decolorize solutions*. Different specimens vary greatly in activity. Tested by methylene blue, blood charcoal is generally the most active, but mineral charcoal may be more active than blood charcoal. Graphite and lampblack are almost inactive (Koltoff, 1919). Wood charcoal prepared from nut shells is highly active; ordinary wood charcoal is poor. Talcum and kieselguhr are used to *clarify turbid mixtures*.

Selective Adsorption.—The affinity of adsorbents varies for different substances. In general, it is most effective for colloids of the opposite electric charge (Koltoff, 1919).

The adsorption of gases by charcoal increases with the pressure and decreases with the temperature. Gases of high temperature of liquefaction are generally better adsorbed. At 20°, active blood charcoal adsorbs about seven volumes of hydrogen, twenty-five volumes of nitrogen, oxygen or carbon monoxide; forty volumes of methane; eighty-five volumes of carbon dioxide; 200 volumes of ammonia or hydrogen sulfide (quoted from Bancroft).

Protection against Chemical Irritants.—The adsorbent powders protect the respiratory passages and the skin against irritant "gases" (Sollmann, 1919).

Intravenous injection of colloidal powders tends to produce allergic shock. Kaolin is hemolytic when added directly to the blood (Friedberger and Tsumeoka, 1913). Saint-Jacques, 1934, claimed beneficial results in infections from intravenous injection of animal charcoal, 3 cc. of 2 per cent suspension, repeated six times. He attributed the improvement to phagocytosis.

PREPARATIONS.—*Activated Charcoal*, U.S.P. (Carbo Activatus), is the residue from the destructive distillation of various organic materials, treated to increase its adsorptive power. It may be dispensed when "Wood Charcoal" (Carbo Ligni) is prescribed. A black, odorless, tasteless powder; free from gritty particles. Dose, 1 Gm., 15 grains. The dry powder, in a bag of gauze, is used locally as deodorant for fetid ulcers. *Bone Black* (Carbo Animalis) is used against dysentery, in dosage of 30 Gm.

Kaolin (China Clay, Bolus Alba) is a native hydrated aluminum silicate derived from feldspar, powdered and freed from gritty particles by elutriation. It is used externally as a poultice mass (Cataplasma Kaolini).

Bentonite, U.S.P., is a variety of clay, hydrous aluminum silicate, occurring as a very fine, practically colorless powder. It is insoluble in water, but swells to about eight times its volume when added to water, forming a gelatinous mass. Suspensions have a high *p*H, to 10.5, producing alkali by hydrolysis. The water-holding capacity is changed by acids and alkalis. *Bentonite Magma*, U.S.P., is a 5 per cent suspension in water. Bentonite increases the viscosity of suspensions and is used for this purpose in *Chalk Mixture*. *Fuller's Earth* is also a variety of native aluminum silicate. It absorbs grease readily.

Lycopodium, U.S.P., the spores of Lycopodium clavatum, is used as a light, nonadhesive dusting powder.

Magnesium Trisilicate, U.S.P., $2MgO.3SiO_2.nH_2O$, is a tasteless white powder, almost insoluble in water, partly soluble in acids. Dose, 1 to 4 Gm., 15 to 60 grains, before meals. *Magnesium Trisilicate Tablets*, U.S.P., 0.3 and 0.5 Gm.

Talcum, U.S.P., a hydrous magnesium silicate, insol. in water and dilute acids and alkalis, is used for dusting.

Zinc Stearate, U.S.P., is a compound of zinc, corresponding to 14 per cent of ZnO, with varying proportions of stearic and palmitic acids. It is a fine, white, bulky powder, insoluble in water.

MECHANICAL PROTECTIVE AGENTS

Collodion, U.S.P. (Collodium), is a solution of not less than 5 per cent Pyroxylin, U.S.P. (soluble gun cotton, chiefly cellulose tetranitrate), in a mixture of ether and alcohol, 3:1. A clear or slightly opalescent syrupy liquid; colorless or slightly yellowish and having the odor of ether. Highly inflammable; should be kept in a cool place remote from fire. Pyroxylin is also soluble in acetone. Collodion dries rapidly into a firm film, which is used to protect small wounds. The film cracks easily and contracts considerably, exerting pressure on the tissues. Collodion applied over the harvest-mite itch gives prompt relief and kills the parasite (C. D. Fowler, 1944). *Flexible Collodion*, U.S.P., is collodion rendered flexible by castor oil and camphor.

Purified Cotton, U.S.P. (Gossypium Purificatum, Absorbent Cotton), consists of the hairs of the seed of Gossypium herbaceum freed from adhering impurities, deprived of fatty matter (so as to make it absorbent), bleached and sterilized. Almost pure cellulose. It is used in bandaging, as the fiber (Absorbent Cotton), as gauze (Tela, Carbasus), and as lint (Lintum). It may be impregnated with antiseptics or astringents.

Plasters serve for protection against irritation, for mechanical support; and rarely for the slow conveyance of drugs to or through the skin. They are somewhat irritant, partly by preventing evaporation from the skin, and partly by the small quantities of volatile oils contained in the resins from which they are often prepared. *Adhesive Plaster*, U.S.P., is a mixture of rubber, resins, waxes and an absorbent powder (starch, zinc oxide, etc.), spread on cloth.

Adhesive plaster irritation may be minimized by painting the skin with merthiolate solution before the plaster is applied (R. E. Legge, 1941). Previous application of a varnish (Compound Tincture of Benzoin) facilitates removal of the plaster.

Rubber eczema, usually vesicular, occurs in some individuals on prolonged contact with rubber. It is often due to the accelerators and antioxidants used in its manufacture, or to substances formed in the cold-vulcanization with sulfur dichloride. The latter become innocuous on soaking the rubber in 4 per cent sodium hydroxide (Overmayer, 1933). Rubber tubing used for intravenous injection should be thoroughly boiled.

Lead Oleate Plaster (Diachylon Plaster) is a lead soap. *Court Plaster* is made of isinglass (Ichthyocolla), a variety of gelatin prepared from the swimming bladder of the sturgeon.

Plaster of Paris (Calcii Sulfas Exsiccatus, Burnt Gypsum), $CaSO_4 \cdot \frac{1}{2}H_2O$, is made by heating native gypsum, a hydrous calcium sulfate, to 250° to 400° F., with the loss of about ¾ of its water. It forms a fine white powder used in bandaging. Mixed with half its weight of water, it forms a hydrate, which is first colloidal, then crystallizes into microscopic interlacing needles, "setting" into the stony plaster in fifteen to twenty minutes. This may be delayed to an hour by the addition of 5 per cent of glycerin, colloids, gelatin or glue. It may be hastened by the addition of sodium silicate or other sodium or potassium or calcium salts. Plaster of Paris must be kept dry. A mixture with flour 1:2 is used as rat poison (Holsendorf, 1937).

Sodium Silicate is used in bandaging in the form of *Liquor Sodii Silicatis* (*waterglass*) containing about 20 per cent. It is a colorless syrupy liquid, of alkaline properties, but not corrosive, and forms a solid glassy mass on exposure.

Actions of Sodium Silicate.—When given by mouth or skin, this acts like a typical mild alkali without showing any specific features. It is readily absorbed from the alimentary canal, and excreted by the urine. Injected intravenously it causes agglutination of blood corpuscles, and consequently intravascular clotting.

Colloidal Silicic Acid.—Intravenous injection of large doses (150 mg. of SiO_2 per rabbit) produces death within three to five minutes, by intravascular coagulation. With sublethal doses, the coagulation of shed blood is accelerated; but the addition of silicic acid, *in vitro*, does not alter the coagulation time of normal blood. Bronchioconstrictor effects in isolated perfused guinea pig lung have been reported (Filley *et al.*, 1945). With injections of 40 to 60 mg. death occurs after three to five days. The tissues show marked degeneration of the vascular endothelium and focal necrosis of the parenchymal cells, especially in the liver and kidneys. The daily injection of 5 mg. is well tolerated, but in the course of several months it leads to extensive fibrosis, especially in the liver and kidneys (Gye and Purdy, 1922, 1924). Colloidal silicic acid has been tried in tuberculosis, including experimental tuberculosis in guinea pigs, with alleged beneficial effects (Messner, 1922; Kahle, 1921). It failed to establish itself clinically.

Organic Silicates.—*Tetraethyl ortho silicate*, used as solvent in industry, produces toxic effects, chiefly pulmonary capillary hemorrhages, regardless of the method of administration. Surviving animals develop nephritis (Kasper *et al.*, 1938). The toxicity of ethyl silicate has been studied by H. F. Smyth and Seaton, 1940.

Silicosis is an occupational disease, characterized by pulmonary fibrosis, produced by prolonged inhalation of dust rich in silica, such as sandstone, and known as "miners' consumption." The fibrosis is a chronic condition which favors the development of tuberculosis.

Etiology.—Crystallized silica, SiO_2, is present in most mineral dusts, but the pulmonary irritation develops only if the silica content is high, and if the powder is fine, for particles larger than 10 microns do not reach the alveoli (H. B. Wulff, 1934). Colloidal silica is probably the most active, but other silicate dusts also produce the lesions, especially asbestos and talcum. The mechanism is not known, but it seems to involve a special toxicity of the silica, which is appreciably soluble in body fluids. Carborundum dust with particles as sharp and hard as those of silica does not result in comparable lesions (L. U. Gardner, 1923; L. T. Fairhall, review, 1945). More than a million workers in the United States are exposed to silica dust, and a fourth of those exposed acquire some degree of silicosis, but few die of it directly (Proske and Sayers, 1934). About three per cent of the miners who have worked ten years or more become silicotic annually (Watkins and Pitchford, 1927).

Clinical Phenomena.—The onset is slow and insidious. The symptoms consist of shortness of breath, decreased chest expansion, diminished capacity for work, without fever (J. S. Haldane, 1914). The essential *anatomic lesion* is a distinctive type of nodular fibrosis, the "*silicotic nodule*," which has also been produced experimentally in animals by long-repeated inhalation or insufflation of silica, borosilicate glass and quartz. The particles are soon engulfed by macrocytes and moved to the lymphatic tissue, where they cause marked proliferation of the fixed tissue cells. After some months the macrocytes degenerate. The liberated silica is then taken up by other cells and giant cells are formed, the whole enveloped by fibrous tissue, similar to the nodules of tuberculosis (L. U. Gardner, 1937; review, O. H. Robertson, 1941). Many believe that the nodules are really tuberculosis modified by silica irritation. Pure silicosis is rarely of clinical significance. It is nearly always associated with tuberculous infection (review, King and Belt). The effects are likely to progress after the exposure is discontinued, for the deposited silica continues to irritate (review, R. R. Sayers, 1934; W. I. Clark, 1936). Hypodermic injection of finely powdered quartz into the external ear of rabbits provokes inflammation in which the silica particles appear to have toxic effects on the various white cells (Fallon and Banting, 1935).

Aluminum Powder as a Preventive of Silicosis.—J. J. Denny *et al.*, 1939, found that the solubility of silica *in vitro* is almost completely prevented by the addition of small quantities of powdered aluminum. This is converted to the gelatinous aluminum hydroxide, which surrounds the silica particles with an insoluble coating, and adsorbs any that may have been dissolved. They report that inhalation of silica does not produce silicosis in rabbits if 1 per cent of powdered aluminum is added. The aluminum particles should be less than 5 microns in diameter, and free from grease. Prolonged inhalation of 1 per cent aluminum had no bad effects, locally or systemically. E. J. King *et al.*, 1945, found much less favorable results in rats. The aluminum disappeared in time, leaving the quartz, so that the effect would not be permanent. There is some further question whether equal protection would be conferred under the somewhat different conditions of industrial exposure. Control of dust should not be neglected (Report of Councils, 1946, J.A.M.A., *130:*1223).

Occurrence of Silica.—Very small amounts of silicates are normally present in all tissues (Siegfried, 1901). There is no evidence that they play any physiologic role. Silica is also constantly present in hairs and feathers (H. Schulz, 1901). It constitutes up to 77 per cent of the total ash of the feathers of the dove (Gonnermann, 1918).

Silica occurs normally in the urine of man, dogs and cats, and in larger amount in that of herbivorous animals, due largely to the greater intake in their food. In men not exposed to silicosis, the urinary concentration ranges from 0.25 to 2.25 mg. SiO_2 per 100 cc. (L. J. Goldwater, 1936), averaging 16.2 mg. per day, but varying with the diet (Page *et al.*, 1941). If a fine quartz suspension is administered by stomach tube, the urinary excretion is promptly increased, for about six hours. Silicate absorbed from oral administration of silicic acid or sodium silicate (or magnesium trisilicate, Page *et al.*, 1941) passes rapidly into the urine without material increase of the silicate level of the blood. Intravenously injected soluble silica promptly takes the same path (King *et al.*, 1933). *The silicate content of human tissue* normally ranges from 10 to 200 mg. per 100 Gm. of dry weight. The normal content of the human spleen is about 15 mg. per 100 Gm. of dry weight; 140 mg. in normal lung, and $>$ 200 mg. in silicosis lung (E. J. King *et al.*, 1933). Because of the normal inhalation of dust, it is relatively high in the lungs of adults even without silicotic lesions (review, E. J. King and Belt, 1938). It is concentrated especially in the root glands, where the percentage may reach fourteen times that of the parenchyma (Antoine, 1935; King and Belt, 1940). Youngsburg and Youngsburg, 1940, found 0.086 to 1.3 per cent of SiO_2 in the dried lungs of fourteen silicotic patients; 3 to 91 per cent of the total Si existed as free SiO_2. There is no direct correlation between silica concentration and the degree of fibrosis of the lung (King and Belt, 1940). Spectroscopic methods reveal little in human blood, generally less than 0.1 mg. per cent; even exposed workers show little (H. Weil, 1938).

Asbestosis.—Workers exposed to the dust of asbestos (hydrated magnesium silicate) develop pneumoconiosis and pulmonary fibrosis, demonstrable by x-ray shadows, of a somewhat different type than silicosis, with milder symptoms, usually with little disability and with no marked disposition to tuberculosis, pneumonia or other lung infections.

Asbestosis was first described by W. E. Cooke, 1927. The *clinical symptoms* consist of progressive dyspnea, cough, substernal pain, blood-stained sputum, decreased chest expansion, weakness, clubbed fingers; in later stages, cyanosis and distressing dyspnea, paroxymal coughing, tenacious sputum, containing particles of asbestos. Microscopic examination shows a large amount of finely granulated pigment in the peribronchial tissue and alveolar cells (Lanza, 1936; Sayers and Dreessen, 1939). The difference from silicosis is probably due to the larger size of the asbestos dust particles, so that they do not enter the alveoli. Macrophages form giant cells around the asbestos, giving rise to asbestos "bodies." Fibrosis occurs much more slowly (review, O. H. Robertson, 1941).

LOCAL IRRITANTS, CORROSIVES AND ASTRINGENTS

The local actions of drugs are simple and much alike, since they occur ordinarily in only a few situations, especially the skin and mucous membranes. The majority of local poisons produce the typical phenomena of inflammation ("irritation"), by causing injury of protoplasm through coagulation, liquefaction, etc. Many of these reactions can be reproduced in the test tube with proteins, but the extreme sensitiveness of protoplasm to reagents renders almost all substances—even water—irritant under suitable conditions. All irritants are somewhat *antiseptic*, by injuring the protoplasm of the bacteria.

The differences between the various irritants involve chiefly the strength of their action in different situations. Some act especially on the alimentary canal, and to a very small extent on the skin. This is probably connected with differences of absorbability. A drug which can not penetrate the skin does not act upon it. The epidermis is impermeable to many substances. In order to penetrate, the irritants must be either fat-soluble like croton oil or turpentine, or they must actually destroy the epidermis, like caustics. The degree of the local action depends usually upon the *concentration* rather than on the absolute quantity of the irritant. A small quantity of concentrated acid does more damage than much larger quantities diluted.

Degrees of Cutaneous Irritation.—The general phenomena of irritation can be studied typically on the skin. They are identical with the familiar changes produced by scalds or burns of increasing severity. They may be observed by applying the agent to a small piece of filter paper or gauze attached to the skin, the "*patch test*," used especially to study hypersusceptibility to drugs (Schwartz and Peck, 1945), or to a very superficial scratch, as in testing for allergies.

Rubefaction.—The first degree of irritant action consists in arterial and capillary hyperemia, at first active, later passive. This constitutes rubefaction ("dermatitis erythematosa"), and the agents which produce it are called *rubefacients*. The dilatation involves at first the most superficial vessels, but progresses to the deeper subcutaneous structures, partly directly and partly by reflexes. The congestion is accompanied by itching, burning or pain, sometimes succeeded by more or less anesthesia. If the irritant action does not go further, resolution takes place by the return of the vessels to normal, without leaving any lesions. The pain may outlast the congestion. The upper layers of the skin are usually desquamated. If the action is stronger than rubefaction, it may pass into vesication or pustulation.

Inflammatory Edema.—Increased permeability of the vessels is an early phenomenon of acute inflammation. It may result in edema. The *permeability to dissolved substances* is also increased. For instance, when trypan is injected by vein, it appears much more abundantly in the aqueous humor of an inflamed than of a normal eye (P. A. Lewis, 1916).

Urticaria.—Localized edema of the corium is a rather special mild inflammatory reaction to many drugs, particularly in susceptible individuals. It may occur on systemic administration, or more readily by application to the scarified skin. The more important drugs producing this effect are: morphine and its esters; histamine and peptone. Milder grades occur with atropine, cocaine, formaldehyde, urea and many amines (Sollmann and Pilcher, 1917; Sollmann, 1917).

Mechanism of Inflammatory Edema.—Increased capillary filtration in inflammation involves both transient increase of capillary pressure (by local vasodilatation and increased number of functioning capillary channels) and increased permeability of capillary endothelium to fluid and to dissolved substances of large molecules, such as the plasma proteins, trypan blue, graphite particles, india ink, antitoxin, vaccine virus (V. Menkin, review, 1938). If these are injected intravenously in the early stages of inflammation they are deposited in the irritated area (R. H. Rigdon, 1940). Lewis and Grant, 1924, referred the capillary dilatation to a histamine-like substance liberated by the injury. Menkin, 1938, believes that histamine plays only a subsidiary role. He attributes the phenomena to a diffusible polypeptide, "*leukotaxine*," which he has isolated from inflamed tissues. It increases the permeability of small vessels, and is followed by rapid immigration of leukocytes. Neither its chemical nor its pharmacologic properties agree with histamine.

Vesication (blistering) occurs if the exudate is greater than can be carried off by the lymphatics. The liquid accumulates in the parts of the tissues offering the least resistance to distention. In the skin, it penetrates readily through the lower layers of the rete Malpighii, but is arrested by the impermeable stratum corneum. It is therefore confined between the upper and lower layers of the rete and separates them, causing blisters or vesicles. The agents which produce these are called *vesicants* or *epispastics*. The vesicles appear as small points which gradually coalesce into a large blister. The fluid is at first clear, but becomes turbid by leukocytes. The sensory stimulation is stronger than in rubefaction. Resolution takes place without loss of tissue by the formation of a new stratum corneum from the rete. The area may remain pigmented for years. If the overlying and separated layers of epidermis are removed, infection may occur, the lower layers of the rete offering but little resistance. The infection may lead to loss of substance. If the vesicant is allowed to act after the blister has been formed, the infiltration becomes purulent, with deeper destruction of the skin, and healing with scar formation. This degree of action should be avoided.

Pustulation occurs if the irritant does not penetrate the epidermis, but only the cutaneous glands. Discrete and later confluent pustules are formed, which heal with more or less "pitting." They produce severe sensory irritation, but are now rarely used. The principal pustulants are croton oil and tartar emetic.

Aseptic Pus Formation.—A few drugs possess specific chemotactic power on leukocytes; their injection (hypodermic or into serous cavities) leads to pus, even when asepsis is perfect. Turpentine, croton oil, petroleum, mercury, silver nitrate, digitoxin, cadaverine, aleuron suspensions, etc., are the principal examples. The chemotropic response of polymorphonuclear leukocytes involves only the direction, not the speed of their movements (H. M. Dixon and McCutcheon, 1936).

Influence of Systemic and Local Conditions on Cutaneous Irritation.—There are *local differences* in susceptibility, and if an irritative reaction has once been induced, the skin remains hypersensitive for some time. Roentgen ray and radium treatment may leave the skin hypersensitive for months (Mackee and Andrews, 1921). Sunshine and ultraviolet rays sensitize to *tar* irritation (Herzheimer and Nathan, 1917). The *tuberculin reaction* in children is markedly decreased by the local injection of epinephrine or pituitrin for long after the vasoconstrictor effect has subsided. Drugs that cause an urticarial reaction also decrease the tuberculin reaction. It is increased by caffeine. The *Schick test reaction* is increased by epinephrine and pituitrin, decreased by caffeine and by urticarial agents (von Gröer *et al.*, 1929).

Dermatitis from Systemic Drugs.—Many drugs cause *dermatitis* when they are given by mouth (belladonna, arsenic, iodoform, quinine, salicin, antipyretics, iodides and bromides, digitalis, chloroform, etc.). This is sometimes due to changes in the cutaneous circulation, sometimes to the excretion of the drug by the skin, and often to allergic hypersusceptibility. It may take the form of scarlatinal, desquamating urticarial or papular rashes or acne. The more common sources of drug eruption may be grouped as *Erythematous or Polymorphic Eruption:* Antipyrine, arsenic (including arsphenamine), benzoic acid, boric acid, bromides, copaiba, chloral, iodide, morphine, quinine, salicylates. *Scarlatiniform Rashes:* Antipyrine, atropine, benzoate, belladonna, chloral, iodoform, ipecac, mercury, salicylates, sulfonal. *Urticaria:* Benzoate, copaiba, cubebs, iodide, quinine, salicylates, valerian. *Purpura:* Antitoxin, arsenic, barbiturates, chloral, copaiba, cubebs, iodide, mercury, quinine, sulfonal. *Morbilliform Eruptions:* Antipyrine, antitoxin, belladonna, copaiba, cubebs, mercury, opium.

Occupational dermatoses constitute two-thirds of all cases of occupational disease in the United States, and most of these are due to chemicals and plants, the most common being petroleum products and greases (12 per cent of all occupational dermatoses); plants (11 per cent); alkalis (10 per cent); solvents (9 per cent); metals and plating (8 per cent). Hypersensitivity is a frequent cause; cleanliness is protective; oily skins are more resistant than are dry, Negroes and brunettes more than blondes (review, L. Schwartz, 1939). Solvents act largely by removing the fat from the skin, leading to dryness and fissures (S. M. Peck, 1944). Skin hazards in the production of synthetic rubber are discussed by L. Schwartz, 1945; fabric finishes by Schwartz, Spolyar *et al.*, 1940. Paraphenylenediamine, methanamine and other amines, phenols, coal tars, dyes, photographic developers and terpenes used in perfumes, cosmetics and wearing apparel (Schwartz and Peck, 1945) frequently cause dermatoses. Dermatosis has been reported from the rind of citrus fruit dyed with "yellow O.B." (ortho toluene-agobetanaphthylamine) (Traub, Gordon and Van Dyke, 1937), and from lipstick containing methyl heptine carbonate (H. L. Baer, 1935). *The methods of studying irritation and toxicity on local application* are discussed by Draize, Nelson and Calvery, 1944. *Patch tests for susceptibility to contact dermatitis in industry* should be used routinely, especially for new chemicals and new personnel. The U. S. Public Health Service classifies cutaneous irritants as (1) *primary*, with direct action on normal skin; and (2) *sensitizers*, which cause a specific change of susceptibility, so that dermatitis develops after five or more days by further contact at the same or other location. These allergic reactions tend to increase for a day or two after the patch is removed, while primary irritation generally decreases. An agent may produce both primary irritation and sensitization (L. Schwartz and Peck, 1945). The anaphylactic sensitization by simple chemical substances is attributed to formation of antigenic compounds with tissue proteins. Sometimes this may be initiated by a nonspecific irritant; for instance, picric acid does not produce sensitization if it is applied to the normal skin of guinea pigs, but does so if the skin is first irritated with cantharidin (Landsteiner and Di Somma, 1940). *Hyposensitization* ("hardening") develops with most primary irritants on repeated exposure. *The technic and interpretation of patch testing* are explained by L. Schwartz, 1944.

Corrosion, cauterization or direct destruction of tissue occurs if the agent (cauterizant or escharotic) acts chemically on the protoplasm, as do strong acids or alkalis, iodine or bromine, some metallic salts, etc. This leads to the production of a scab or "eschar," and resolution by scar formation. The chemical destruction of tissue is generally preceded by inflammatory necrosis. Chemical cauterization therefore shows three areas: the first, situated at the depth and periphery of the ulcer, is an area of simple inflammation and hyperemia. Then follows a layer of necrotic tissue, the result of the inflammatory action; and last, a layer in which the chemical cauterization results in solution of the cells which have already been killed by the inflammatory process. These three—hyperemia, inflammatory necrosis and chemical solution—are successive stages in the same action; and by proper dilution, the second or first degree of action may be obtained without the succeeding stages. The *eschar* (scab) is formed by coagulation of the inflammatory exudate and by chemical products (albuminates, etc.) of the interaction of the corrosive agent with this exudate and with the killed cells. If the proteins are dissolved (as by alkalis), the scab is soft; if they are precipitated (as by most metals), it is hard. If the scab is soft, the corrosive agent penetrates it and spreads and extends deeply, so that the alkalis are not manageable for cauterization. If the scab is solid, it prevents deeper penetration, and the action can be confined to the desired areas.

Malignant tumors may be induced by prolonged exposure to a variety of irritant agents, such as radium, x-ray, ultraviolet radiation, polycyclic hydrocarbons, sex hormones, tumor extract, "butter yellow" dye, arsenic and viruses. The disposition varies for different agents, and the susceptibility differs greatly with individuals, chiefly by their genetic constitution, so that animal experiments should be made on pure-bred strains (fifteen generations of inbreeding in mice: C. L. Little, 1937).

Astringent Action.—Agents which are strongly precipitant produce relatively mild irritation; and if their concentration is not too high, their primary inflammatory effect does not proceed to necrosis; on the contrary, it leads to diminution of any existing inflammatory process. This "astringent" (drawing together) action is characterized by visible contraction of the tissue; blanching and wrinkling of mucous membranes; and diminished exudation, or secretion of mucus, according to the place of application. These agents also possess a peculiar "astringent" taste. The effects are probably due to precipitation and hardening of the cell surface and cement substance of the capillary endothelium, producing contraction and decreasing the permeability of the capillaries; and thus counteracting the essential phenomena of inflammation (congestion and exudation). Astringents are *used therapeutically* to check diarrhea, reduce inflammation of mucous membranes, promote healing, and to arrest hemorrhage (by coagulating the blood). They should not be employed in the early stages of bacterial invasion, when the inflammatory reaction is needed for defense. The *principal astringents* are: metallic salts, tannins, dilute acids and strongly hypertonic solutions.

Quantitative Estimation of Astringent Action.—This has been measured by Motolese, 1910, by noting the degree in which the extensibility of frogs' lungs is reduced after immersion in the astringent solution (Dreser's method). With 1 per cent solutions, the order was: silver nitrate > tannin > lead subacetate > picric acid > lead acetate > alum > zinc sulfate. Astringency may also be studied by the suppression of mucus secretion from the frogs' skin (Schuetz), and more simply by the tanning of blood corpuscles or even by quantitative precipitation of proteins (Sollmann, 1920). Heubner and Schreiber, 1937, describe the microscopic changes as seen by darkfield illumination.

Astringent Effects Are Strictly Local.—Since astringents are precipitated by proteins, they can not be absorbed or exist in the blood or tissues in effective form. Before this was understood astringent action throughout the body was attempted by external application or by giving astringents by mouth.

Astringents on Peristalsis.—In the *intestinal canal* the astringents form a deposit along the lumen of the intestine, and diminish absorption, the penetration of other irritant substances and peristalsis.

Irritation of Mucous Membrane.—Differences in detail are seen when irritants are applied to the mucous membranes. There is less tendency to vesication, since the epithelium is not impermeable. The oral mucous membrane presents a transition; it blisters, but less readily than the skin. Pustulation can not occur since this depends upon the cutaneous glands. The mucous glands are stimulated to increased activity, producing "*catarrhal*" conditions.

Gastro-Enteritis.—The actions of irritants on the alimentary tract present special features; the effects being stomachic, carminative, nauseant or emetic; diarrhea, dysentery; abortion; corrosion and perforation; according to the nature and degree of their action.

Respiratory Passages.—If an irritant poison is *volatile*, its main effects may be upon the *respiratory passages*. The general phenomena are those of acute laryngitis, bronchitis or pneumonitis. Similar effects follow the aspiration of nonvolatile irritants.

Local Irritation of Wounds and Ulcers.—The effects are usually more marked than on the intact skin. Even the milder irritants destroy the superficial cells, especially if diseased; but the deeper cells multiply more rapidly, partly through direct stimulation and partly through the hyperemia. Mild irritants therefore *promote healing.* Astringents, balsams, quinine, salts and even water have this therapeutic action.

Hypodermic injection of irritants produces more or less pain, and often aseptic abscesses or fibrosis. The danger of infection is considerable if the tissues are killed by the irritant. With intramuscular injection, the pain is less severe.

Irritant Effects after Absorption.—Many irritants are not absorbed; and even when absorption occurs they are too greatly diluted to have much effect, except at the place of their absorption and excretion; *i. e.*, the liver and kidneys. Other tissues are involved only if the administration is long continued, as in alcohol or lead poisoning. These may lead to increase of connective tissue, arteriosclerosis, hepatic cirrhosis, etc.

Drug nephritis is produced by all absorbable irritants and often occurs acutely. The inflammation may involve all the renal tissues, or it may be predominantly glomerular or parenchymatous, according to the poison. Continued administration leads to interstitial nephritis.

Phenomena.—The inflammation is characterized by albuminuria, casts and the histologic lesions. The urine flow is increased in the early stages, and decreased later (Schlayer and Hedinger, 1907). The excretory efficiency is diminished (Eisenbrey, 1911, 1913). The changes in nitrogen and chloride excretions are complex. The nitrogen excretion is decreased in tubular nephritis (uranium), not in glomerular (arsenic). Retention of nitrogen in the blood occurs especially in tubular nephritis (Foster, 1915). Renal glycosuria may occur (E. Franck, 1913; Pollak, 1911); also hepatic edema (Opie, 1912), and sometimes slight myocardial changes (Walker, 1911). Hemorrhagic nephritis is seen with cantharides, turpentine, formaldehyde, etc. Edema occurs only with uranium, at least in animals. The restoration of the blood volume afert saline injections is delayed in uranium. chromate and tartrate nephritis (Bogart. Underhill & Mendel, 1916)

Tubular nephritis with little or no primary glomerular injury is produced by uranium, chromate, mercuric chloride and aloin. The anatomic changes in the early stages of *uranium* and *chromate* nephritis are confined essentially to the tubules, especially the proximal convoluted, and consist of granular and fatty degeneration and necrosis. *Mercury* acts similarly, but mainly on the ascending loops of Henle, with deposition of lime salts. This occurs also with uranium and chromate, but to less degree (J. P. Simonds and Hepler, 1945). The glomeruli are at first unaffected, but later show thickening of the capillary walls, and vascular disturbances can be shown by physiologic methods

Glomerular nephritis, generally with some secondary involvement of the tubules, is produced by arsenic, cantharides and snake venom. Diphtheria toxin acts on all the structures; and many other irritants act diffusely. The anatomic changes vary according to the poisons. *Arsenic* produces little or no anatomic change, except dilatation of the capillary tufts, filling Bowman's capsules. Physiologic methods, however, show serious vascular injury. The *cantharides* changes involve both the glomerular tufts and space. The capsules are filled with desquamated cells, whose origin is disputed. There is also functional vascular injury. The functional changes are not proportional to the anatomic.

Chronic nephritis is difficult to produce experimentally, the acute experimental lesions usually ending in rapid and complete recovery. Positive results have been obtained by Ophuls with lead, by Dickson with uranium, and by Klotz, 1914, with infections.

Aging Process and Tissue Resistance.—Recovery from hepatotoxic agents, such as uranium, mercuric salts and chloroform, is effected by regeneration of less specialized but more resistant cells. This regeneration is less effective in senile than in young animals (review, MacNider, 1942).

Reflex Effects of Irritants.—Stimulation of sensory areas acts reflexly on the vasomotor, cardiac, respiratory and other centers, producing changes in the circulation, respiration and other functions. These vary with the place, extent, speed, intensity and kind of stimulation, and with the state of the centers. They are used in therapeutics, especially for "counterirritation."

Consciousness may be restored by counterirritation, in fainting, light coma and narcosis. The usual measures for this purpose are dashing with cold water, slapping with wet towels, or inhalation of dilute ammonia vapor (smelling salts or aromatic ammonia).

The Respiratory Reflexes.—If the respiratory center is depressed, as in collapse, morphine poisoning, anesthesia, asphyxia, etc., moderate counterirritation produces marked stimulation; and if the collapse is not too deep, natural respiration may be restored (Meissner, 1923). *If the respiration is normal,* mild cutaneous irritation may either slow or quicken the rate. If the irritation is strong, the respiration is always slowed. Sudden and extensive stimulation, as by cold douches, produces momentary standstill, followed by deep inspirations. Continued painful stimulation causes deeper and often faster breathing Hanzlik, 1923, utilized the respiratory response as an index of local irritation.

Circulation.—Local irritation gives rise to augmentatory and inhibitory vasomotor and cardiac reflexes. Heat causes general vasodilatation of the skin, while cold results in constriction. *Mild tactile stimulation* (for instance, blowing on the skin) also tends to produce widespread vasoconstriction and therefore some rise of blood pressure (Gruetzner and Heidenhain, 1877). Reflex vasoconstriction involves mainly the cutaneous vessels, except those which are dilated by direct contact with the irritant. The renal vessels are also constricted, while those of the brain are dilated (Wertheimer; Roy and Sherrington). The heart rate is quickened (Naumann). The tactile and auditory constrictor reflex occurs only if the brain is intact, *i. e.*, it requires psychic stimulation; the heat and cold reflexes persist after decerebration. *Stimulation of sensory nerves, if weak or slow, i. e.,* of the kind to evoke reflexes of the voluntary muscles, tends to produce vasodilatation and fall of blood pressure, seen most typically with the depressor nerve. It involves inhibition of the vasoconstrictor tone, stimulation of the vasodilator innervation, and stimulation of the cardiac inhibitory center (Bayliss, 1908). *Strong stimulation of sensory nerves* produces vasoconstriction and rise of blood pressure, increasing with the intensity of the stimulation, which must be twenty to 200 times that which suffices for the depressor response (Stiles and Martin, 1915). This is also the primary response of *pain.*

Reflex Shock.—If strong stimulation is prolonged, especially if the subject is conscious, the rise of pressure is followed by fall of blood pressure and internal temperature, especially if there is violent pain, in connection with extensive corrosion. Different mechanisms may be concerned. The heart may go into fibrillation by disturbance of conduction, the response of the vasomotor centers may be inverted by the psychic impulses or by exhaustion, and in corrosion, toxic shock may develop by the absorption of the proteolytic products.

Hypodermic Injection of Mild Irritants.—The injection of ether, camphor, whisky or oil of turpentine generally produces a slight and transient rise of blood pressure; the effect differing quantitatively according to the site of the injection, being, for instance, greatest from the nasal septum. It fails when the vasomotor center is depressed, as in deep anesthesia, shock or hemorrhage (Lieb and Herrick, 1917).

Gastro-Intestinal Irritation.—Sollmann, Brown and Williams (1907) showed that irritation of the stomach or peritoneum has practically no early effect on the blood pressure in anesthetized animals, even when the anesthesia is light. There is generally a marked increase of respiration, and sometimes a slight and momentary rise of blood pressure, but no fall is noticed for several hours. This holds true both for mild irritants, such as peppermint, mustard or moderate heat, and for strong corrosion by formaldehyde, concentrated acids or actual cautery, even when these measures produce perforation. *Irritation of the mouth and larynx* produces very much more marked effects (Sollmann); even contact with 5 per cent acetic acid causes struggling, convulsive rise of blood pressure and dyspneic respiration.

Volatile Irritants on Blood Pressure.—The vapors of strong smelling substances, when applied to the nose of rabbits, raise the blood pressure; but lower it when applied to the trachea. Both effects are reflex (Yamada, 1920).

Carotid Sinus Reflexes.—Various drugs provoke respiratory, circulatory or other reflexes on contact with the chemical receptors of the carotid glomus, but their action is by specific stimulation, not by general irritation (C. Heymans *et al.*, 1932; Comroe and Schmidt, 1937).

Renal Reflexes.—Heat (diathermy), cold, and cutaneous irritants (mustard, capsicum, cantharides, ultraviolet erythema) applied to the lumbar dorsal region cause reflex diuresis, which may be prevented by cocainization of the area, or by removal of the kidney on that side (Brings and Molitor, 1932). Irritation of the urinary bladder by irrigation with 7.5 per cent resorcin or 2.5 per cent collargol, or by overdistention with water, retards renal secretion. This is prevented by anesthetizing the bladder with procaine (Bebeshina and Konradi, 1934).

Counterirritation.—Irritation of the skin may relieve inflammation in deeper seated structures, diminishing the pain and probably the congestion, and perhaps leading to an earlier and more conservative termination.

This treatment by "counterirritation" was employed more extensively by the older physicians, who imagined that the dilatation of the skin vessels would draw the blood out of the neighboring vessels, and so "deplete" the congested area by a direct "derivative action." This crude mechanical conception had to be abandoned as the anatomy and physiology of the circulation became better known. The fact of such "action at a distance," however, may be definitely shown: Cold applied to one hand constricts the vessels of both hands, and heat dilates them (G. N. Stewart, 1913), while irritation of the hand by mustard does not increase the local blood flow, as might be expected from the rubefaction (Wood and Weisman, 1912; Hewlett, 1913); nor is the skin temperature increased by mustard or turpentine rubefaction (N. B Taylor, 1923).

The effects of counterirritation are due mainly to nervous reflexes, partly sensory and partly vascular. The sensory vasomotor reflexes which have been described, like reflexes in general, exhibit the predilection for the homologous nerve paths, *i. e.,* a quantitative localization of the response to definite areas. They are the reversal of the "referred pain," which occurs in definite skin areas when the corresponding viscera are irritated (Head). This explains the empirical observation that counterirritation is most effective when applied at a definite place for each internal inflammation.

The relief of pain by counterirritation is explained partly by homologous reflexes, and partly by the diversion of the attention of the patient from the disease pain, to the usually more bearable sensations of the counterirritant.

Influence of Pain on Inflammation.—According to some observers, the response to chemical inflammation may be diminished or abolished by local anesthesia or central analgesia. Others have failed to find anything more than the normal individual variation.

Bruce, 1913, reported that mustard oil failed to produce conjunctival congestion and edema (chemosis), if the sensory fibers were degenerated, or paralyzed by local anesthetics. The observations were confirmed by Januschke and Bardy, 1914, who also claimed that the inflammation was prevented by nicotine, and that therefore the phenomena involved the sympathetic synapse. Others, however, believed that spinal reflexes were involved, especially as central analgesics, such as ether and morphine, were also said to be effective. Similar results were claimed for calcium chloride, antipyrine, quinine, salicylates, cinchophen, bromides, etc., and substances yielding available oxygen (Amberg, Loevenhart and McClure, 1917). On the other hand, H. H. Stevenson and Reid, 1915, reported that neither nerve degeneration nor local anesthesia influenced the ordinary course of mustard oil chemosis. Morphine and chloral tended to prevent the edema, but only in toxic doses, and presumably as a result of the circulatory collapse. They call attention to the fact that patients with degenerated nerves, with hysteria and with central anesthesia all react to cantharidin vesication. Hanzlik *et al.* showed that paraphenylenediamine edema is not influenced by the analgesics and anesthetics, but only by agents that markedly restrict the local circulation.

Changes in the Blood.—Irritation of the skin produces changes in the blood which may influence inflammation: Winternitz, 1896, found at first *leukopenia*, then *leukocytosis*. Van den Velden, 1912, claims that the coagulability of the systemic blood is increased by a number of local irritant and especially vasoconstrictor processes (ice to the skin; astringents or epinephrine to the mouth; cocaine to the nose; turpentine inhalation, etc.).

Therapeutic Indications of Cutaneous Irritation.—This is employed mainly in the following conditions: (1) *In certain skin diseases*, for the local effects—alkalis, sulfur, chrysarobin, etc. (2) *To promote diaphoresis*—alcohol, friction, heat, etc. (3) *For reflex stimulation of the central nervous system*, in fainting, collapse, narcotic poisoning, accidents of anesthesia, etc.—ammonia inhalation, heat or cold. (4) *To alter the distribution of blood*, to prevent colds—mustard; to relieve congestion of viscera—poultices, vesication; or to promote the absorption of exudates—iodine, vesication. Counterirritation is, as a rule, useful only in chronic inflammation. In acute inflammation there is danger of increasing the process or of causing it to extend to neighboring organs. (5) *To diminish pain*, especially in neuralgic and rheumatic affections—turpentine and other volatile oils, capsicum, chloroform. (6) *As a general tonic*, in the form of salt-water baths or alcohol frictions.

Therapeutics of Cauterization.—Cauterization is sometimes employed for severe *counterirritation*, but particularly to *remove tissue:* (1) In cases of poisoning, snake bite, etc.; (2) for the removal of pathologic tissue, tumors, warts, etc.; (3) indolent granulations, etc.; (4) to cause cicatricial contraction of hypertrophied mucous membranes (nose, etc.); (5) for removing the nerves of teeth; and (6) to remove superfluous hair. In many cases chemical cautery has been replaced by galvano- and thermocautery, which are more prompt and permit a more exact limitation of the cauterized area. On the other hand, the slower effect of chemical caustics is of advantage in permitting a graduation in the strength of the action, or in confining it to certain tissue elements. Pathologic formations, with poor blood supply, are in this way more profoundly altered than normal tissue. The caustics may be applied in solid form (sticks, or fused at the end of a probe), in paste or in solution—the first being the most strictly localizable, the last the most diffuse. In the latter case, or when the tissue liquefies, the surrounding skin should be protected by petrolatum.

GENERAL TOXICOLOGY OF IRRITANTS

The phenomena produced by irritant poisons depend on the part of the body with which they are brought into immediate contact. The most prominent symptoms arise from the skin, alimentary canal or respiratory organs; the last only in the case of volatile poisons. Later symptoms may appear in the urinary organs. The extent of the action depends on the concentration of the poisons, the time during which they act, and the extent of surface with which they come into contact—less upon their absolute amount. If taken by the alimentary canal, their action is modified by the presence of food.

Cauterization of the skin may be accidental or criminal. In the latter case it is often by sulfuric acid ("vitriol"). The *results* are the same as in extensive burns. The *diagnosis* usually offers little difficulty. The character of the stains is that described in the next section. Enough of the corrosive can generally be collected from the clothing, etc., to establish its identity by chemic means. The *treatment* is like that for burns, after previous neutralization and removal of the corrosive agent. Salves and oils are useful.

Caustics in the eye are best washed away by liberal application of water. Attempts to neutralize acids or alkalis generally increase the injury (Cosgrove and Hubbard, 1928).

Irritant Poisons in the Alimentary Canal.—The phenomena differ according to whether the irritant produces actual cauterization—a destruction or solution of the tissues—or only inflammation.

Irritants which Do Not Destroy the Tissue.—To this class belong elaterium, croton oil and most other organic irritants, such as volatile oils, formaldehyde, etc. The symptoms are those of a violent *gastro-enteritis:* nausea, vomiting and diarrhea. If the poison acts only when dissolved, and is insoluble in the stomach, as is croton oil, the nausea and vomiting may not be present, only the diarrhea. The symptoms appear correspondingly late. The abdomen is usually distended and painful, especially on pressure. There is extensive dilatation of the splanchnic vessels and withdrawal of blood from other parts of the body. This produces marked changes in the circulation. The pulse is soft, small and quick. The *lowered circulation* reacts upon other organs, and most conspicuously upon the *central nervous system.* There is great anxiety, vertigo, delirium, convulsions, then *collapse,* and finally coma and death. This picture is common to the entire series of irritant poisons. All the abdominal organs partake in the hyperemia, although they do not come into direct contact with the irritant. The organic irritants, especially oil of savin, of tansy and of pennyroyal, have been used to procure criminal *abortion.* The ecbolic effect is secondary to the gastro-enteritis, which is often fatal without accomplishing the object for which it was produced. *Postmortem appearances* consist in intense congestion of the entire alimentary canal, often with inflammatory exudate into the lumen of the intestine. The congestion may be so violent as to produce ecchymoses. If these are present, the vomit and stools are tinged with blood during life. Destruction of tissue is rare. It may occur from gangrene due to the interference with the circulation.

Fixed Caustics.—The most important are the mineral acids; oxalic acid, which, however, stands apart on account of its specific toxic action; other organic acids, the alkalis and their carbonates; the haloid substances, bromine, chlorine and iodine. Phenol and the metallic salts are also to some extent corrosive, but not usually enough to produce perforation. The alkalis and bromine produce the most extensive destruction of tissue, because of their deep penetration. With them, the scar formation is also the most extensive. *Corrosive effects* occur especially in those situations which are in prolonged contact with the caustic: the lips; mouth and pharynx; esophagus at its beginning and end, and where it crosses the left bronchus; and the stomach, especially the pyloric end (because the caustic follows the lesser curvature and accumulates at the pylorus). The firm closure of the pylorus furnishes more or less protection to the intestines. The *appearance of the corrosions and stains* is of diagnostic importance, since they may be recognized about the mouth during life: Alkalis cause transparent swelling of the epithelium, which may detach as a gelatinous mass, exposing the scarlet-colored inflamed area beneath. The other corrosives, which precipitate proteins, produce at first a grayish-white opaque stain. This persists in the case of the metallic poisons. The acids change the hemoglobin in the neighboring area into the dark acid hematin, and the color of the stain consequently becomes dark or black. Nitric acid is an exception: its stain takes on a yellow color. This differs from that of picric acid by being changed to orange by alkalis, while the picric acid stain remains unaltered. Bromine produces a light brown or orange stain; iodine stains a mahogany color. The silver stain turns black after a time.

The symptoms of corrosive poisoning begin in the mouth, with burning pain, dysphagia and loss of tissue. The *taste* of many of the substances is characteristic—acid, alkaline, metallic, astringent, etc. The further symptoms are those of gastro-enteritis, similar to those described under noncorrosive irritants, but generally more severe. The vomiting and diarrhea are more frequently bloody. In the case of acids the vomited blood is darkened by acid hematin, the so-called "coffee-grounds" vomit. The pain is much more marked with corrosive poisons. The destruction of the tissue gives rise to reflexes which may take the form of "shock." The absorption of the chemic products of corrosion may produce fever; or the temperature may be lowered by collapse. If perforation occurs, the clinical picture turns into that of peritonitis. *Death* may occur from shock before the local symptoms have time to develop, it may follow after one or two days of more gradual collapse, or it may result later from peritonitis; or finally, after recovery from the acute effects, the formation of *scar tissue* in the corroded areas may lead to stenosis and thus to gradual starvation. *Postmortem examination* shows stains and corrosions in the mouth, esophagus, stomach and duodenum; with the metallic corrosives, the cecum and large intestines may exhibit the principal changes, since many metals are excreted in these situations. When the action has not progressed to actual corrosion, there is often marked hyperemia and ecchymosis. The color may be much darker than corresponds to the amount of congestion, especially in the case of acids (due to acid hematin).

Treatment of Poisoning by Corrosives.—The first measure is *dilution*, drinking of water and washing out the stomach. If corrosion is already advanced, it is not advisable to pass a stomach tube. The further treatment consists in the administration of *demulcent* substances, such as mucilage or boiled starch, white of egg or milk. Proteins are useful against the metallic poisons, since they form rather insoluble albuminates. The pain may require *narcotics* in free doses. Most of the irritant poisons can be treated by *chemic antidotes; alkalis*, by acids (vinegar, lemon juice or any acid diluted to 1 to 5 per cent); *acids*, by noncorrosive alkalis, preferably magnesium oxide. The free alkalis are usually too caustic, and the carbonates involve danger of rupturing the corroded stomach by the evolution of carbon dioxide gas. Potassium compounds are objectionable because of the danger of toxic absorption from the corroded mucosae. In case of necessity any alkali may be used, such as whitewash or chalk. *Iodine, chlorine or bromine* may be neutralized by sodium bicarbonate.

After the immediate emergency, the esophagus and stomach should be rested to prevent stricture by scarring, and to avoid bacterial decomposition. Instead of drinking water, 5 per cent dextrose should be administered by rectum. Oral feeding should be restricted to olive oil, a teaspoon to a tablespoonful at intervals to a total of 200 cc. per day. This is also protective. Other feeding should not be begun until healing has started, as judged by the visible mucosae, and it should remain soft and liquid till healing is completed (Leschke).

FIXED ALKALIS

These include sodium and potassium hydroxide, which corrode even the skin; quicklime, which because of its limited solubility is caustic only when used in substance; the carbonates of sodium and potassium, which are not caustic, but produce inflammation and necrosis; and the mildly alkaline salts, such as the bicarbonates, borates and basic phosphates, which merely soften the epithelium. The free alkalis combine with the tissue elements to form alkaline albuminates, or with the fats to form soaps, and in this way destroy the substance. They are also hygroscopic, and withdraw water from the cells, which contributes to the necrosis. They gelatinize the tissues. The scab which they produce is soft, and the compounds they form are soluble; consequently the alkalis penetrate deeply, are very painful, and their action continues for several days and leads to extensive scar formation. It is therefore difficult to circumscribe their effects.

This is only partly remedied by mixing them with the nondiffusible quicklime as in the "*Vienna Paste*," a mixture of equal parts of KOH and CaO, stirred into a thick paste with alcohol. Chemical "*hair straighteners*" consist generally of sodium hydroxide (about 6 per cent), which may cause severe burns if it remains on the skin (F. Lewis, 1939).

Poisoning by caustic alkalis (*lyes*) is common. Half an ounce of potassium carbonate would generally be fatal. Sodium carbonate is less toxic. On account of the deep action, *stricture of the esophagus* is a frequent sequel, and the fatality is fairly high. The *treatment* consists in dilution with large quantities of water, to which vinegar, lemon juice or other dilute acid should be added. This should be followed by a tumbler of olive oil or other salad oil. The further treatment is described under Corrosive Poisoning.

Cement burns are caused by quicklime. The immediate treatment is washing with water. They form tough scabs adhering firmly to the underlying tissue, with necrosis progressing underneath. A soothing ointment should be applied for twenty-four hours to loosen the scab, leaving a clean ulcer. Petrolatum may be used for prophylaxis (Meherin and Schomaker, 1939).

Dilute alkalis on the skin soften the epidermis and hair, and emulsify and dissolve fats. They are employed in skin diseases (seborrhea, acne, ichthyosis, psoriasis and epidermal proliferations); to facilitate the penetration of antiseptic remedies into the skin (in scabies, favus, ringworm); to emulsify cutaneous remedies (mercury, tar, sulfur); as lubricants for liniments (soap liniment); as cleansing agents (detergents), especially in the form of soaps and borax; and as depilatories (especially the sulfides). Application of sodium bicarbonate deodorizes hyperidrosis (J. H. Lamb, 1946).

Alkaline baths, used in skin diseases, are best administered at bedtime; sodium carbonate or bicarbonate, potassium carbonate, or borax, in the proportion of about 100 Gm. per bath; for lotions, 2 per cent. *The internal actions and uses* are discussed in another section (see Index).

The "actual" or immediately effective alkalinity of a solution depends on the dissociated OH ions; but as these combine with the tissues, further OH ions are split off ("potential" alkalinity), which continue the action. The total effect, therefore, depends upon the total quantity of OH ions which can be split off under the conditions of the body (Dreser, 1910).

PREPARATIONS.—*Potassium Hydroxide*, U.S.P. (Caustic Potash), KOH, and *Sodium Hydroxide*, U.S.P. (Caustic Soda), NaOH, occur as white masses or pencils, very soluble in water and in alc. They are used as caustics, to remove warts, etc., and to soften epidermis (2 per cent). *Monohydrated Sodium Carbonate*, U.S.P., $Na_2CO_3.H_2O$, is freely sol. in water (1:3) and glycerin, insol. in alc. Used as lotion (0.5 per cent). Dose, 0.25 Gm., 4 grains, diluted. *Washing Soda* contains 10 molecules of water and is about half as strong as the monohydrated. *Potassium Carbonate*, U.S.P. (Salt of Tartar), K_2CO_3, is also very sol. in water and practically insol. in alc. Dose, 0.12 to 1 Gm., 2 to 15 grains, diluted.

Lime Solution, U.S.P. (Liquor Calci Hydroxidi; Lime Water), is a saturated solution (about 0.14 per cent) of *Calcium Hydroxide* (Slaked Lime, $Ca(OH)_2$) prepared from Calcium Oxide. A clear, colorless, odorless liquid, of alkaline taste; *incompatible* with carbonates and "hard" water. Used as antacid, against diarrhea, and externally against burns. It is often added to milk (1:4). Dose, 15 cc. (to 120 cc.), 4 drachms (to 4 ounces). *Lime Liniment* (*Carron Oil*) is an emulsion of equal volumes of lime water and linseed oil. Applied to burns, on cloths, frequently removed. *Unslaked lime* (Quicklime, CaO) is used for disinfecting excreta, adding enough so that the mixture boils; or, less effectively, by slaking the lime with four parts of water, adding this to the excrement in equal volume, and letting stand for two hours before disposal. *Whitewashing* with lime disinfects walls.

AMMONIA

This differs from other alkalis by its volatility. It passes through the stratum corneum of the epidermis and, acting upon the lower layers of the skin, may produce blisters. It is sometimes used for this purpose instead of cantharides, especially in nephritis, where the latter can not be employed. It is, however, more painful. It is used in more dilute form as liniment for counterirritation. *The inhalation of ammonia*, free, or in the form of the aromatic spirit, or of carbonate, is used for reflex stimulation in fainting, etc. Care must be used, since too high concentrations of the vapor may produce bronchitis or pneumonia. For man, it becomes insupportable in the concentration of 1:1000.

Poisoning by swallowing ammonia presents the same phenomena as other caustic alkalis except that the respiratory passages are more involved by the inhalation of the vapor. Five to 10 Gm. of the official solution would be toxic; 30 Gm. is generally fatal, although recovery has occurred from 60 Gm. The *treatment* is the same as for fixed alkalis.

Ammonia burns of the eye should be washed, and the anterior chamber should then be drained by paracentesis, or the absorbed ammonia may destroy the vitreous humor and retina, causing permanent blindness.

For *Preparations*, see Index.

SOAPS

These are alkali salts of fatty acids which dissociate readily so that they act both as mild, noncorrosive alkalis and as fatty acids. Their actions are due chiefly to their high surface affinity and to the formation of tough surface films, by which they emulsify fats. They are therefore detergent. They tend to sterilize the skin by the mechanical removal of bacteria. They also alter the protective surface membranes of the bacteria, but are unreliable as direct germicides. They irritate wounds and so actually increase infection; green potash soap more than white (L. W. Peterson, 1945). Their efficiency is not materially increased by incorporating other antiseptics (Morton and Klauder, 1944). Red blood cells are hemolyzed. The lubricant properties of soap are utilized in liniments that are applied by friction. Soap may be used in skin diseases, similarly to the alkaline salts. On mucous membranes and exposed surfaces, soap is markedly irritant. It is emetic if swallowed. In the rectum, soap secures prompt evacuation. It is used for this purpose as warm soapsuds enemas; or solid, formed into a suppository. Sodium morrhuate is used as a sclerosing agent, especially for varicose veins. *Triethanolamine* combines with fatty acids to form soaps of high emulsifying power. In the newer detergents the fats are replaced by sulfonation products or sulfates of fatty oils, acids or alcohols.

Detergents are classed as (1) *anionic*, soaps, R—COONa; alkylsulfates, R—OSO$_3$Na; (2) *cationic*, substituted ammonium salts, $R_4{\equiv}N$—Cl; (3) *nonionic*, condensed glycol esters ("Medical Uses of Soap," symposium edited by Morris Fishbein, 1945, Lippincott).

Soaps appear to have been used by the Gauls and Germans before they were employed by the Romans and Greeks. They were known, however, when Pompeii was destroyed in 79 A.D.

The detergent action of soaps is due to the mechanical effect of the foam, the emulsification of the grease, and the softening of the epidermis, so that the superficial layers are readily removed with the adherent dirt.

Cleansing creams remove most easily what is soluble in the external phase of their emulsion.

Antiseptic Action.—Strong soap solutions are fairly antiseptic. Even weak solutions are rapidly fatal to *Treponema pallidum* (Reasoner, 1917). J. W. Walker, 1931, found soaps not germicidal for staphylococci or typhoid and spore-forming organisms, but markedly so against the organisms of respiratory infections, gonococci, streptococci, pneumococci, meningococci, diphtheria and influenza. Hot water (35° C.) nearly doubled the potency. J. F. Norton, 1920, found that ordinary soaps remove bacteria from the hands more effectively than the special antiseptic soaps, and pointed out that the addition of germicides would not be effective under practical conditions. White soap and ether are the least injurious *detergents for burns and wounds.* Tincture of soft soap, 95 per cent alcohol, and hydrogen peroxide solution produce superficial necrosis of the cells. Tannic acid and silver nitrate cause deeper necrosis (Z. Baker, 1944). *Phagocytosis* is stimulated by soaps, even in fairly high concentrations; but excessively strong solutions are detrimental (Hamburger and de Haan, 1913).

Intra-uterine injection of soap has been used to induce abortion, but is dangerous. Severe and sometimes fatal effects have been described; profound hemolysis, pulmonary embolism, generalized septicemia, local inflammation and its sequels, total occlusion, peritonitis, circumscribed necrosis of uterine tissue, severe and continued bleeding (Tilcher, 1932).

The chemistry of soaps is not fully understood. The molecules of all active detergents contain both hydrophilic and lipophilic radicles which cooperate in emulsification. The *lipophilic radicle* is a hydrocarbon. The hydrophilic radicle of soap is COONa; in the sulfates the COO is replaced by OSO$_3$; in the sulfonates by SO$_3$ (Land and Black, 1942). The sodium soaps are generally solid, potassium soaps gelatinous. Both form clear solutions with alcohol and more or less turbid colloidal solutions with water. Water hydrolyzes part of the soap into alkali (NaOH) and "acid soap," the latter in colloidal solution or suspension. Its nature is not quite clear, but it is probably chiefly of the pattern NaHR$_2$. The "acid soap" remains suspended as an electro-negative colloid (Diasio, 1934). The degree of hydrolysis increases with dilution and depends also on other conditions. It does not exceed 6 per cent, even with laurate, the most dissociable soap. In alcoholic solutions it exists chiefly as unhydrolyzed electrolyte. Because of the limited hydrolysis, the alkalinity of soap solutions is quite low, generally about $\frac{1}{1000}$ N (corresponds to 5 per cent of hydrolysis in a 1 per cent soap solution); never above $\frac{3}{100}$ N. Higher alkalinity would be due to free alkali (Beedle and Bolan, 1921). Soaps with the largest carbon chains are the most hydrolyzed or alkaline. The alkalinity is decreased by moderate amount of sodium salts, and by lowering the temperature (review, L. D. Edwards, 1939). The concentration of soap in thick lather is about 8 per cent; in dishwashing and laundry solutions it is about 0.3 to 1 per cent.

The hemolytic action of soaps reaches a maximum at a certain *p*H, generally near to neutrality, which is characteristic for each fatty acid, and decreases on the acid and especially on the alkaline side. It is therefore not due to the alkali, but to the fatty acid molecule, acting presumably as acid-soap. This is quite different from *foaming*, which increases with alkalinity; and as foaming is due to decreased surface tension, this must be due to neutral soap. At the optimal *p*H, the hemolytic potency of the soaps decreases in the *sequence* of laurate, myristate, palmitate and stearate; but at their natural *p*H, the hemolysis increases with the length of the carbon chain of saturated fatty acids. Unsaturated acids are more hemolytic, proportional to the number of double bonds. Potassium and sodium soaps have similar hemolytic values (L. D. Edwards, 1939; Buckendahl, 1933; Hettche, 1934). Erythrocyte destruction *in vivo* is increased by the intravenous injection of even very small quantities of soap or fatty acid (5 mg. per Kg.). It is estimated from this that the food fat is responsible for one-twelfth to one-third of the daily erythrocyte destruction (Freeman *et al.*, 1944). *Arbacia ova* are cytolysed by soap solutions between *p*H 6 and 9; the maximum being toward the alkaline end for oleate and linoleate, toward the acid end for ricinoleate (I. H. Page *et al.*, 1932). *The toxicity for earthworms* decreases in the direction of laurate, myristate, oleate, ricinoleate, palmitate, stearate (Edwards, 1939). *Blood coagulation* is prevented by the addition of small quantities of soaps, 3 mg. of sodium stearate or 10 mg. of sodium oleate per liter of blood diluted to two-thirds. Calcium does not inhibit the effect, although it is slightly weakened (Rabbino, 1927). The proteolytic action of trypsin is inhibited by small amounts of soap (R. L. Peck, 1942).

Skin irritation (eczema) by soap appears to be less common than is ordinarily supposed. Even patch tests with .1 per cent solution gave only 14 per cent of positive reactions, and these generally mild. They depended on the added antiseptics and on the nature of the fatty acid, the alkalinity playing a minor role. Ordinary household soaps were found no more alkaline than the best toilet soaps (Beedle and Bolam, 1921). Even "laundry" soaps are probably no more irritating, except by the prolonged contact. "Superfatting" of soaps has no advantage (Land and Blank, 1942). Workers in soap industries do not commonly develop dermatitis.

The percentage of positive reactions was inverse to the molecular weight of the saturated fatty acids. Oleate ranked with saturated acids of high molecular weight. Coconut oil soap (which gives a stiff lather) had a somewhat higher percentage. Hypersensitivity to soap is usually acquired. Newborn infants react less frequently than older infants and children. Patients with contact dermatitis and with allergies react more frequently (J. W. Jordan *et al.*, 1936; I. H. Blank, 1939). With prolonged application of 0.0225 N solutions, B. E. Emery and Edward, 1940, found that soaps from oils containing lauric and myristic acid are the most irritant; but castor oil soap was also relatively irritant. Potassium soaps are generally more irritant than sodium soaps. Sodium alkyl sulfites are less irritant than the Na or K salts of the fatty acids; lauryl and myristicyl are also the most irritant of this series.

Soaps and Other Dental Detergents.—The effects on the ciliary activity of the epithelium of frogs' esophagus were studied by R. L. Perrine *et al.*, 1939, as an index of protoplasmic and epithelial injury. Hard soaps and sodium alkyl sulfates averaged about ten times more toxic than perborate or borate, but various soaps differ considerably. Aromatic oils and camphor in saturated water solution have little effect.

"Soapless soaps" consist of sodium or triethanolamine, $N(C_2H_4OH)_3$, salts of sulfated or sulfonated alkyl derivatives of higher alcohols from fatty acids; for instance, $R.C.O.SO_3Na$ (sulfated) or $R.C.SO_3Na$ (sulfonated), with various modifications. The sulfates are made by heating the oil with sulfuric acid at about 50° C.; higher temperatures produce the sulfonates. They were introduced as detergents by W. Schrau, 1931. They lower surface tension in much greater dilution than do ordinary soaps. They have a neutral reaction, do not turn rancid on standing, and do not precipitate with the calcium and magnesium of "hard" water. They are used for laundry, shampoo and dentrifices (sodium laurylsulfate and sulfacetate; Epstein *et al.*, 1939). They foam so freely that they are employed in about a tenth of the customary concentration of soap. "*Turkey red oil*" consists of ammonium salts of sulfated castor oil. They are also employed to aid absorption through the skin and as thrombotic agents for varicose veins. Some carry positive and others negative electric charges. Higher germicidal potency is claimed for the cationic detergents (Baker *et al.*, 1941). They are less irritant than soap to the skin (Emery and Edwards, 1940), but more irritant to mucous membranes (and also to ciliated epithelium) in equal concentrations, but less so in the lower concentrations in which they are used. As powders they are highly irritant. Hypodermic and intramuscular injections even of 1 cc. of 0.01 per cent of sodium laurylsulfate ("Duponal") produces local necrosis. Intravenous injection causes fall of blood pressure and depression of respiration (Macht, 1944). Continued ingestion of large doses of laurylsulfate by rats is more toxic than ordinary soap, resulting in degenerative changes in the intestinal mucosa, liver, and kidneys (Hatton *et al.*, 1940). They have been used, however, in the treatment of gastric ulcer, since relatively high dilutions denature pepsin *in vivo* and *in vitro*. Doses of 0.2 Gm. every two hours were administered without toxic symptoms, and with symptomatic relief in two-thirds of the patients (Fogelson and Shoh, 1944; Kirsner and Spitzer, 1944).

PREPARATIONS.—***Hard Soap,** U.S.P. (Sapo Durus), is a soda soap; occurs as a solid; slowly sol. in water and alc. ***Medicinal Soft Soap,** U.S.P. (Sapo Mollis Medicatus, *Green Soap*), is a potassium soap made from vegetable oils without removal of the glycerin. It occurs as a translucent, yellowish, unctuous mass. *Liniment of Soft Soap,* U.S.P. (Tincture of Green Soap), is a 2:1 solution of soft soap in alcohol, perfumed with lavender oil. Since the soap does not hydrolyze in alcohol, it is a less effective detergent than water solutions. *Camphor and Soap Liniment,* U.S.P. (Soap Liniment; Opodeldoc), is a solution of hard soap (6 per cent), camphor (4.5 per cent), and rosemary oil (1 per cent) in 65 per cent alcohol.

Sodium Laurylsulfate, U.S.P., is a mixture of normal sodium alkyl sulfates, chiefly sodium laurylsulfate. It is soluble in water (1:10), forming an opalescent solution.—*Triethanolamine,* U.S.P., $N(C_2H_4OH)_3$ (with some mono and diethanolamines in the technical grades usually employed) combines with fatty acids to form nearly neutral detergent soaps which are soluble in water, alcohol, fatty oils and lipoid solvents, only slightly in petroleum oils. It is used in ointments as an emulsifying agent. *Benzylam Chloride,* U.S.P. (*Zephiran Chloride*), is a mixture of alkyl benzylammonium chlorides, which lowers surface tension and acts as detergent similar to soap. It is used as a disinfectant. Its toxicity is low, but it is irritant in concentrations above 1 per cent.

SODIUM MORRHUATE AND OTHER SCLEROSING SOLUTIONS

The sodium soap of the unsaturated fatty acids of cod liver oil is used to destroy the endothelium and to set up localized sclerosing inflammation for the obliteration of varicose veins, by injecting these with a 5 per cent solution of soap, containing also 2 or 3 per cent of benzyl alcohol as local anesthetic. Other irritant agents are used for the same purpose. The solutions are also employed for the obliteration of vascular birthmarks (Kaessler, 1938), and for closing the hernial canal The latter procedure is often ineffective, generally dangerous, and should be restricted to special indications.

Varicose Vein Injection by Sodium Morrhuate.—A 5 per cent solution, with 2 per cent of benzyl alcohol, is marketed in ampuls of 2 and 5 cc. The first injection should be 0.5 cc. of 5 per cent solution, to test for hypersusceptibility. If no bad consequences ensue in twenty-four hours, further injections may be made, usually of 1 cc. and not more than 2 cc. at one site. The total amount injected at a sitting should not exceed 2 to 5 cc., the injections being repeated at intervals of three to seven days. The veins begin to harden in a few minutes and become firm within twenty-four hours. The leg is then firmly bandaged. The sclerosis usually extends 2 to 4 inches below the site of injection. Toxic effects are rare, but collapse has been reported (M. L. Dale, 1937). The injection is usually painless if benzyl alcohol is added; otherwise there may be muscular cramps. Painful infiltration about the vein may last for seven to ten days. Extravasation must be avoided, but does not usually cause gangrene (T. T. Higgins and Kittel, 1930; R. A. Cutting, 1926; F. L. Smith, 1932; W. Cooper, 1933). Solutions stronger than 5 per cent should not be employed; 10 per cent has caused suppurative phlebitis and fatalities.

Other solutions employed for sclerosing veins by the same technic are: dextrose, 50 per cent; dextrose, 25 per cent, with sodium chloride, 15 per cent; invert sugar, 60 and 75 per cent; quinine dihydrochloride, 13 per cent, with urethane, 6.5 per cent; also ethyl alcohol, sodium iodide, iron salts, mercuric chloride, sodium citrate, quinine and urea hydrochloride, sodium salicylate, which is said to be very painful. Dextrose and invert sugar are least liable to produce sloughing if they escape from the vein. *Invert sugar solution* is marketed in ampuls of 6 Gm. and 7.5 Gm. in 10 cc., injecting 5 to 20 cc. of the solution. *Experimental investigations* on dogs with twenty-nine sclerosing solutions gave the most effective thrombus formation with sodium morrhuate. Destruction of the venous endothelium is the chief factor in the production of the thrombus (A. Ochsner and Mahorner, 1934). *In perfused vessels* (rabbit's ear and frog's leg) very dilute solution of soap (1:11,000 in Ringer's solution) causes intense vasoconstriction, not inhibited by atropine, but prevented by the serum colloids, and by *p*H below 6 (W. Ludwig, 1927).

The injection treatment of hernia consists in the production of fibrosis by repeated local injections of sclerosing solutions, which should be "tissue stimulating" but not irritating. Soap solutions appear best; powerful sclerosing solutions, such as are used in varicose veins, should be avoided. The treatment should be employed by only those who have special experience and realize the dangers. These are diminished by careful selection of cases and skillful technic. The treatment is not simple, and requires detailed care for considerable periods, averaging twelve to sixteen injections and check-ups during five months. The results are generally inferior to those of operation; under the best conditions only 57 per cent were "cured" and 15 per cent failed completely. It should be limited to small, recent, indirect hernias of young persons, and to reducible inguinal hernia of children. The complications are transient swelling and hydrocele of the cord, and epididymitis. Intraperitoneal injection is fairly common (5 per cent) and causes shock, which is generally transient, but may be fatal. Subsequent surgery is not materially complicated (F. J. Harris and White, 1938, 1936; C. J. Berne, 1938; C. O. Rice, 1935; Council on Pharmacy and Chemistry Report, 1940, J.A.M.A., *115*:533).

Sodium Morrhuate Injection, U.S.P., a sterile watery solution; usual sizes, 5 per cent in 2, 5 and 30 cc.

ALKALINE SULFIDES AND POLYSULFIDES

When applied to the *skin*, the sulfides (K, Na, Ca) soften the stratum corneum, much like the alkalis. Their action on hair is even greater, so that they are employed as depilatories, especially calx sulfurata and barium sulfide. When taken by *mouth*, they act as irritants and corrosives, through the liberation of hydrogen sulfide and free alkali.

Therapeutic Uses and Preparations.—The sulfides are used externally, in skin diseases (psoriasis, acne, seborrhea), especially as "Vleminckx's lotion," *Solution of Sulfurated Lime*, N.F., a solution of calcium polysulfides and thiosulfate, generally diluted with nine parts of water, and sponged on the surface once or twice daily or as a bath, 2 drachms per gallon. Diluted with an equal volume of water, it is used against scabies. Pusey, 1920, recommends it against warts. These are covered with a dressing soaked in the undiluted solution, applied every night until irritation is produced; then less frequently till the wart disappears or can be removed.

"White Lotion" (*Lotio Alba*), N.F., a freshly prepared suspension of zinc sulfide and sulfur, resulting from the mixture of zinc sulfate and sulfurated potash (4 per cent of each in distilled water), is also used in acne and seborrhea.

Sulfurated Potash, U.S.P. (Liver of Sulfur), is a mixture composed chiefly of potassium polysulfides and potassium thiosulfate; freely sol. in water (1:2); is used in baths (30 to 200 Gm., 1 to 6 ounces, per bath).

Sulfurated lime is a mixture containing about 55 per cent of CaS. A pale gray or yellowish powder; odor of hydrogen sulfide; nauseous alkaline taste; slightly sol. in cold water. Used as depilatory, mixed with an equal quantity of starch and made into a paste. Internally, it is used against boils and other suppurations. Its efficiency is doubtful. *Dose*, 15 to 60 mg., ¼ to 1 grain.

Toxic doses of sulfides produce the systemic effects of hydrogen sulfide. Death has occurred from 12 to 15 Gm. Smaller doses have little systemic action, as they are rapidly oxidized. They are *excreted* in the urine mainly as sulfates; but there seem to be also some organic sulfur compounds. A small amount of some volatile sulfur compound is also excreted by the *lungs*, giving the peculiar H_2S odor of the breath, and causing some *expectorant action*. With *intravenous injection* part is excreted as hydrogen sulfide and part is oxidized to sulfate (W. Denis and Reed, 1927).

Ammonium hydrogen sulfide is a severe skin irritant, penetrates the skin more rapidly than hydrogen sulfide, and may be fatal (Land and Draize, 1942). Ammonium sulfide, $(NH_4)_2S$, when applied to the head in "permanent wave" solutions, has caused acute death (Bunce *et al.*, 1941).

The systemic effects of intravenous injections (2 mg. per Kg. for dogs) consist in brief but intense stimulation of respiration, rise of blood pressure, slowing of the heart and violent convulsions, followed by depression of the medullary centers. The respiratory and circulatory effects have been interpreted as chiefly reflexes from the carotid sinus (C. Heymans *et al.*, 1932, 1933; Winder and Winder, 1933); but Koppanyi and Linegar, 1942, brought evidence that the pressor action is peripheral, so that the respiratory stimulation occurs also after excision of the carotid bodies. Direct application of sodium sulfide to the floor of the fourth ventricle also stimulates respiration (Owen and Gesell, 1931).

HYDROGEN SULFIDE

This gas (H_2S) occurs in sewer gas, in chemical industries and laboratories. It acts as local irritant, partly through its *acidity*, partly by forming sodium sulfide on contact with moist tissue. Even high dilutions produce conjunctivitis and roughening of the *cornea* with gray pinpoint stippling of its outer margin, and keratitis with blebs and ulcers, but these generally recover on treatment (Sjörgren, 1939). More concentrated gas, especially with prolonged exposure, causes pulmonary irritation and pulmonary edema. In acute poisoning, violent systemic effects predominate. They consist mainly in stimulation of the respiration and spinal convulsive centers; and with higher concentrations, in direct paralysis of the respiratory center. Hydrogen sulfide is much more toxic than is commonly realized. It approaches hydrocyanic acid in toxicity and rapidity of action.

Occurrence.—Hydrogen sulfide is formed in putrefaction, particularly of sewerage. "Sewer gas" consists essentially of CO_2, NH_3, CH_4, and 2 to 8 per cent of H_2S Small quantities are also formed in intestinal putrefaction, giving rise to diarrhea and possibly to some of the symptoms of "intestinal autointoxication." Operatives in artificial silk factories are subject to ophthalmic irritation, which is attributed to H_2S; but it has been suggested that the irritation may be due to other gaseous by-products (Bakker, 1924). It is *absorbed through the skin*, sufficiently to produce toxic effects on prolonged exposure to high concentrations (Schütze, 1927). *Prophylaxis* is secured by adequate ventilation, and by the wearing of masks and goggles. The odor of the gas is characteristic, but is about as strong with nearly harmless concentrations as with those that would be immediately fatal. Indeed, high concentrations promptly paralyze the olfactory nerves so that the danger may not be perceived (A. W. Freireich, 1946). Hydrogen sulfide is readily detected in air by blackening lead or silver paper. In case of death, it may be recognized by the blackening of a silver coin laid on the skin.

Treatment of Acute Poisoning.—Artificial respiration (by Schaefer's prone method) promises success if started while the heart is still beating. It may be aided by the inhalation of oxygen containing 5 per cent of carbon dioxide, during and for a short time after artificial respiration (Y. Henderson and Haggard, 1922).

Symptomatology in Relation to the Concentration of H_2S.—Dilutions of 1:200,000 cause definite symptoms. With dogs, 1:10,000 for some hours produces irritation of the conjunctiva and bronchial mucosa. With 2 to 3 parts per 10,000 an hour's exposure is followed by these local irritations, and more prolonged exposure may cause slight systemic symptoms resembling asphyxia, *i. e.*, hyperpnea, nausea, giddiness, headache, cerebral excitement and finally narcosis; 1:15,000 produces death within an hour under coma, often with convulsions; with 1:1000, these phenomena lead to death by apnea in fifteen to thirty minutes. With 1:500 death occurs almost immediately through paralysis of the respiration (Lehmann, 1892; Haggard, 1925). In case of survival, *recovery* occurs promptly; but *pulmonary edema and pneumonia* are liable to follow prolonged exposure to nonfatal concentrations, since the relatively low solubility of H_2S causes it to penetrate the alveoli before it is bound. Severe cases therefore have a bad prognosis. The acute action is chiefly on the *respiration.* Violent hyperpnea occurs with 1:1500, and is followed by acapnia and apnea. With 1:500, the respiration is paralyzed almost immediately. The action is due chiefly to irritation of the carotid sinus, as explained under sulfide. Muscular symptoms, jactitation, rigidity and convulsions are due chiefly to asphyxia. Marked slowing of the *heart*, profuse salivation and cold perspiration may occur with concentrations too small to produce other acute systemic effects. Aside from the occasional slowing, the heart is little affected and may beat strongly for several minutes after the respiration has stopped (Haggard).

Chronic Poisoning.—Repeated prolonged exposure to dilute concentrations produces local irritation of the eyes and respiratory tract, rhinitis, bronchitis, severe conjunctivitis with photophobia and corneal opacity, stomatitis, pharyngitis, digestive disturbances, headache, lassitude, skin eruptions.

Fate.—Hydrogen sulfide is readily absorbed from the lungs and the alimentary canal. It exists in the blood partly free, and partly as sulfides. It is excreted as H_2S by the lungs, and as sulfides by the urine. It is rapidly oxidized into nontoxic products (sulfate, etc.). "*Sulfur bacteria*" oxidize hydrogen sulfide to sulfur as a source of energy (Winogradsky, 1887).

Sulfhemoglobin.—This characteristic hemoglobin derivative, with maximal absorption at wavelength 620, is formed *in vitro* by a two stage reaction involving hydrogen peroxide: $HbO_2 + H_2S = Hb + S + H_2O_2 = HbS +$ unknown products. Reduced hemoglobin does not react with sulfide unless a peroxide is added. The reaction is catalyzed by phenylhydrazine and paraminophenol, presumably by their forming peroxide. The reaction is irreversible. Sulfhemoglobin contains one atom of S for each atom of Fe. Its iron is ferrous, but can be oxidized to ferric by ferricyanide, analogous to methemoglobin. Its properties are similar to those of hemoglobin, except that it does not bind oxygen; but with carbon monoxide it forms a loose and reversible compound (H. O. Michel, 1938; Barkan and Walker, 1942). Sulfhemoglobin appears brown in thick layers and dirty green in thin strata. It is responsible for the *discoloration of cadavers.* It is not formed in life by the administration of sulfides, and is therefore not responsible for the asphyxial symptoms, although the apnea lowers the oxygen saturation (Haggard, 1921; Wolynski, 1932). It may be formed in rabbits by continued ingestion of sulfur (Hijmans van den Bergh and Engelkes, 1922). *Clinical sulfhemoglobinemia* occurs with the administration of acetanilid, sulfanilamide and other benzene derivatives, presumably by the catalytic action mentioned above. It also occurs spontaneously (references in Haggard).

Sulfur Springs.—Hydrogen sulfide is contained in small quantity (ordinarily 1:300,000 to 100,000; but up to 1:4000 in volcanic waters) in a number of mineral waters (sulfur springs) which are used against a variety of obscure disorders—rheumatism, gout, diabetes, etc. When these waters are administered for some time, they cause diuresis and diaphoresis, irritation of the urinary passages, intestinal irritation and muscular pains. Their therapeutic effects are probably due to their laxative, diuretic and diaphoretic actions, although the general hygienic conditions must contribute largely to the results, as with other mineral waters (Boecker, 1895).

SULFUR

Sulfur is employed as a parasiticide in itch; as a mild cutaneous irritant in skin diseases (sulfur ointment); and internally as a laxative for softening the stools, especially for patients with hemorrhoids. It may be mixed with an equal amount of potassium bitartrate. Intramuscular injections of oil solutions of sulfur are used to produce fever for "nonspecific therapy." Colloidal sulfur is injected intravenously or intramuscularly in arthritis, but its usefulness is doubtful.

Manner of Action.—Sulfur itself is inactive, but contact with proteins and alkalis converts it slowly into the active sulfides. This process is so gradual that the action is mild and protracted, unless the finely divided "precipitated" or colloidal sulfur is used. Ordinary or "washed" sulfur therefore deserves preference. Sulfur is somewhat soluble in ointment bases, and this facilitates its action (Sabbatani, 1913). Sulfur is burned for fumigation, the disinfectant action being due to the sulfur dioxide.

The formation of sulfides is effected on the skin by the cutaneous secretions. No change occurs in the stomach; but a considerable amount (to 10 per cent) is converted into H_2S in the intestine, as may be judged from the increased secretion of sulfate by the urine (Denis and Reed, 1927), which is much greater and more prompt with colloidal than with powdered sulfur (Greengard and Wolley, 1940). This change was formerly referred to the alkalis of the intestine; but Heffter (1904) pointed out that the alkali exists as bicarbonate, which can not affect the conversion. He showed that it is produced by proteins of all kinds even after these are boiled. Hydrogen sulfide is formed most abundantly in the large intestines (Taegen, 1912).

Skin Diseases.—Sulfur Ointment, U.S.P., is used for acne and seborrhea; 5 per cent ointment is applied to ulcers to hasten keratinization; 2 to 4 per cent is employed in alopecia; 10 to 25 per cent in petrolatum for scabies. Colloidal sulfur may be used, but in lower dosage (H. E. Miller, 1935).

Alopecia.—Sulfur (2 to 4 per cent) is used in the seborrheic form, as are also other irritants (salicylic acid, 1 to 2 per cent); mercuric chloride, 0.1 to 0.4 per cent; betanaphthol, 1 to 2 per cent; pilocarpine, 0.15 per cent; cantharides; resorcin (1 to 2 per cent; discolors the hair). These agents may be dissolved in water, glycerin or oils, or applied as ointments (Dore, 1914).

Scabies.—The itch mites and their ova are destroyed by the application of ointments containing sulfur (10 to 25 per cent) or betanaphthol (10 per cent) or by balsam of Peru. As the parasites are accessible only when they come to the surface at night, the ointments should be applied in the evening, alternating with scrubbing of the skin and a film of oil. The itching is relieved with the first application, so that this is almost a therapeutic test; but several treatments should be given (J. H. Stokes, 1936).

Nutrition of Chicks.—Sulfur is commonly fed to control coccidiosis. When such chicks are kept away from sunlight they require four times as much vitamin D as those without sulfur. Sunlight prevents this deficiency. The requirements for carotene and riboflavin are not increased (Sherwood *et al.*, 1943).

Colloidal Sulfur in Chronic Arthritis.—Intramuscular and especially intravenous injections of colloidal sulfur solution were reported to give temporary symptomatic relief and often induce febrile reactions which may serve as "nonspecific fever therapy"; but the reactions are uncertain and it can not be predicted whether they will be useful or harmful. The contraindications are practically unknown and the optimal dosage has not been determined. It is no longer employed in the leading arthritis clinics of the United States (report, Council on Pharmacy and Chemistry, 1933, J.A.M.A., *111:*1657).

Colloidal sulfur injections were introduced about 1907 against various diseases, including tuberculosis and syphilis, but were soon dropped, except for arthritis, for which they had been recommended by Cawadias, 1917, who claimed rapid cessation of pain, correction of the deformities and restoration of function. Others obtained variable results, about like those of nonspecific protein therapy (Pemberton, 1930). Recent writers incline to consider the improvement as imaginary. The dosage is 10 to 30 mg. twice weekly. Intramuscular injections sometimes cause extensive necrosis. Advanced age, feebleness, organic disease and obesity are cited as contraindications.

The *effects of intravenous colloidal sulfur* are physical and chemical. Both vary with the degree of dispersion, which is always more or less mixed, depending on the method of preparation and age of the solution (the preparation is described by Luman, 1917). Commercial colloidal sulfur preparations always contain enough sulfide to produce acute rise of blood pressure and respiratory stimulation (Koppanyi and Linegar, 1942). The colloidal suspension tends to produce *anaphylactoid shock reactions*, as such, or after flocculation (this may protect against true anaphylaxis; Montagnini, 1927). The *acute toxicity* depends chiefly on this factor, which varies with the dispersion, the alkalinity of the solution, and the rate of injection (Chistoni, 1933; Wheeldon and Main, 1933).

Fate of Colloidal Sulfur.—With oral administration to man or rabbits, colloidal sulfur is absorbed promptly and almost completely as sulfide, oxidized and excreted as sulfate in the urine, within twenty-four hours. Massive doses administered to rabbits by stomach tube produce toxic sulfide effects in a few minutes (Greengard and Wolley, 1939). Attempts have been made to explain the supposed effects of sulfur in arthritis on the basis of disturbances in sulfur metabolism which were supposed to exist in this disease, such as deficiency of chondroitin sulfuric acid in the cartilage (Meyer-Bisch *et al.*, 1921). Other workers, however, have failed to find these changes or effects (H. A. Reimann and Pucher, 1924; Cawadias, 1925). Freyberg *et al.*, 1939, confirmed that the administration of colloidal sulfur by any method, or of thiosulfate, does not significantly increase the conjugated sulfate, either in normal subjects or in rheumatoid arthritis; nor does it increase the cystine content (in fingernails)

Intramuscular Injections of Sulfurated Oil.—One to 2 cc. of olive or other oils boiled with 0.1 to 2 per cent of sulfur cause local reaction with considerable pain, leukocytosis and fever of about 102° F., beginning in about seven hours and lasting about fifty hours. It was originally tried in paralytic dementia (K. Schroder, 1929), but the results were not good (McCartan, 1932). It was then used for chronic infections, rheumatism and arthritis with variable results, similarly to milk injections. The latter deserve preference, as they are quite as effective and their local effects are less severe (L. M. Waller and Allen, 1931; T. D. Power, 1932).

PREPARATIONS.—*Sublimed Sulfur,* U.S.P. (Sulfur Sublimatum; Flowers of Sulfur), occurs as a fine yellow, crystalline powder; insol. in water and alc., sol. in olive oil, freely sol. in carbon disulfide. Two pounds per 1000 cubic feet is used for fumigation. Sufficiently pure for medicinal use in dose of 4 Gm., 1 drachm, but *Washed Sulfur,* N.F. (Sulfur Lotum), is preferred. It is sublimed sulfur treated with ammonia water and thoroughly washed to remove the free acid. *Precipitated Sulfur,* U.S.P. (Milk of Sulfur), is prepared by precipitating sulfurated lime with acid. It is finer than sublimed sulfur and therefore more active, but is given in the same dose. *Sulfur Ointment,* U.S.P. (Ung. Sulfuris), contains 15 per cent of precipitated sulfur.

SODIUM THIOSULFATE

This salt is used as a reducing agent in photography, under the name of "hypo" or "hyposulfite." Taken by mouth, it acts as a *cathartic* (1 Gm. in water, every 2 hours if necessary; Petteys). It is used externally against *parasitic skin diseases.* For the prevention of the spread of *ringworm* of the feet, it has been advised to rinse these in 10 per cent sodium thiosulfate (W. L. Gould, 1931), or in 0.5 per cent sodium hypochlorite (Osborne and Hitchcock, 1931). Its *intravenous injection* is used against exfoliative and other *dermatitis,* especially those resulting from arsphenamine and other arsenicals and against manifestations of arsenical poisoning, and of poisoning by *metals* in general. Its success in dermatitis and arsenical hepatitis is about equal to that of nonspecific colloid therapy, and perhaps explainable by the separation of colloidal sulfur. Experimental investigations give no evidence that it has any value in arsenical or other metal poisoning (Muir *et al.,* 1940). It is a fairly good antidote to cyanide poisoning by forming thiocyanate; but this action is slow, so that it should be combined with more promptly acting agents, such as nitrite, which forms cyanhemoglobin.

Action in Arsenic Poisoning.—The use of thiosulfate against arsenical and other dermatitis appears to have been introduced by Ravaut, 1920. It was suggested that it converts the arsenic into less harmful compounds, such as the sulfide, but there is no chemical proof for this suggestion. Since thiosulfate has a similar beneficial effect on nonarsenical and nonmetallic dermatitis, it is quite conceivable that the action is not on the arsenic, but by the precipitation of colloidal sulfur.

Administration.—In arsenic and other metal poisonings the thiosulfate is injected intravenously as a 10 per cent solution in the dose of 0.3 Gm. of the crystallized salt on the first day, repeating the injection daily with increasing doses, namely, 0.45, 0.6, 0.9, 1.2 and 1.8 Gm. (McBride and Dennie, 1923). At the same time it may be administered by mouth, 2 Gm. twice a day, in 120 to 200 cc. of normal saline, which is said to diminish the tendency to vomiting.

Local Injection vs. Neoarsphenamine Irritation.—If neoarsphenamine solution accidentally enters the subcutaneous tissue, the injection of 5 or 10 per cent thiosulfate solution diminishes the irritation. This is probably due merely to dilution, and the injection of normal saline solution would probably be equally effective.

Thiosulfate against other metals has been tried, especially against mercury and lead poisoning (Dennie and McBride). Animal experiments indicate that it is ineffective (Haskell *et al.,* 1925; A. G. Young and Taylor, 1931), although it tends to form soluble double-salts with metals. *Sodium p-sulfhyril phenyl sulfonate* is also ineffective. *Sodium formaldehyde sulfoxylate* intravenously gives some protection against mercurial poisoning. By mouth it is effective only if administered within a few minutes (report, Council on Pharmacy and Chemistry, J.A.M.A., 1942, *120:*124).

H. M. Rabinowitz and Kahn, 1936, introduced intravenous injections of sodium thiosulfate against *obliterative thrombo-angiitis.* This was indorsed by F. W. Bancroft *et al.,* 1937, but its value appears questionable. R. V Theis and Freedland, 1940, proposed *sodium tetrathionate* for this purpose, but this would be dangerous, as it produces necrosis of the convoluted renal tubules in animals (Gilman, Philips *et al.,* 1947; report, Council on Pharmacy and Chemistry, 1947).

Fate.—Thiosulfate is distributed in the extracellular fluid. With intravenous injection, 70 to 80 per cent is recovered in the urine of dogs (A. Gilman *et al.,* 1946). The remainder is oxidized to sulfate.

Toxicity.—Lasch, 1919, states that sodium thiosulfate may be consumed without harm up to 12 Gm. per day. It would, however, produce catharsis, and possibly emesis. Intravenous injection of ordinary "C.P." sodium thiosulfate is often toxic, sometimes with fatal convulsions; but if the salt is purified by precipitating its aqueous solution with alcohol, it is tolerated in doses of 0.2 to 1.5 Gm. per Kg. (S. Goldblatt and Dennie, 1928).

Sodium Thiosulfate, U.S.P. (Sodii Thiosulfas; Sodium Hyposulfite), $Na_2S_2O_3 5H_2O$, is very sol. in water (1:0.5). Dose, 1 Gm., 15 grains, by mouth or intravenously.

SODIUM SULFITE

This is sometimes used as mouth wash against aphthae, and as 10 per cent lotion against ringworm and other parasitic skin diseases (pityriasis versicolor). The principal importance of the sulfite is its use in preserving foods. The quantities ordinarily employed are not directly harmful. Even much larger quantities do not act systemically, being rapidly oxidized to sulfates; but they may produce local gastric irritation by the liberation of sulfurous acid. Their harm is mainly indirect in that they improve the odor and appearance of spoiled meat so that it is sold as fresh. They are therefore properly prohibited.

Sodium bisulfite is most commonly used as antiseptic "*canning powder*." It requires an acid medium for the liberation of H_2SO_3, and is therefore not reliable. It destroys thiamine, but helps to preserve the ascorbic acid and carotene (Council on Foods and Nutrition, 1944, J.A.M.A. *125:355*).

Toxic Effects.—The harmlessness of ordinary quantities, even when continued for long periods, has been shown particularly by Rost and his co-workers (1904, 1912) and by Lehmann and Treutlein, 1909 (Long, 1912). The metabolism is not deranged. With larger doses by mouth, there are signs of gastro-intestinal irritation, due to the liberation of sulfurous acid (Jacobj and Walbaum, 1906). Toxic phenomena with histopathologic lesions occur when 0.1 per cent of sodium sulfite is added to the diet of rats; 0.25 per cent produces stunted growth, polyneuritis, atrophy of bone marrow, and other changes (O. G. Fitzhugh *et al.*, 1946). The absorbed sulfite is rapidly oxidized to sulfate (Rost and Sonntag, 1904), and it is only when this capacity is exceeded by large doses or intravenous injection that toxic effects appear. These lower the blood pressure, depressing the central nervous system, especially the medulla, the cardiac and arterial muscle without hemolysis or pathological lesions. The fatal intravenous dose for rabbits is 5.5 mg. per Kg. Death occurs by paralysis of respiration (Rost, 1914; Piva, 1933). In man, 1 Gm. produced no effects; 4 to 6 Gm. caused violent colic, diarrhea and circulatory disturbances (Rost; Franz, 1912).

Exsiccated Sodium Sulfite, U.S.P., Na_2SO_3, is sol. in water (1:4). Dose, 0.3 to 1.2 Gm., 5 to 20 grains. It oxidizes in air to sulfate.

SULFUR DIOXIDE (SULFUROUS ACID)

This was formerly used for disinfection of rooms, but is not reliable against bacteria (Koch), and is objectionable by bleaching colors. It kills most insects (McClintock, etc., 1911), including mosquitoes and bedbugs; and is therefore somewhat effective against certain insect-borne diseases, malaria, yellow fever, etc. It is quite ineffective against lice (Barot, 1918). Sulfur dioxide is generated by burning 3 pounds of sulfur for each 1000 cubic feet of space. To avoid danger of fire, the sulfur is placed in tin pans raised from the floor by bricks. Its action is materially greater when the air is saturated with moisture.

Toxic effects arise from leaking refrigerators, and from its use in disinfecting and bleaching. Large quantities occur also in coal smoke and become particularly objectionable in foggy weather. It is eventually oxidized in the air to sulfuric acid (T. W. Schaefer, 1907). SO_2 vapor produces strong irritation of the exposed mucosae, of the eyes, nose, and less so of the mouth. Its inhalation affects chiefly the upper respiratory tract, trachea and bronchi. The strong sensory stimulation often causes spasm of the glottis, which protects the deeper passages. Recovery from the effects of short exposure is rapid, but asthma may persist (Romanoff, 1939). Death may occur through edema of the lungs or of the glottis, but is uncommon, since lethal concentrations are so irritating that they are almost irrespirable (Henderson and Haggard, 1927).

Effective Concentrations in Air.—With man, inhalation of concentrations of 0.0006 to 0.0012 per cent by volume (1 per cent = approximately 28.2 mg. per liter) produces immediate irritation of the throat, and continued exposure often causes chronic catarrh (A. Fieldner and Katz, 1919). This may explain the apparent tolerance developed by continued exposure to low concentrations, since the increased secretions probably dull the respiratory reflexes (Henderson and Haggard, 1927). A concentration of 0.003 per cent may be tolerated for hours by men accustomed to the fumes, but sensitive people are immediately made ill, with irritation of the nose, sneezing, and cough (R. Kobert, 1906). The maximum concentration allowable for half an hour's exposure is 0.005 to 0.01 per cent (A. Fieldner and Katz, 1919). Inhalation of this concentration, daily for thirty days, by guinea pigs, mice and dogs results in loss of weight and an increase in the number of red blood corpuscles. Inhalation of concentrations of 0.04 to 0.05 per cent is dangerous, even for short periods. Concentrations of 0.05 to 0.06 per cent inhaled for one-half to one hour are fatal for cats (Lehmann, quoted by Rost in Heffter's Handbuch), and 0.06 to 0.08 per cent produces death in mice, guinea pigs and dogs in ten minutes to six hours (R. Kobert, 1906; A. Hamilton, 1925). With continued exposure of mice and guinea pigs to 0.0065 per cent (65 ppm), a third showed acute gastric distention by the ninth day. With 300 ppm most of the animals had distention and multiple hemorrhagic gastric ulcers by the third day, often with perforation (F. R. Weedon, 1942). Data for insects as well as vertebrates are given by Weedon *et al.*, 1939.

SULFONATED PETROLEUM DISTILLATES (ICHTHYOL AND SUBSTITUTES; AMMONIUM SULFOICHTHYOLATE)

Treatment of certain petroleum distillates with concentrated sulfuric acid and subsequent neutralization with ammonia results in tarry products, miscible with water or glycerin, and containing considerable quantities of sulfur compounds of alkyl radicals, *i.e.*, sulfonic acids (RSO_3H), sulfones (RSO_2R) and sulfur ethers or sulfides (RSR). The original product, "*ichthyol*," was introduced into dermatology by Unna, 1882, on the basis of a now disproved "reduction theory." Its use became a fad in dermatology, gynecology and proctology, but was not supported by critical control observations, and its popularity has waned. The limited usefulness of these products is due mainly to their physical, demulcent and emollient effects. They are reported to be somewhat astringent for mucous membranes or exposed tissues; and when concentrated, are mildly irritant, and stimulating and antiseptic. Their miscibility with water gives them some advantage for mucous membranes.

Epithelial hyperplasia is reported to follow repeated stroking the skin of mice or rabbits with a pencil dipped in ichthyol. The growth is somewhat atypical but not a hyperkeratosis (Mencarelli, 1930). Ichthyol was tried *internally*, especially against tuberculosis, on the basis of mistaken theories. Larger doses produce gastro-intestinal irritation and diarrha.

Origin.—"Ichthyol" was originally prepared from a Tyrolian bituminous shale containing the remains of fossil fish. Sulfonated oils have a long, although not prominent, history in medicine; for instance, "*Harlem oil*," *i. e.*, linseed oil saturated with sulfur. The *composition* varies considerably for the various products, and even for different samples of the same product. All, however, contain the three classes of sulfur compounds. The individual constituents have not been isolated. The total sulfur content of commercial "ichthyol" is about 10 per cent, of which about half consists of sulfides (sulfur ethers and mercaptans). The addition of acid to the ammonium salts precipitates a tarry mixture, "sulfoichthyolic acid."

Ichthammol (Bitumen Sulphonatum, Ammonium Ichthyosulfonate), similar to Ichthyol or identical with it, is a black viscid liquid, of strong characteristic odor. Sol. in water and glycerin, partly sol. in alc. and ether, miscible with fats.

THIOCRESOL AND THIOGLYCEROL

Reimann and Hammett believe that the sulfhydryl group (SH^-) is essential to cell production. Reimann, 1930, reported that *Thiocresol* application as a $\frac{1}{4}$ per cent ointment hastens the healing of ulcers and promotes the growth of skin grafts. *Thioglycerol*, CH_2OH $CHOH$ CH_2SH, acts similarly and appears preferable, as it is more stable. It is applied as a dressing of 1:5000 solution in glycerol, which checks excessive granulations; or as $\frac{1}{4}$ per cent ointment in hydrous wool fat. Wounds are reported to heal 20 per cent faster by its use. It should not be employed if malignancy is suspected or if the skin becomes irritated (review, L. E. Sutton, 1935). Watery solutions of *cysteine* were reported to have a similar effect (Brunsting and Simonsen, 1933).

Antagonism to Carcinogenic Agents.—Although sulfhydryl normally increases the rate of cell division, the injection of parathiocresol into mice delays or prevents the development of cancer by dibenzanthracene (Reimann and Hall, 1936).

Thiourea, $H_2N.CS.NH_2$, has been used in 1 per cent solutions for stimulating granulating tissue and for healing ulcers. The dressing should be discontinued when granulation is well established, to avoid excessive fibroblastic stimulation. Solutions may be boiled and keep well (W. R. Fearon, 1942). Its toxicity is low. The effects on the thyroid are discussed under that heading. Thiourea and other sulfhydryl compounds protect fats against oxidation and rancidity, but only in the presence of water. The reason for this is not clear (P. György *et al.*, 1943).

GLUTATHIONE

This tripeptide, glutaminyl-cysteinyl-aminoacetic acid, also contains a sulfhydryl group (SH^-) which changes readily to disulfide, and the reverse. It occurs in almost all animal tissues and in plants, and has been prepared synthetically. It probably plays an important role as acceptor for hydrogen, with the liberation of oxygen for oxidative processes, so that it catalyzes oxidations and reductions (Hopkins). Cells contain enzyme systems which work in both directions (review, Elvehjem *et al.*, 1942). It protects ascorbic acid against oxidation by ascorbic oxidase and by copper. Its role in living metabolism is not clear. Large doses continued through generations did not accelerate the growth of rats (Sherrod and Struck). It is not employed therapeutically.

Carcinogenesis and Growth.—The growth of cancer in mice is markedly slowed by diets deficient in cystine; the growth resumes on administration of cystine or glutathione. The growth of normal young mice or rats is affected in the same direction (C. Voegtlin *et al.*, 1936; Dyer and Du Vigneaud, 1936). Cystine is not essential to normal growth, however, as is *methionine* (Womack *et al.*, 1937).

Trichogenic Action.—A strain of hairless rats was not affected by feeding glutathione, but cystine produced temporary, and cysteine permanent, hair growth. The hairless condition was attributed to hereditary absence of an enzyme capable of breaking down glutathione (G. J. Martin and Gardner, 1935).

Blood coagulation is inhibited by the addition of glutathione. Cysteine and other thiol compounds are less potent (Kühman and Morgenstern, 1934).

Cystine, diamino-dithiolactic acid, forms 15 per cent of hair, 12 per cent of nails, in firm combination. Internally, it occurs in relatively small amounts as a constituent of glutathione. Its reduction yields cysteine, amino-thiolactic acid. Normal growth requires that the diet contain the cystine complex, although rats may form it from methionine (Tarver and Schmidt, 1939). Ingested cystine enters into cysteine, taurine, glutathione and keratin. Directly or through cysteine or glutathione, it liberates sulfur for the sulfonation and detoxication of injurious material (review, M. X. Sullivan, 1932). *Cysteine* and *thioglycolate* inhibit various antibiotic agents, penicillin, clavacin, penicillic acid, and some alpha, beta unsaturated ketones, menadione, etc. (Colwell and McCall, 1945).

Solutions of *Thioglycolic Acid*, $HSCH_2.COOH$, are used in "coldwave" hair treatments, up to 5 per cent in excess of ammonia. Some persons appear to have or develop allergic susceptibility, with rashes of the skin and mucosae. Severe cases may involve the blood count and liver function (L. H. Cotter, 1946).

CAUSTIC ACIDS

Dilute acids alter the solubility of colloids, and produce stimulation and irritation. Concentrated acids are corrosive, destroying tissues by direct chemical action. They convert the proteins into acid proteinates, which are soluble in concentrated and in very weak acids, but insoluble in moderately strong acids. Concentrated acids are therefore penetrating caustics, and moderately strong acids are astringent. *Connective tissue* is not dissolved, but is softened and rendered more soluble in boiling water. (This explains why meat becomes more tender on keeping.) Concentrated acids have a similar effect upon *epithelium.* Without actually dissolving it, they soften it in such a manner that it is readily detached. Dilute acids, on the other hand, harden it. Concentrated acids withdraw water from the cells. This affinity is so strong in the case of concentrated H_2SO_4 that it produces carbonization. All soluble acids and acid salts dissolve calcareous material, including the enamel of the teeth.

Members.—The most typical acids in regard to the local action are *sulfuric* and *hydrochloric acid. Nitric acid* produces the same effects, but differs from these in its chemic action, forming xanthoproteic acid from the proteins. *Sulfurous acid* also has a marked corrosive power. **Hydrofluoric acid** has a special toxic action. It causes intense pain, which may be delayed so that the patient does not know that he has been burned until a few hours later, when the area begins to smart (L. Schwartz, 1939). The pain then persists for several days. The destruction proceeds under the toughened coagulated skin, so that the ulcers extend deeply, heal slowly, and leave a scar (Schuermann, 1937). They may be treated by applying a paste of magnesium oxide and glycerin, and injecting a 3 per cent solution of calcium gluconate around the lesion. If the injection is made within three hours, it shortens by a third the healing time of experimental wounds from 40 per cent hydrofluoric acid, and lowers the incidence of suppuration by half. Daily injections are no more effective than a single treatment (A. Paley, 1941). Inhalation of air containing 0.02 per cent of hydrofluoric acid produces acute catarrhal irritation. Of the *organic acids,* those of the fatty series act similarly, but are weaker. *Trichloracetic acid* is the most corrosive of these. *Oxalic acid* has specific actions, probably by the precipitation of the calcium. The *compound acids*—such as ethyl-sulfuric, etc.—act like organic acids. The *aromatic acids* act partly as acids, but this is greatly obscured by their collapse action. The irritant action of the acids is shared to some extent by the *acid salts,* acid tartrates, acid sulfates, etc.

Uses.—The severe pain, deep penetration and extensive scar formation make acids undesirable cauterizants. *Nitric* and *trichloroacetic acids* form relatively firm eschars, so that their action is more circumscribed and less painful. *Sulfuric acid* has been made into a paste with inert powders (charcoal, sawdust, lead sulfate, etc.) to localize its action, but is still painful and difficult to control (Pusey, 1913). *Lactic acid* has a relatively mild action on normal tissues, but administration of insufficiently diluted lactic acid to infants produces esophageal corrosion, stricture and death (G. E. Young and Smith, 1944). *Chromic acid* may cause poisoning when used as a caustic. The destruction of proteins makes acids *antiseptic.* Even quite dilute solutions, such as the gastric juice, suffice to limit the growth of bacteria. Concentrated acids destroy them outright.

Local Effects of Dilute Acids.—These produce mild irritation and harden the epithelium without destroying it. They do not penetrate as deeply as the volatile organic irritants and do not cause nephritis.

They may be used in the form of baths, in the strength of about 30 cc. (1 ounce) of concentrated acid to the bath (30 gallons). They may be applied as lotions, especially formic acid in the strength of about 4 or 5 per cent in alcohol. Acids are used to harden the epidermis against excessive secretion of *sweat* (sweating feet); 5 or 10 cc. of concentrated hydrochloric acid are put in a basin of water and the feet placed in this until they become painful. This is done about twice a week. The irritant action of the volatile acids is sometimes employed to produce *reflex stimulation* of the central nervous system by inhaling vinegar, etc.

Poisoning by concentrated acids presents the usual phenomena of caustic poisoning. It is very painful. The "coffee-grounds" vomit is characteristic. Scar formation and stenosis are frequent. The prognosis and toxic dose depend upon the concentration and the parts affected. Sulfuric acid poisoning is the most common. The *treatment* consists in liberal dilution with water, and the administration of mild alkalis, preferably magnesia, but in its absence, of chalk or even sodium bicarbonate or soap. This should be followed by a demulcent, a tumbler of oil or, better, of thin flour paste.

Continued exposure to the vapors of acids, such as occurs in certain trades, gives rise to chronic bronchitis. They attack the teeth, especially the front teeth, which are most exposed; their destruction is often completed in two or three years. The necrosis may spread to the jaw, as with phosphorus. The local respiratory effects and systemic changes produced by inhalation of *toxic concentrations of hydrochloric acid* are described by Machle *et al.,* 1942.

PREPARATIONS.—*Hydrochloric Acid,* U.S.P., contains about 36.5 per cent of HCl; *Nitric Acid,* U.S.P., about 70 per cent of HNO_3; *Sulfuric Acid,* U.S.P., about 95 per cent of H_2SO_4.

Lactic Acid, U.S.P., is a syrupy liquid containing about 87.5 per cent of $CH_3.CHOH.COOH$. It absorbs water on exposure and is very soluble in water or alcohol. Used as a caustic, especially for dissolving diphtheric membranes. *Trichloroacetic Acid,* U.S.P., CCl_3COOH, occurs as deliquescent colorless crystals, very sol. in water and alc. A caustic, used especially against warts. *Osmic Acid,* OsO_4, is injected directly into the preferably exposed nerve in ½ to 1 cc. doses of 1 to 2 per cent solution to produce its degeneration for the relief of persistent neuralgias (Billroth and Neuber, 1885). The result is sometimes immediate, but more commonly it is not complete until after one or two weeks, or it may fail entirely. If it is successful, the effects persist for at least several months, when it may become necessary to repeat the injection. They are rarely if ever permanent. The local reaction is always painful but not serious. It is probably not advisable to use osmic acid in the presence of renal disease (Eastman, 1906).

THE LOCAL ACTIONS OF METALLIC SALTS

Metallic salts combine with proteins to form more or less difficultly soluble compounds containing varying amounts of the metal and proteins. The acid of the metallic salt is thus set free. Both factors are concerned in the actions. Some metal albuminates are almost insoluble in water; some are soluble in excess of protein, especially when neutral salts are present; others are not. If the precipitate is soluble, penetration and action are deep. If the precipitate is insoluble, as in the case of lead salts, penetration can not take place; the irritation is confined to the surface and an astringent action results. Lead is the most astringent metal ion; then comes aluminum; then iron; then zinc, copper, silver and tin, which are about equal; the most caustic is mercury. Hydrochloric acid is the most caustic of the liberated acids commonly used; then comes nitric acid; then sulfuric; then phosphoric; the weakest are the organic acids—acetic, citric and tartaric. By proper combination between the metals and the acids, one may obtain any grade of action from pure caustic to pure astringent.

The irritant, astringent and caustic actions are degrees of the same process. The astringent action always precedes the caustic action; and, consequently, by proper dilution one may obtain astringent effects from salts which are ordinarily purely caustic.

The caustic action of metallic salts was formerly used extensively, but has been largely abandoned. Most are not sufficiently powerful, others are too toxic (arsenic, antimony and mercury). Zinc chloride and antimony chloride (Butter and Antimony) are active caustics, but their scab is so soft that their action can not be kept within bounds. Silver nitrate in the form of sticks (Lunar Caustic), and to a less extent copper sulfate, are practically the only metallic salts used to produce a purely caustic action. *Arsenic,* were it not for its toxicity, would be a useful corrosive, for its action is so slow that it can be readily limited. *Silver nitrate* is easily controlled, since its action may be stopped at once by washing with NaCl, which converts it into AgCl.

Therapeutic Applications.—For use on *open wounds, ulcers, abscesses,* for the astringency and a mild stimulation leading to repair, silver nitrate is used extensively, also the soluble zinc salts and alum. They are applied in strengths of from ½ to 5 per cent. The insoluble astringents, zinc oxide and carbonate, bismuth subcarbonate or subnitrate, may be used as dusting powders, or in the form of ointments, 5 to 20 per cent. Absorption is fairly free from open surfaces, and calomel, bismuth, lead, etc., must be used with caution. Zinc oxide is safe. Astringents cause actual constriction of the mucous membranes, and may in this way bring about the complete disappearance of small *polypi.* The *mucous membranes* which are easily accessible to the local action of astringents are those of the mouth, conjunctiva, nose, genito-urinary tract and rectum. The same salts as for open wounds can be used, as also tannic acid. They are employed in somewhat weaker solution, as gargles, washes or injections. The usual strength is from ½ to 1 per cent, perhaps a fourth of this for the conjunctiva and urethra. double for vagina or rectum.

The usual concentrations for urethral injections are: Mild protein silver, 5 per cent; strong protein silver, 0.5 per cent; acriflavine, 1:3000; silver nitrate, 1:5000; potassium permanganate, 1:8000. They should not be long continued or they will keep up a urethral discharge (Pelouze, 1940).

Astringent treatment of the nasal schneiderian mucosa by tannic acid, alum, zinc salts or trinitrophenol hinders infection by viruses which ordinarily enter through this path (Olitzky and Cox, 1934). It was tried as prophylaxis against poliomyelitis and is quite successful in monkeys (C. Armstrong and Harrison, 1936), but proved disappointing clinically since the olfactory tract is rarely the portal of entry for the viruses in clinical cases (Sabin and Ward, 1941; American Orthopaedic Association, 1946).

Injury to Mucous Membranes.—The irritation provoked by astringents shows that they are not indifferent to cells, and may do harm; the injury is usually brief and easily repaired,

Fenton and Larsell, 1936, found for *frontal sinuses* infected with hemolytic streptococcus, in patients and experimentally in cats, that weak astringents (alum, tannic acid) generally decreased the severity of the infection, but that practically all antiseptics were harmful, as also histamine and acetylcholine. P. R. Cannon and Walsh, 1938, produced bronchopneumonia in rabbits by intranasal application of watery solutions of astringents; but these would not be so likely to reach the bronchi in man.

Ciliary Activity of the Upper Respiratory Tract.—On local application, in guinea pigs, 0.5 per cent silver nitrate is immediately fatal to the cilia; 2 per cent mercurochrome or 2 per cent zinc sulfate depresses severely; mild silver proteinate, 5 to 20 per cent, causes some slowing, partly by its viscosity. Of vasoconstricting agents, 0.1 per cent epinephrine causes some slowing (perhaps by its preservative), 3 per cent ephedrine has no effect. Of local anesthetics, 5 per cent cocaine hydrochloride had no effect, 10 and 20 per cent produced slowing but with good recovery. Of aromatic agents, 0.5 and 1 per cent menthol are mildly depressant, 0.5 per cent thymol and 1 per cent eucalyptol somewhat more so. Water also slows the beat (Lierle and Moore, 1934).

In the alimentary canal astringents are useful mainly by diminishing the results of inflammation; *i. e.*, the vomiting and diarrhea. Against *vomiting*, especially when caused by ulceration, bismuth subnitrate or subcarbonate seems to be the most useful. These act not only by their astringency, but also somewhat after the manner of inert dusting powders, affording an artificial protective covering to the walls of the viscus by adhering to them. Silver nitrate is also sometimes used in doses of about 10 mg. ($\frac{1}{6}$ grain), dissolved in water and given three times a day. Their action on *diarrhea* is entirely similar. Bismuth is again preferred; silver nitrate is often useful in the summer diarrhea of infants. Further details will be found under the respective metals.

Oligodynamic Action of Heavy Metals.—When applied directly or in pure solutions, especially to isolated cells, the heavy metals and their salts may produce marked effects in extreme dilutions. These are concentrated by adsorption on the cell surface. The action is sometimes beneficial, more commonly destructive.

The growth of *moulds* is markedly favored by traces of Zn and Mn (Raulin, 1870); the presence of zinc in a dilution of 1:25,000,000 increases the crop of the mould Aspergillus by more than 50 per cent (Bertrand and Javillier, 1912). On the other hand, the alga Spirogyra is killed by copper in a dilution calculated as 1:72,000,000 (Naegeli, 1893, who introduced the term oligodynamic action). Similar effects are produced by Hg, Pb, Sn, Fe and Ag, but Cu is by far the most toxic (Locke, 1895). The addition of metallic Hg, Ag or Pb to blood gradually produces hemolysis, while Cu hardens the corpuscles (Bechhold, Ascoli). If metals are placed in water, the containers, even after rinsing, impart to fresh water considerable catalytic and protein precipitant properties; the order of efficiency being: (most) Cu, Hg, Ag, Pb, Sn, Zn, Al, Fe, Mn, Pt (Falta and Richter-Quittner, 1921). Touching the His bundle of the mammalian heart with a rod of clean, polished copper produces instant heart block (v. Egmond, 1920). The oligodynamic action is due simply to the solution of traces of the metal (*f. i.*, silver, Freundlich and Söllner, 1928). It may be assumed that in these dilute solutions the metals exist first as colloidal metals, but that they pass rapidly into colloidal hydroxides and carbonates (Traube-Mengarini and Scala, 1912) with positive charge, which are therefore adsorbed (and detoxicated) by negatively charged solids (Bayliss). Charcoal and proteins give similar adsorption of the metals (A. J. Clark, 1937).

Astringent Styptics.—All metallic salts, the irritant as well as the astringent, and also the vegetable astringents, act as local styptics; *i. e.*, arrest capillary hemorrhage. They do so mainly by the formation of precipitates which occlude the lumen of the small vessels. They also injure the vessel walls and so tend to produce thrombosis. Astringents act only when they come into *actual contact* with the bleeding vessels. They can not act through a large clot of blood, and if such exists it must first be removed. They were formerly used internally with the idea of producing astringent action in remote places; iron was given by mouth to check bleeding in the uterus; but their action can not extend beyond the stomach, since they are precipitated or decomposed in the intestine. The *indications* for styptics are to lessen bleeding, especially capillary oozing. They have no effect on spurting arteries or large veins. They are sometimes injected into hemorrhoids, and have even been injected into aneurysms. Their injection into larger vessels may produce embolism.

Other Hemostatic Measures.—Any substance which gives a precipitate with proteins may act as astringent styptic; *e. g.*, dilute acids in concentrations which need not be caustic (vinegar and lemon juice). A number of purely mechanical measures favor the formation of clot; for instance, ordinary cotton or Pengawhar Djambe (this also contains tannic acid). Cobwebs were used in folk medicine, but are usually septic. The same effect may be obtained by fine powders which have a strong attraction for water. Cephalin and tissue extracts hasten coagulation *in vitro*, but are of little use on wounds. Other styptic measures are depression of the vasomotor center by narcotics; direct constriction of the vessels by the application of cold, or by drugs, such as epinephrine, *Microscopic observations* on the mechanisms of various hemostatic measures are discussed by Gramenitzky, 1937. *The efficiency of local styptics* has been tested experimentally by noting the quantity of blood lost when a skin wound is irrigated with the styptic (Hanzlik, 1918).

Methods of Testing Astringent Action.—Ordinarily, astringent action depends on the precipitation of the proteins (Mitscherlich, 1842; Lewin, 1881; Harnack, 1889). This may be tested directly; or by measuring the diminished extensibility of tissues, for instance the lungs (Dreser); or by the shortening of tissues which ensues when their proteins are precipitated (Crawford, 1918; tendon of rat tail, Komiyama, 1926); or by rendering red corpuscles resistant to hemolysis (Sollmann, 1920); or by the suppression of secretion on the frogs' skin (Schuetz); or by observation of blood vessels in the exposed mesentery (Heinz); or by the clinical response in catarrhs or diarrheas; or simply and with rather surprising accuracy, by the taste.

TANNINS AND VEGETABLE ASTRINGENTS

Tannins or tanic acids are a group of widely distributed vegetable principles, which give a blue or green ink color with iron salts, and which precipitate proteins, gelatin and connective tissue (as in the tanning of leather) and therefore act as astringents, styptics and antiseptics, the latter chiefly by depriving the bacteria of food. They are less destructive than the metals; being practically nontoxic, they are especially suited for use in the alimentary canal and for the treatment of extensive burns. They do not decrease peristalsis directly, but do so indirectly by allaying the underlying inflammation. Their employment in diarrhea dates back at least beyond the fourth century B.C. They form more or less insoluble compounds with many metals, alkaloids and glucosides, and are therefore used as antidotes. The different tannins are not equivalent in these respects. Some (which are perhaps misnamed), such as those of coffee and ipecac, are practically nonprecipitant. Others present differences in the firmness and solubility of the precipitate. The official tannic acid is obtained from nutgalls. In the course of its absorption, tannic acid is decomposed into the nonastringent gallic acid, pyrogallol, etc.

Varieties of Tannin.—Ordinary "tannic" or gallotannic acid is derived chemically by the elimination of a molecule of H_2O from two molecules of gallic acid (trihydroxy-benzoic acid, $C_6H_2.(OH)_3.COOH$). The numerous other varieties are of different composition, in many cases unknown. Some are compounds of gallic acid with sugar or phlorhizin.

As local astringent, tannic acid is used as 1 to 10 per cent solution, generally 5 per cent. Since watery solutions decompose readily, it may be prescribed as the *Glycerite* of *Tannic Acid,* U.S.P., which contains 20 per cent of tannic acid. This may be diluted extemporaneously. A 20 per cent ointment and suppositories of 10 per cent or less are used against hemorrhoids. The 5 per cent watery solution is used on bedsores (Latimer, 1934). *Bacterial cultures* are killed in twenty-four hours by 10 per cent of tannic acid; 5 per cent is ineffective (J. D. Martin and Fowler, 1934).

The tannic acid treatment of burns by repeated applications of freshly made 3 to 5 per cent tannic acid solution coagulates the devitalized tissue and forms a crust which protects its surface and prevents the pain and the irritation of drying and the loss of fluid by serous exudation, which is one of the factors of collapse. The effects are so striking that the treatment quickly obtained wide acceptance when it was introduced by E. C. Davidson, 1925. It became apparent, however, that it has limitations and drawbacks, and it lost favor rapidly—a common fate of methods of treating burns!

The treatment of burns by a 2 or 3 per cent ethereal solution of tannic acid is mentioned in Merck's Index of 1896, but it was little known. Davidson aimed to prevent the absorption of toxic protein decomposition products, but this does not play a significant part (Kapsinow, 1933). The *advantages* are that it is one of the most effective methods of relieving pain, preventing external loss of plasma and protecting against invasion of bacteria and secondary infection. It facilitates the handling of a large number of casualties and has saved many lives. Minor burns, however, do not heal more rapidly, and serious burns are reported to give a higher mortality with tannic treatment than with surgical cleanliness, pressure dressings and rest (D. B. Wells *et al.*, 1942). The *disadvantages* inhere chiefly in the character of the eschar, which develops slowly and requires frequent applications; it is inflexible, immobilizes or cracks; infection may spread unobserved under the opaque covering; the crust may produce pressure necrosis in circumferential burns; near body orifices, especially in the peritoneum, it dissolves and becomes infected; it delays the healing of third degree burns; the germinal epithelium may be injured, granulation tissue is not easily controlled, and unnecessary scarring may result (review, A. M. A. Councils, J.A.M.A. *125*:909). *Absorption of tannic acid* from large surfaces has been blamed for increased incidence of liver damage (see below). Painting the tannic crust with 10 per cent silver nitrate (A. G. Bettman, 1935) forms a drier, softer, thinner and more elastic eschar and so diminishes the difficulties, but does not remove them. Similar objections apply to coagulation crusts formed by 1 per cent gentian violet proposed by R. H. Aldrich, 1933, and by other dye mixtures. From industrial statistics it appears that the quickest healing of minor burns is secured by simply covering them with petrolatum-impregnated gauze and protecting with thick dressings, after cleansing with soap and water. Tannic acid and various medicated salves and emulsions averaged materially slower healing (McClure and Lam, 1943). In severe burns the dominant indication is to protect against excessive blood concentration through loss of fluid to the exterior and into the tissues. Intravenous injection of plasma is especially useful (Weiner *et al.*, 1936; H. N. Harkins, 1944). Pain should be controlled by adequate morphine.

Liver damage following clinical tannic acid treatment of burns, with focal necrosis of the cells, was described by W. C. Wilson *et al.*, 1938, and confirmed by others (Erb *et al.*, 1943). However, the same lesions occur clinically and experimentally with burns that had not been treated with tannic acid (Buis and Hartman, 1941) and in other forms of circulatory shock (Moon and Morgan, 1936). On the other hand, injection of tannic acid into animals that had not been burned produces similar and fatally severe focal hepatic necrosis (Wells, Humphrey and Coll, 1942; Baker and Handler, 1943); but this requires considerable amounts, so that it does not occur from oral administration (Handler and Baker, 1944) or even from application to denuded surfaces in rabbits (H. J. Robinson and Graessler, 1943). It is doubtful whether tannic treatment is dangerous on this account clinically unless the burn involves a third of the body surface (Saltonstall *et al.*, 1945). The risk is greatest if moist tannic acid dressings are kept in contact with burned surfaces for long periods (review, H. N. Harkins, 1945).

Constipative Action.—Administration of tannic acid has little effect on the movement of the normal intestinal tract, but tends to arrest diarrhea by allaying intestinal inflammation through its astringent action. This can be of only limited benefit if the cause of the irritation persists. The protein tannate precipitation occurs only within a restricted range of *p*H, ordinarily between 1 and 8.3, best between 3 and 5 (Sollmann, 1920).

The constipative action was studied on cats with the x-ray method by Hesse, 1913. In the absence of diarrhea, tannalbin has no effect on the intestinal movements beyond a slight delay in the emptying of the stomach; nor had it any influence on the diarrheas produced by milk feeding or senna; and but little on the catharsis of castor oil. However, it arrested certain dietetic diarrheas (bread), and that produced by the colon action of colocynth.

Astringent Plant Extracts.—Preparations of krameria, gambir (catechu), kino, etc., have been supposed to act more slowly than tannic acid because of the protective influence of their colloids. *In vitro,* they precipitate proteins just as readily; but the colloids probably protect the gastric mucosa somewhat by hindering its contact with the tannin. In practice, however, they have been generally displaced by the synthetic compounds.

Synthetic tannin compounds were devised with the aim of being insoluble in water and acid fluids, and soluble in alkaline solutions. This ideal was based on mistaken views as to the true reaction of the intestinal contents; but these properties have not been realized in any instance (Leech, 1920). All the commercial preparations are somewhat soluble in water; and most are about as soluble in dilute acid as in dilute alkali. Their tannin is dissolved, however, or becomes active quite slowly, whatever the reaction, so that they have little effect on the stomach and extend their astringency farther, into the intestines. The principal compounds, exsiccated tannin albuminate and acetyl-tannic acid, are about equally effective, and there seems to be little difference between them clinically.

Exsiccated tannin albuminates (*Albutannin; Tannalbin*), contrary to the prevailing opinions, dissolve rather better in artificial acid gastric juice than in bicarbonate-trypsin solutions. *Tannyl-acetyl esters* (*Acetannal; Tannigen*) are mixtures of varying quality; some specimens contain considerable free tannin. The best specimens appear fairly uniform and but slightly soluble and astringent in acid solution. Bicarbonate dissolves them and hydrolyzes them slowly (Sollmann, 1920).

Tannins of Beverages.—The small quantities of tannin ordinarily taken with the food and drink are not injurious; but large quantities (excessive tea drinking) are probably deleterious. The tannin of coffee is scarcely astringent, and therefore lacks this action.

Tannic acid interferes somewhat with *absorption,* chiefly by precipitating proteins. These combinations are again decomposed in the alkaline intestine, so that the interference is not large. The absorption of normal saline solution from a Vella fistula was accelerated by 0.01 per cent of tannin; 0.04 per cent had no effect; 0.1 to 1 per cent delayed absorption (Biberfeld, 1903). *Large doses* produce irritation and corrosion, especially if the stomach is empty, pain, vomiting, diarrhea or constipation.

The use of tannin as antidote is discussed under "General Toxicology."

The fate of tannic acid is imperfectly known; but it is completely decomposed, even on intravenous injection, into gallic and pyrogallic acid and other decomposition products before being excreted. These appear both in the urine and feces (E. Rost, 1897). Only the insoluble tannates pass in part undecomposed into the feces. With oral administration, the urine contains at most 1 per cent of the gallate of the tannin.

Preparations.—***Tannic Acid,** U.S.P. (Gallotannic Acid, Digallic Acid, Tannin), is an amorphous powder usually obtained from nutgall. Sol. (1:1) in water, glyc., or alc. Watery solutions gradually spoil (hydrolyze to gallic acid) on keeping. *Incompatible* with alkalis, alkaloids, salts of iron and most other metals, proteins and gelatin. Dose, as antidote, 1 Gm., 15 grains. Locally, for urethra, 1 to 2 per cent; vagina, 5 per cent; enema, 1 to 2 per cent; rectal irrigation (cholera), ¼ to ½ per cent; skin and ulcers, 5 to 20 per cent or the Glycerite. The U.S.P. *Glycerite* and *Ointment* contain 20 per cent tannic acid, preserved by sodium sulfite, and keep well.—*Gallic Acid* occurs in many plants, usually with tannic acid. Does not precipitate alkaloids. The reputed astringent effect is perhaps due to a small quantity of tannin which is usually present. Soluble in water, alc. or glyc. Dose, 1 Gm., 15 grains. Externally, 1 per cent, as weak astringent. *Acetyltannic Acid* (Acetannin, Diacetyltannic Acid, Diacetyltannin [H. Meyer, 1894]), Tannigen, Tannyl Acetate) is a yellowish- or grayish-white powder. Dose, 0.6 Gm., in capsules. *Albumin Tannate* (Albutannin, Tannalbin) is a yellowish-white powder containing about 50 per cent tannic acid (Gottlieb, 1896). Dose, 2 Gm., in powder or tablets, followed by water; infants, 0.3 to 0.5 Gm. in gruel.

Tannin-containing drugs include *Galla,* Nutgall; *Catechu, Gambir, Kino, Krameria* (Rhatany), and many others which are rather obsolete.

Diarrhea mixtures are "shotgun" prescriptions, generally containing an opiate, a tannin drug and an aromatic, sometimes with rhubarb and bismuth subnitrate.

NONVOLATILE ORGANIC IRRITANTS

Fixed organic substances produce local inflammation quite disproportionate to their apparent chemical reactions. They irritate the skin in various degrees, without astringent or caustic action, and are used in dermatologic practice and for counterirritation. They are also the cause of many accidental dermatites, especially industrially and by cosmetics. Pepper, capsicum and ginger are used as condiments, but the gastro-intestinal action of most of the others is too violent. Cantharidin causes marked irritation of the genito-urinary tract in the course of its excretion. Several insecticides may be discussed in this connection.

CANTHARIDIN

Cantharides (Spanish Flies) may be used for vesication and for prolonged counterirritation in pleurisy, neuralgic and rheumatic pains, etc. The irritation is active, but the penetration slow, so that the effects are gradual, with only moderate pain, and without involvement of the deeper layers of the skin. The blisters therefore heal readily and without scar. On mucous membranes and open wounds, the effects are more severe, leading to local necrosis, and slowly healing, suppurating ulcers. Internally, cantharis is highly toxic by gastro-enteritis and nephritis; even the absorption from a large blister may cause severe irritation of the kidneys and urinary passages. It is contraindicated in nephritis, and should never be used internally, although it was formerly employed as a diuretic, being one of the few drugs mentioned by Hippocrates. It injures the cells directly, not the capillaries, so that its nephritis is epithelial, not glomerular.

For vesication, it may be employed by spreading cantharides cerate on adhesive plaster, leaving a margin around the edges. It may require from six to ten hours to raise a blister, according to the thickness of the skin, its content in fat, and individual susceptibility. The plaster adheres poorly, and must usually be fixed with adhesive plaster. At the end of six hours (or two to four hours with children), the plaster is removed and the site dressed with petrolatum and sterile gauze. If the blister has already formed, the plaster should be carefully lifted without rupturing the vesicle, which is then pierced and dressed with an ointment, to prevent further pain, irritation or infection. By a "flying blister" is meant a series of small blisters raised along the course of a nerve by the application of successive plasters. When they are employed for counterirritation, they should not be applied directly over the inflamed part, but at some distance from it. They might otherwise render the inflammation more violent. Blistering has almost gone out of use. It is contraindicated in people of feeble condition, since it may then lead to ulceration.

Other Vesicants.—When cantharis is contraindicated—*e. g.*, in cases of inflammation of the urinary passages—it may be replaced by ammonia water or chloroform, which vesicate if their evaporation is prevented, as by covering with a thimble. These are rather more rapid in action, but much more painful than fly blister, and are therefore avoided if possible. Iodine, croton oil and mustard have also been used, but act too deeply.

Origin of Cantharidin.—Cantharidin is a crystalline anhydride of cantharidic acid. It forms soluble salts with alkalis, and these produce the same local and systemic actions. Cantharidin is contained in a number of insects, especially beetles. A similar substance exists also in some caterpillars. It is present in varying amount, even in the same species. It was isolated by Robiquet in 1810 from the Spanish "Fly" (a beetle—Cantharis or Lytta vesicatoria). It is contained in the soft parts, particularly the blood. More than two hundred species of vesicant beetles have been described in the United States (Swarts and Wanamaker, 1946). Cantharis was recommended by Hippocrates in dropsy and amenorrhea; it was popular in the days of heroic medication.

The hollow hairs of *caterpillars* produce local irritation; the active constituent is not known (F. Flury. 1929).

Absorption and Excretion.—Cantharidin is readily absorbed from all surfaces, even from the skin. It is excreted mainly by the kidneys (Eliaschoff); but since it irritates the gastro-intestinal tract when injected hypodermically, some must be excreted by this channel.

Symptoms of Poisoning.—When cantharis is taken by mouth, it produces successively: burning in the mouth, thirst, difficulty in swallowing, swelling and blistering of the tongue, asthma (Wade, 1929), salivation, nausea, vomiting, colic and sometimes bloody diarrhea and tenesmus (the gastro-intestinal symptoms may be less pronounced in rapid poisoning); kidney pain, burning in urethra, frequent micturition, albuminuria, casts, hematuria, painful erections, abortion, weak and slow pulse, chill, syncope and collapse. Recovery may occur in about five days, the urine returning to normal. Toxic effects have been produced by 0.6 Gm.; death by 1.5 to 3 Gm., but recovery has also occurred from much larger doses. Of cantharidin, 30 mg. is probably fatal.

The treatment of poisoning consists in gastric lavage, demulcents, opiates, alkalis and plenty of fluid, heat to the gastric and renal region, and warm baths. No oils or fats should be given by mouth; but the Arab physician Rhases advised washing the bladder with oil, through a catheter, and this would probably diminish the tenesmus.

Central Actions.—When injected into the circulation, cantharidin affects the *central nervous system,* producing short stimulation, excitement and increased reflexes, followed by paralytic symptoms, coma, etc. This central action is not often seen, being obscured by gastro-enteritis or nephritis.

Cantharidin Nephritis.—The kidneys are highly sensitive to cantharidin. Small doses act entirely on the glomeruli, which are greatly dilated; numerous leukocytes are found in Bowman's capsule. The urine becomes albuminous within half an hour after subcutaneous injection. The smaller doses increase its amount, while larger doses diminish it. The epithelium of the convoluted tubules is affected only by large doses, and rather late in the course of the poisoning. The interstitial tissue escapes entirely in the acute intoxication, and is but slightly changed even in the subacute form (Mürset, 1886; Pearce, 1913). The excretion of phthalein is delayed (Eisenbrey, 1913); the nonprotein nitrogen of the blood is increased (Folin, Karsner and Denis, 1912).

Hepatic changes and edema are seen in dogs, with fatal doses. Opie, 1912, found fibrinous clots in the lymph nodes of the hepatic region, around the injured cells, and considers their obstruction responsible for the edema. In their absence, the lymph flow is increased independent of the renal changes.

Polycythemia occurs after acute clinical or experimental poisoning. It sets in slowly and is rather persistent (Lipsitz and Cross, 1917; Morgulis and Muirhead, 1919).

Racial Tolerance.—The hedgehog, chicken and duck are remarkably tolerant to the nephritic action (Ellinger, 1900). This is not due to differences in the absorption or to destruction of the poison, for the cantharidin is found in the urine; nor are these animals immune to other nephritic poisons. The immunity to cantharides is only partial; even a single injection of a large dose causes chronic nephritis. But taking the fatal dose for man (30 mg. by stomach) as the unit, that for the same weight of hedgehog is about 3000. For the dog and cat it is about 2.5 (1 mg. per kilo); for the rabbit, about 45. This immunity to the nephritic action does not extend to the local action on the skin. In this respect, the hedgehog is even more susceptible than the rabbit, which is almost immune to the cutaneous action. The nephritic action is lessened by rendering the urine alkaline (Ellinger, 1905). In the rooster, cantharidin causes changes in the comb, analogous to those produced by ergot. Frogs are not susceptible.

Vesication in Animals.—Animals respond to irritation of the skin by cutaneous edema, rather than by vesication. This is probably due to anatomic differences. Of the experimental animals, the horse alone seems suited to test the action of vesicants (Ewe, 1920).

Tar cancer of rabbits is reported to have disappeared after three or four applications of cantharidin (R. Dubois and Ball, 1933).

Alopecia.—Cantharis is used in the treatment of baldness, in the form of tincture, greatly diluted with alcohol. It has little if any effect clinically. Hair growth is accelerated in rabbits by agents that cause local hyperemia (C. W. Hale, 1945). In undernourished rats, irritants activate the quiescent hair follicles; histamine is equally effective; thyroxin has similar results (E. O. Butcher, 1940).

Treatment of Impotence.—Many drugs have been employed for this purpose, but with questionable results. *Cantharis* produces erection through reflex irritation from the urethral mucous membrane. It is dangerous, since effective doses may set up nephritis. Many *essential oils* act in the same manner and are less dangerous and less active. Here belong, *e. g., daminana, ginseng, mint, garlic,* etc., and possibly *camphor. Strychnine* was thought to be effective by raising the tone of the spinal centers, but is probably useless, as are *phosphorus* and *arsenic. Alcohol, morphine, cannabis* and other narcotics may act as aphrodisiacs by stimulating the imagination. *Yohimbine* has a special action on the blood vessels.

Cantharides, N.F. (Cantharis; Spanish Flies, Russian Flies), is the dried insect Cantharis vesicatoria. Contains not less than 0.6 per cent cantharidin. The *Tincture*, N.F. (10 per cent), is added to liniments to prolong their local action; in hair lotions (1:50). It was used as a diuretic (0.1 cc., $1\frac{1}{2}$ minims), but is too dangerous. *Cantharides Cerate*, N.F., contains 35 per cent. *Cantharidin* is slightly sol. in water or alc., more sol. in chlorof., ether or oils. It may be employed as a blister, 0.05 to 1 mg. in a drop of oil, covered with simple plaster. The preparations of the British Pharmacopoeia are made with cantharidin.

Capsicum produces marked sensory irritation and rubefaction, but not usually vesication. It is used as a condiment and stimulant to the gastric mucosa, and externally as counterirritant against neuralgic pains, rheumatism and sore throat, as the ointment (25 per cent) or equal parts of tincture and soap liniment. The action is fairly lasting, and has the advantage that it does not injure the skin. Care must be taken that it does not get into the conjunctiva.

Capsicum (Red, Cayenne or African Pepper) is the dried fruit of Capsicum frutescens, grown in Africa. The dose of the *Tincture* (10 per cent) is 0.5 cc., diluted. The *Ointment*, N.F., contains 5 per cent of the oleoresin. The action of capsicum is due to 0.02 per cent of *Capsaicin*, a crystalline neutral principle. This produces persistent burning of the tongue in dilution of 1:100,000 (Nelson, 1901). The toxicity of capsicum is low: Gastric administration of 28 cc. of the oleresin to fasting young rabbits caused diarrhea and loss of weight, followed by complete recovery; 56 cc. were fatal (Carmichael, 1939).

Paprika, the fruit of C. annum, is a condiment (red pepper). It has little effect on gastric secretion, with normal stomach or in hyperacidity, but may cause marked increase in hypoacidity (von Berkesy, 1934).

Pepper (Piper) acts similarly to capsicum, but is less irritant. *Black Pepper* is the dried unripe fruit of Piper nigrum. *White pepper* is the ripe fruit, deprived of its outer pericarp. They contain the crystalline alkaloid piperine, a volatile oil, and a pungent resin. *Dose*, 0.5 Gm., 8 grains. *Piperine* (piperyl-piperidine) has been used as an antipyretic and carminative, 0.1 to 0.5 Gm., 2 to 8 grains, in capsules.

Anemonin is the irritant constituent of fresh plants of the buttercup family; for instance, the marsh-marigold, Caltha palustris (Kobert, 1917). It exists in Ranunculus scleratus mainly as a mother substance, proto-anemonin, which is volatile with steam. The structure of this and of anemonin have been determined and confirmed by synthesis (Asahina and Fujita, 1920).

Pulsatilla is the herb of Anemone Pulsatilla and A. liratensis; Europe. Its active ingredient is anemonin. The drug is very irritant, and is almost obsolete, but has been used against asthma, hemicrania, etc., in *doses* of 0.1 to 0.4 Gm. It has a depressant action on the excised uterus (Pilcher, 1916).

Mezereum is the dried bark of Daphne species. The active constituent is the anhydride of mezerinic acid. There is also a glucosid daphnin. The fluid extract is rarely used as an addition to liniments or plasters; also in Fldext. Sarsap. Co.

Arisaema (Indian Turnip; Jack-in-the-pulpit). The fresh corm of this plant is very irritating or "acrid" when chewed. This is probably due to the mechanical effect of its sharp calcium oxalate crystals (Lazenby, 1915; E. D. Brown and Anderson, 1918).

Euphorbium is the dried juice of Euphorbia resinifera; contains a gum resin. The active constituent is the resinous euphorbon, which resembles the active resin of croton oil (Boehm, 1915).

Croton oil (Oleum Tiglii) and *antimony and potassium tartrate* (see Index) were formerly used to cause pustule formation, as a more severe form of counterirritation; and to provoke reactions similar to those of nonspecific protein therapy. Pustulation is likely to lead to permanent scarring and is obsolete as a therapeutic measure.

POISON IVY

Contact with certain species of Rhus, common along roadsides, on fences, in woods and swamps, produces dermatitis (Captain John Smith, 1609), passing through hyperemia and itching to violent vesication, edema and suppuration, according to the specific sensibility of the individual. Many persons are practically immune, although a sufficient quantity of the isolated principle has never failed to produce the dermatitis. It is believed that the dermatitis is an anaphylactic phenomenon requiring sensitization by previous exposure. The susceptibility probably diminishes in time if it is not maintained by repeated exposure. It does not produce bronchial or other anaphylactic symptoms.

The active ingredient of all the species, *urushiol*, a mixture of closely related catechol derivatives, occurs as a resinous oil, contained in the sticky sap of the plants, which exudes when the plant is injured. It becomes inactivated by oxidation through *laccase*, a polyphenolase occuring in the sap of these plants (review, F. A. Stevens, 1945). It is so highly active that $\frac{1}{1000}$ mg. has caused severe vesication (Pfaff). It is not volatile, but it may be carried to some distance on the soot in the smoke of burning plants, and perhaps on dust (E. D. Brown), and by insects alighting on injured plants. None is present in the pollen (Warren, 1913; McNair). It may be conveyed by the hands or clothing from one person to another, as if it were contagious.

Toxic Species.—The most important are: Rhus vernix, synon. venenata (Poison Sumach, the most powerful); Rhus toxicodendron (Poison Oak); Rhus radicans and diversiloba (Poison Ivy); Rhus pumila (a Southern species)—all common in North America. These are largely subvarieties which may be changed into each other, and their toxic principle is identical (F. A. Stevens, 1945). It agrees with that of the Japanese lacquer tree (Rhus vernicifera). The common sumach, Rhus glabra, does not have this action. McNair, "Rhus dermatitis," Chicago University Press, 1923, gives extensive *references*.

Chemistry.—Pfaff, 1897, showed that the toxicity is not due to a volatile alkaloid or to a volatile acid, but that it is caused by a fixed oily substance, "*toxicodendrol*." McNair, 1923, obtained a purer extract, "*lobinol*," by differential solvents. Maijama *et al.*, 1922, isolated the pure substance "*urushiol*" from the oriental lac tree and identified it as a mixture of closely related o-dihydroxybenzene derivatives with unsaturated sidechains. Poison-ivy extracts yield apparently the identical substance (G. A. Hill *et al.*, 1934). It is soluble in alcohol and oils and is precipitated by lead acetate and other metallic salts. It is not destroyed by heating an hour at 100° C. (v. Adelung, 1912, 1913). On exposure to the air it becomes gradually oxidized, blackens, and loses its activity. This is due to the *laccase* of the sap. When it is separated from this enzyme by ether it is quite stable in slightly acid solution.

Symptoms.—The dermatitis begins after a latent period of one-half to nine, usually four or five, days, depending partly on the sensitiveness and thickness of the skin, partly on the quantity of the poison. The toxicodendrol may penetrate directly through the epidermis, for it may infect portions of the skin that are devoid of glands; but where these are present, the infection is usually more severe. The dermatitis does not spread beyond the area of contact. The cutaneous reaction begins with rubefaction, swelling and itching, and passes through the stages of macule, papule, vesicle and pustule, with leukocytic infiltration of the skin. There is also some systemic reaction: severe leukocytosis, febrile symptoms and slight renal irritation (McNair, 1916). The attack generally subsides in four to six days. Internally and hypodermically it produces gastric and intestinal irritation, proctitis, vulvitis and nephritis, but the systemic toxicity is relatively low.

Congenital differences of susceptibility are marked. Krause and Weidman, 1925, found half the subjects clinically immune to application of the plant to the intact skin; this was reduced to a fourth immune if the skin was scarified. They found no definite difference between blondes and brunettes, or obese and thin. Children are probably more susceptible than adults. At the age of fifteen years, 30 to 85 per cent give a positive skin test; of adults, 50 to 85 per cent. About half of those with positive test become affected on casual field exposure. All the chief races, including American Indians, appear about equally susceptible (review, F. A. Stevens, 1945). The tolerance varies from time to time, and is sometimes lost, and one attack generally leaves the skin more sensitive to future exposures. Infants at birth are not sensitive to rhus extracts (B. Shelmire, 1939), but they can be sensitized artificially (H. W. Strauus, 1931). Animals are relatively insusceptible (Krause and Weidman)- but guinea pigs can be sensitized to rhus (Simon *et al.*, 1934; Kile, 1936) and to urushiol (Landsteiner and Jacobs, 1936). 3 n-pentadecyl catechol may be used to test rhus hypersensitivity (H. Keil *et al.*).

Treatment of Ivy Poisoning.—Susceptible persons should avoid exposure to the plant, *e. g.*, by wearing rubber gloves. As soon as possible after contact, the area should be scrubbed thoroughly with soap and brush, followed by alcohol, to remove the unabsorbed poison. Nonirritating oxidizing agents have been recommended, such as 10 per cent sodium perborate in a special vanishing cream (L. Schwartz *et al.*, 1942), but its effectiveness is questioned (B. Shelmire, 1941). Frequent washing with a ferric chloride lotion (one part of the tincture to two of water) inactivates any toxicodendrol that is still on the surface, and tends to diminish irritation through the astringent effect. However, it sometimes causes extensive permanent pigmentation by the deposition of yellowish ferric granules in the epidermis and corium (Traub and Tennen, 1936). Calcium hypochloride, 1 per cent solution, may be used for decontamination of clothing and tools.

When the dermatitis has developed, its course is not materially influenced by treatment, but dressings wet with astringent lotions give some relief, especially if applied ice cold: aluminum acetate, 5 per cent; potassium permangante, 1:5000; tannic acid, 10 per cent (L. Schwartz and Warren, 1941). Saturated solution of lead acetate in alcohol was formerly popular, but implies some risk of lead poisoning. Salves should be avoided, especially in the early stages, since they might spread the area of infection by dissolving the toxicodendrol.

A large number of other measures have been tried, but without advantage (v. Adelung; McNair). They may be grouped as astringents (metallic salts, iodine, bromine, tannic extracts); analgetics (phenol, quinine); protective ointments and resins (grindelia); detergents (soap-paste dressing); alkalis (bicarbonate, borax, lime water); nondescript (expressed juice of "Touch-me-not" [Impatiens fulva]). Purified mushroom *tyrosinase* catalizes the oxidation of urushiol and related substances and diminishes their dermatitis. It is reported effective when applied to the skin (Sizer and Prokesch, 1945).

Desensitization for prophylaxis and treatment has been attempted by daily oral ingestion or intramuscular injection of gradually increasing doses of extracts of Rhus species, which may be used interchangeably. The results are controversial. Stevens, 1945, concludes that there is preponderant evidence that desensitization of limited duration but sufficient for prophylaxis can be produced by the oral method, but that this must be done slowly (in seven or eight months) or it involves danger of rashes and gastro-intestinal disturbances. Results with intramuscular injections are more doubtful. The extract must not come in contact with the epidermis. Overdosage causes fever and other constitutional reactions.

Clinical immunizations were attempted by Schamberg, 1919, and developed especially by Strickler, 1918 to 1923. *Chewing of the leaves* is dangerous. Three leaves produced severe stomatitis in two days; dermatitis on arms, hands and legs on the fourth day (R. K. Sassaman, 1945). A fatality has been recorded (Alumbaugh, quoted by McNair). Lighter cases develop pruritus ani, rectal irritation (S. H. Silvers, 1941) and aggravating hemorrhoids.

Other plants producing dermatitis include a number of tropical trees belonging to the same family—Lithrea caustica; Anacardium (active principle, cardol, an oily substance); Semecarpus, a variety of ornamental woods, especially tropical but also domestic, with marked difference of susceptibility (review, Senear, 1933). The sap of a variety of tropical plants of the Anacardiaceae, including the mango, produces allergic dermatitis, probably by an identical or related substance (E. D. Merrill, 1944). Mango susceptibility has been studied by H. Keil *et al.* "*Dhobie*" dermatitis in East India results from contact with linen marked by native launderers with a fluid from the fruit of Semecarpus Anacardium (N. R. Goldsmith, 1943). The latex of Semecarpus atra, the "acajou" tree of South Pacific islands, produces severe dermatitis; the natives believe that this may occur from sleeping under the tree (J. H. Hitch, 1944). *Manzanilla* tree dermatitis and keratoconjunctivitis are produced by the milky sap of a tree of the Euphorbiaceae, growing in the Carribean area (Snow and Harley, 1944). Some florists' and garden plants, primula, chrysanthemum, arbor vitae and many other plants (vanilla beans, Claveric, 1908); the fruit of the ornamental ginkgo tree (Starr, 1913), affect sensitive persons in the same manner. *Tomato-vine* juice has apparently produced mild dermatitis in susceptible individuals (Lain, 1918). *Primula dermatitis* is caused by direct contact with the common Chinese house plant, Pr. obconica, and a few other species. Nestler describes toxic crystals in the resinous secretion of the leaves. The treatment consists in cleansing with alcohol or ether, and the application of zinc ointment (O. H. Foerster, 1910; Rost, 1914). Primrose dermatitis has also been studied by Simpson, 1917.

CHRYSAROBIN

Chrysarobin is a mixture of neutral principles extracted from the "Goa powder," in cavities of a leguminous tree, Andira Araroba, of Brazil. It consists chiefly of chrysophanolanthranol, and yields *chrysophanic acid* on oxidation and is sometimes itself misnamed "medicinal chrysophanic acid." It is strongly irritant to the skin and mucous membranes, and is employed as 0.1 to 10 per cent ointment against chronic dermatoses, psoriasis, pruritus and ringworm, applied daily, but reducing the concentration as soon as an effect is obtained, else it may produce excessive and harmful irritation. A saturated ethereal solution is used on *warts*, painting it on daily and paring off the dead tissue. It should not be employed on the face, genitalia or scalp. The hands must be carefully washed. It stains the keratin of the hair and skin, and also linen, a brownish-violet color. This can be removed by chlorinated lime or benzol (Mankiewicz, 1916). Caution must be used lest it reach the eyes and produce violent conjunctivitis (or rather keratitis; Igersheimer, 1912) and corneal opacity. It is absorbed from the skin, and excreted partly as chrysophanic acid, which is easily formed by its oxidation, especially in alkaline solutions. The urine is therefore colored red by alkalis. A part is excreted unchanged, and causes renal irritation, casts and albuminuria. By mouth, 0.18 Gm. produces vomiting, diarrhea, renal pain and hematuria.

Chrysarobin has a strong affinity for oxygen, abstracsing it from the tissues. This was suggested as the basit of its action, the oxidation product, chrysophanic acid, being relatively inactive. The oxidation occurs only in water suspensions in the presence of alkali. Fats diminish its activity (Schamberg, Raiziss and Kolmer, 1915).

Chrysarobin, U.S.P., is an orange-yellow, microcrystalline powder, tasteless, odorless and irritating to the mucous membrane. Very slightly sol. in water, slightly sol. in alc. (1:385), partially sol. in fats. The *Ointment*, U.S.P., contains 6 per cent; that of the B.P. 4 per cent.

Anthralin, 1,8-dihydroxyanthranol, differs from chrysarobin by the lack of a methyl group. It appears to be an effective synthetic substitute for chrysarobin, possibly even more effective in psoriasis, somewhat less likely to cause local or systemic reactions, and producing less discoloration of the scalp or clothing.

It is applied as ointment in petrolatum, beginning with 0.1 per cent and increasing successively to 0.25, 0.5 and rarely 1 per cent, once or twice daily. Severe dermatitis may occur with 2 per cent. The same precautions should be used as with chrysarobin. It was introduced by Galewsky, 1916, and Unna, 1916, under the title *"Cignolin."* It occurs as a yellow crystalline powder, insoluble in water, readily soluble in organic solvents (H. Beerman *et al.*, 1933).

Resorcinol is related to this group (see Index).

PYRETHRUM FLOWERS ("INSECT POWDER")

Pyrethrum or Persian insect powder consists of the powdered flowers of Pyrethrum carneum and roseum, cultivated chiefly in Japan and the Kenya district of Africa. Dalmatian Insect Powder, which furnishes a relatively small supply, is derived from Chrysanthemum cinerariaefolium and appears to be closely related in composition and action. They lose activity on keeping. They should not be confused with Pyrethrum Root or Pellitory, the root of a related plant, Anacyclus pyrethrum, which is an obsolete sialogogue. The insecticidal action of insect powder is attributed to two esters, *pyrethrin* I and II, derived from a five-carbon ring, pyrethrolene (La Forge and Haller). Pyrethrin I is somewhat more potent than II. They are hydrolyzed by weak alkalis, including soaps. A third constituent, probably an oleoresin, produces dermal irritation; and an allergen, probably in the pollen, causes asthma and other allergic reactions in sensitive individuals, who are generally also sensitive to ragweed pollen (S. M. Feinberg, 1934).

Action on Invertebrates.—Insect powder kills all kinds of insects, but is used especially against bedbugs and roaches. An ointment, N.N.R., is employed against scabies (Sweitzer and Tedder, 1935). Extracts made with lipid solvents, dissolved (5 per cent) in oil or propylene glycol and liquified "Freon," are used in spray bombs with good results (Goodhue and McGovran, 1944). Emulsions are used on plants, and these are not injured by pyrethrum. Roaches react one and one-half minutes after application, first with great excitement, then with incoordination, progressive paralysis and death (Hockenyos, 1936). Caterpillars show similar symptoms. A considerable proportion of the insects recover within a day, so that they should be swept up and destroyed. Pyrethrins act on the neuromuscular system (Juillet *et al.*, 1924). The ventral nerve ganglia show vacuolization (F. Krüger, 1931). The heart of crayfish is sensitive to $1:10^{12}$ (Belleuvre, 1938). It is also effective against intestinal parasites of sheep and fowl (Perrot *et al.*, 1933).

The acute toxicity of the pyrethrins for mammals is relatively low, presumably because the esters are rapidly hydrolyzed to less toxic compounds, especially in the stomach (Chevalier and Ripert, 1927), so that there is little danger from the ingestion of small amounts (S. M. Feinberg, 1934). It may cause irritation of the skin about the anus. The toxicity is considerably higher with parenteral injections. These produce diarrhea, clonic convulsions, prostration and death by respiratory paralysis. Local application to the conjunctiva causes chemosis (Shimkin and Anderson, 1936; C. S. Leonard, 1942).

Rotenone, a crystalline neutral principle, is the active constituent of the root of *Derris elliptica*, a plant of Java. This and closely related 5-carbon ring derivatives occur in more than seventy leguminous plants, mostly tropical or subtropical (Acree *et al.*, 1944). They are used by the natives as fish poison, and in Sumatra as arrow poison. Rotenone and plants containing it are employed as insecticide for spraying vegetable crops, in amounts which do not leave sufficient residue to be poisonous to man, cattle or birds (Haag, 1931; J. A. Mathews and

Lightbody, 1936; Ambrose and Haag, 1937). Some insects are more susceptible than others. Toxic doses of rotenone administered to mammals cause vomiting, respiratory depression, incoordination, clonic convulsions, muscular tremors and death by depression of respiration. The fatal dose by mouth is fifty times that of peritoneal injection (Shimkin and Anderson, 1936). The oral toxicity of derris to mammals appears greater than corresponds to its rotenone (Ambrose and Haag, 1936), but 0.2 Gm. per Kg. is not fatal (H. H. Shepard, 1939). Inhalation of the dust may produce fatal pulmonary irritation. Feeding of small doses produces fatty changes in the liver. It is not anthelmintic (Haag, 1931). The toxicity of rotenone and its derivatives for *gold fish* has been studied by Gersdorff, 1930.

MISCELLANEOUS INSECTICIDES

Many substances are toxic to insects, but their practical efficiency varies with conditions, depending on their physical properties, volatility, spreading power, etc., as well as chemical toxicity (W. Moore and Graham, 1918; Shepard, 1939; historical, R. C. Roark, 1935), and these must be weighed against the possible dangers to man and stock.

Commercial insecticide sprays contain principally pyrethrum dissolved in petroleum distillate, supplemented by cheaper poisons, such as paradichlorobenzene ("PDB"), thiocyanates, derris extract, isobutyl undecylenamide, flavored with citronella or pine oil. All these can irritate the skin and produce toxic and even fatal effects if enough is inhaled (L. Schwartz and Warren, 1939).

For field crops and orchards, the most useful agents are lead and copper arsenates, with calcium polysulfide for scale insects; *for horticulture*, nicotine, hellebore and sulfur; against *roaches and ants*, sodium fluoride, borax, cresols and insect powder; against *moths*, naphthalene and camphor; for *house flies*, sodium fluoride and arsenic trioxide; the toxicity of organic compounds is generally proportional to their volatility (W. Moore, 1917). Paradichlorobenzene is used against fly larvae. *To repel mosquitoes*, odorous volatile oils are more or less efficient, presumably by obscuring the human odor (Bacot and Talbot, 1919). Esters are generally more potent than the corresponding alcohols, and these surpass their hydrocarbons (W. Moore, 1934). Mixtures of dimethylphthalate derivatives are more effective (see below). *Bedbugs* are killed by painting all crevices with alcoholic solution of mercuric chloride and dusting with insect powder. Against *lice*, "DDT" is the agent of choice (see below). Mercury, staphisagria, phenol, etc., are effective against limited infections, but they are too toxic and irritant for extensive application. Naphthalene and volatile oils stupefy and paralyze the parasites, but they are likely to recover subsequently. Acids are definitely fatal. Sulfur dioxide is effective (Knaffl-Lenz, 1915). Oiling of underwear destroys the lice mechanically (1 cc. of oil per 4 square inches of medium weight underwear). Creosote and especially heliotropin (piperonal) may be applied in theobroma oil (W. Moore, 1918).

Dimethylphthalate is a potent insect repellant, useful against mosquitoes, mites and leeches (J.A.M.A., 1945, *128:* 30). Clothing may be impregnated with a 5 per cent emulsion, or the repellant may be applied as a spray or thin film, which remains effective for three or four washings. Solutions when *swallowed* produce irritation of the buccal mucosa, nausea, vertigo, vomiting, early coma and fall of blood pressure (Doehring and Albritton, 1944). Dimethyl and dibutyl phthalates are used to repel parasitic *mites*, as is also benzyl benzoate. The latter is lethal to the cercariae of schistosoma (E. C. Faust, 1946). *Other effective insect repellants* are n-butyl mesityl oxide oxalate and 2-ethyl-1, 3-hexanediol (review, F. S. Phillips, 1946)

CHLORINATED DIPHENYL ETHER ("DDT")

This substance, dichloro-diphenyl-trichloroethane, is highly toxic to many insects and is expected to revolutionize insect control. It is most effective as "louse powder," and is also satisfactory against mosquitoes, larval and adult, chigger mites and many others. It is applied as a 5 per cent dust or emulsion, and remains potent on the surfaces for at least three weeks, even after several launderings, acting as prophylactic as well as eradicator. It belongs to the group of chlorinated hydrocarbons and resembles them in its effect on mammalian heart. It is harmless to man when properly applied, but high doses are toxic when absorbed from oily solutions by the skin. Powders and aerosols are not absorbed, and no ill effects ensue from the small amounts that are inhaled. Few unquestioned cases of poisoning have been reported, in spite of its extensive employment, but this may be credited to observance of proper precautions. The "joint statement" of the U. S. Army and U.S.P.H.S., 1945, J.A.M.A., *128:*36, points out that indiscriminate spraying would kill useful as well as harmful insects.

The substance was synthesized by Othmar Zeitler, 1874. It was introduced as insecticide, with the trade name *Gesarol*, by Geigy of Basel. It is a fine powder of faint floral odor, insoluble in water, soluble in many organic solvents. It is chemically rather inert, very stable, and does not volatize materially. It adheres to surfaces, so that it is not likely to become detached as dust.

Action on Insects.—The susceptibility of different species varies considerably; it is greatest for those with chitinous cuticle, which probably adsorbs the poison. Larvae of mosquitoes are highly susceptible, those of flies but little, adult flies considerably. It enters through the tarsi, and kills by excitation and paralysis of the central nervous system. When insects make contact "they begin to fly around in erratic circles for ten to twenty minutes, then fall to the ground, apparently paralyzed, and die several hours later." In roaches the action appears to be on the region between the ventral nerve cord and the nerve endings, while nicotine acts on the ganglia (Yeager and Munson, 1945; review, F. S. Phillips, 1946). The roaches show continuous twitching. This persists in amputated legs and is therefore peripheral. Tremors occur with much lower concentrations. These are associated with high frequency trains of axon spikes in the afferent nerves and are attributable to afferent bombardment of the motor neurons (Roeder and Weiant, 1946). It has similar actions on *crustaceans*, producing repetitive discharge of motor fibrils to a single impulse, resulting in tetanus. Pyrethrin and veratrine produce analogous effects. They are suppressed by calcium ions (J. H. Welsh and Gordon, 1946). Daphnia is immobilized by $1:10^9$ to 10^7 (B. G. Anderson, 1945).

Application as Insecticide.—Dusting with 1 to 5 per cent powder is most effective against *lice* and *chigger mites. Mosquitoes* are controlled by applying it to the walls as 5 per cent emulsion by brushing or, more conveniently, as "aerosol" sprays of liquefied Freon. Ants, roaches, bedbugs, flies, fleas and ticks may be treated with 5 per cent powder or solution in kerosene, with particular attention to cracks. A D.D.T. paint is effective against "fouling" of ships by barnacles.

Clinical Toxicity.—In spite of the inherent toxicity of D.D.T., its use as aerosol spray in 1 to 3 per cent solution in 10 per cent cyclohexanone with 89 to 85 per cent of Freon is not injurious; nor is dusting with 10 per cent dilutions in inert powders. Experimental exposures show that there is a considerable margin of safety. Contamination of food must be avoided (P. A. Neal, von Oettingen *et al.*, 1944, 1946). Oily solutions are absorbed through the skin. Occasional contact is not harmful, but large doses produce serious toxic symptoms in animals. The powders are not irritating to the skin, solutions only mildly so (Draize *et al.*, 1944). There is more danger from the use of unsuitable solvents, especially chlorinated hydrocarbons.

Clinical symptoms in mild cases include nausea, vomiting, anxiety, stiffness and pain in the jaws, sore throat for several days (M. I. Smith, 1946). A group of persons poisoned by mistake for baking powder developed giddiness and weakness in one to two and a half hours. All recovered in forty-eight hours (Mackerras and West, 1946). Fatal poisoning in a child, reported by K. R. Hill and Robinson, 1945, indicates that 150 mg. per Kg. is fatal. This is similar to the LD_{50} dose in animals (M. I. Smith and Stohlman, 1945).

Toxic Effects in Animals.—D.D.T. is acutely toxic to mammals on oral administration of 150 to 750 mg. per Kg. of body weight. It produces anorexia, tremors, of long duration, convulsions, depressions, paralyses and death (G. Woodard *et al.*, 1944). The mammalian symptoms correspond to ablation of the cerebellum and cortex, and the cerebellum shows pathologic changes in chronic poisoning (Crescitelli and Gilman; review, F. S. Phillips, 1946). The myocardium is sensitized to fibrillation, as with other chlorinated hydrocarbons (F. S. Phillips *et al.*, 1946). In dogs, daily doses of 100 mg. per Kg. result in fibrillary contractions of skeletal muscles, passing into tetany, suppressed by calcium gluconate injection (Z. Vaz *et al.*, 1945). Larger doses (150 to 250 mg.) produce severe neurologic symptoms attributable to cerebellar dysfunction (B. P. McNamara *et al.*, 1946). Animals that survive several weeks have moderate central necrosis in the liver, possibly with reparative hypertrophy. The central nervous system does not show significant lesions (A. A. Nelson *et al.*, 1944); but Pluvinage and Heath, 1946, describe diffuse damage to the ganglion cells in acute poisoning of cats. Mice are more susceptible than rats; guinea pigs, dogs and monkeys are much more resistant (P. A. Neal *et al.*, 1945). Goldfish and frogs are considerably more susceptible than mammals (M. M. Ellis *et al.*, 1944). It has no effect on tissue cultures of chick embryos and of the brain and spleen of rats, even when the crystals are in actual contact with the cells (W. H. Lewis and Richards, 1945).

The toxicity for mammals and insects does not differ widely on the basis of tissue concentration; the relatively low toxicity for mammals is due chiefly to slow absorption (J. M. Tobias *et al.*, 1946).

The fate, distribution and excretion of D.D.T., as well as the acute and chronic toxicity for animals, were studied by M. I. Smith and Stohlman, 1944; E. P. Lang and Fitzhugh, 1946; and by Ludewig and Chanutin, 1946. Significant amounts are stored in the body fat, especially if fed in oily solution to dogs (G. Woodard *et al.*, 1945). The milk of poisoned animals contains enough to produce typical toxic symptoms in the sucklings (Telford and Guthrie, 1945). Rabbits fed with D.D.T. excrete di (parachlorophenyl) acetic acid in the urine (W. C. White and Sweeney, 1945).

Tetradichloro diphenyl ethane, "T.D.E.," "*rhothane,*" a related compound, has a similar toxicity for anopheles larvae (Deonser and Jones, 1946). Other related compounds have been studied by M. I. Smith, Bauer *et al.*, 1946.

Betabutoxy-beta-thiacyano-diethyl ether (*Lethane* 384) is safe and highly effective against all household insects, including roaches and moths (E. C. Faust, 1946).

Hexachlorocyclohexane, $C_6H_6Cl_6$, "666," "*benzene hexachloride,*" equals or surpasses D.D.T. against most insects, but has a disagreeable odor. The four isomers which compose the technical product differ widely in potency. The gamma form ("gammexane") is many hundred times stronger than the others on insects, and there are also great differences in mammals; the gamma is convulsant, the delta depressant (review, F. S. Phillips, 1946).

IRRITANT VOLATILE OILS

The volatile (or "essential") oils which give their distinctive odor to plants are usually mixtures of hydrocarbons of various groups, generally containing terpenes and oxidized aromatic derivatives. The balsams and resins which contain volatile oils may be included in the group. These oils occur in numerous plants and determine their use as flavors, aromatics, carminatives, antiseptics and irritants. Their chief application is for their local effects, consisting of deep irritation with a minimum of tissue destruction. The sensory stimulation is followed by some anesthesia. They exert a favorable influence on chronic inflammations, partly by their mild antiseptic and irritant action and partly by chemotactic attraction of leukocytes. In acute inflammations they are more likely to do harm. Their antiseptic action is relatively weak, since they are but slightly soluble in water. After their absorption they are excreted mainly in combination with glycuronic acid (Matzel, 1905). They irritate the kidneys, produce diuresis and act as urinary antiseptics.

Composition.—The terpenes are aromatic, cyclic compounds of the general empirical formula, $C_{10}H_{16}$. Related to them are the semiterpenes (C_5H_8); sesquiterpenes ($C_{15}H_{24}$); and diterpenes ($C_{20}H_{32}$). Other constituents are oxidation products of these and aromatic phenols, ketones, aldehydes, acids and their compounds.

The antiseptic effects have been investigated especially by Kobert, 1906; Rippetoe and Wise, 1912.

Antiseptic Action of Aromatic Fumes.—The smoke of burning wood has been used since antiquity for "purifying" or "curing" meat; the smoke of aromatic resins, incense, etc., for "purifying contaminated air." Macht and Kunkel, 1920, confirmed that these fumes are feebly antiseptic. It is improbable, however, that concentrations which could be inhaled without injury to the mucosa would be directly injurious to bacteria.

The fungicidal action is not necessarily proportional to the antibacterial action (H. B. Myers and Thienes, 1925). *Thymol* is especially effective against yeasts, and was tried clinically against fungal infections of the skin and mouth, but apparently with only limited success. H. B. Myers, 1937, claimed fair clinical result in actinomycosis from local application of 10 to 20 per cent solution of thymol in olive oil, together with oral administration of 2 Gm. daily.

Volatile oils (particularly those enumerated as urinary antiseptics) are used in various *subacute and chronic inflammations* and are said to lessen aseptic inflammations at points remote from the site of their application, by decreasing the formation of exudates and by hastening their absorption. The explanation may be *chemotactic attraction* for leukocytes (Hamburger, 1912).

Systemic Actions of Volatile Oils.—The principal central effects of volatile oils are reflex. With the ordinary doses, no direct action whatever can be observed. Large doses act on the nervous centers, especially the brain and medulla. These are first stimulated, then depressed. The details have been investigated, especially by Hildebrandt, 1901 and 1902, and Geinitz, 1912. The degree of *stimulation* varies for the different oils. Turpentine has scarcely any effect, while absinthe, thujon, fenchon, carvon and camphor produce violent epileptic convulsions (see Index for Absinthe and Camphor). The *depression* is more uniform: the majority (valerian, fennel, chamomile, eucalyptus, mint, rosemary, sabinol, citral, turpentine) diminish the reflex excitability, so that large doses entirely prevent strychnine convulsions in rabbits. The effective doses are, however, too large to make it possible to employ this action in man.

Curare actions have been studied by Hildebrandt and by Matzel; *cardiac effects* by H. Schwalb, 1912. *Isolated intestinal segments* are stimulated by oil of anise, turpentine and chenopodium, in concentrations of 1:50,000 to 1:25,000. Higher concentrations of all volatile oils depress the movements (Muirhead and Gerald, 1916). If volatile oils are injected *hypodermically*, they produce the reflex action in a more marked degree than when they are applied to the surface of the skin. Later their systemic, and still later the renal, actions take place. *The hemolytic action of terpenes* varies with the surface tension; but the alcohol or ketone character also has an influence (Ishizaka, 1914). Some form *methemoglobin*, especially the terpenes, ketones and aldehydes with unsaturated sidechains or methylene groups (Dessemontet, 1927).

OLFACTORY STIMULANTS

Odorous substances produce reflex effects. Pungent and aromatic drugs cause prompt medullary stimulation, increasing the respiration and blood pressure, and slowing the pulse. They are used in fainting, as *Tinctura Lavandulae Composita* (U.S.P., B.P.) and Aromatic Ammonia, the latter often by inhalation. Any pungent substance may answer; the burning of a feather under the nose of the patient is a popular household measure.

The respiratory reflex for ether, carbon disulfide and ammonia appears to be transmitted chiefly by the olfactory nerve, the trigeminal path being only supplementary (Ciurlo, 1933). Substances which produce sneezing (*sternutatoria* or *errhines*) cause reflex stimulation, presumably trigeminal. Their use as counterritants in nasal catarrh is obsolete, as they are more likely to do harm than good.

HYSTERIC SEDATIVES OR ANTISPASMODICS

Asafetida, valerian, musk and similar drugs of marked and peculiar odor have been used since antiquity as sedatives in hysterical and similar nervous conditions. They are often effective, presumably by olfactory and psychic reflexes. Modern psychiatric methods, aiming at the causes, give better and more permanent results. Sydenham (1624–1689) attributed their effects to their "strong and noisome smell, to recal the exorbitant and deserting Spirits to their proper Stations." Asafetida is also carminative, and has been used by mouth and enema (emulsion) in tympanites; but it imparts its odor to the excreta and eructations. Large doses (½ ounce) have been taken without other noticeable effects. Large doses of valerian produce systemic action, but it is doubtful whether these occur with the ordinary doses. Valerian was formerly used as a perfume and as a spice for meat, and asafetida was reported to be employed as condiment in Persia.

Preparations.—*Asafetida* is the gum-resin obtained by incising the rhizome and roots of species of Ferula. A soft, yellowish-brown mass of characteristic odor, bitter and acrid taste. Dose, 0.4 Gm., best as pills. When rubbed with water, forms the milk-white *Emulsion of Asafetida*, 4 per cent, used especially as enema against tympanites in dose of 15 to 60 cc. (½ to 2 ounces).

Valerian (Valeriana) is the dried rhizome and roots of Valeriana officinalis. Dose of the (20 per cent) *Tincture of Valerian* is 2 to 4 cc. (½ to 1 drachm). Valerian contains ½ to 2 per cent volatile oil, valeric and other organic acids; tannin and resins. The oil consists of esters of valeric (valerianic) acid, especially with borneol. These are probably the bearer of the action, but this was doubted by Haffner, 1929. Free valeric acid and its salt are quite ineffective. The fresh root is also ineffective, the esters being formed only during drying by the action of oxidases (Kochmann, 1904). The juice of the fresh plant produces different effects from the dried valerian (Pouchet and Chevalier, 1905). The esters again deteriorate by oxidation on keeping. Certain synthetic esters are said to be more stable. *Injection of valerian oil* produces the usual effects of volatile oils (Pouchet and Chevalier; Kionka, 1904); in small doses, psychic exaltation and rise of blood pressure from cardiac and vasomotor stimulation; in larger doses, central sensory and motor depression. Petlach, 1938, observed no apparent effect of valerian or borneol on the central nervous system of guinea pigs. Large doses cause death by hepatitis. *Excised frog heart* is weakened by very dilute solutions, and arrested by stronger solution of valerian or borneol (Petlach, 1938). *Excised uterus* is stimulated by valerian oil (Pilcher, 1916). *Excised intestines* are depressed by valerian oil (Delzell, Burman and Pilcher, 1916). *Synthetic Valerian Esters.*—Amyl valerate; Bornyval (borneol isovalerate); and Valyl (valeryldiethylamide) have been introduced.

Valerates (*Valerianates*) have little value. They are given in *doses* of 0.06 to 1 Gm., generally in capsules. They are colorless crystals of a valerianic odor, readily soluble in water; Zinci Valeras, Ammonii Valeras.

Minor drugs of this group include Sumbul (Musk Root), Moschus (Musk), Castoreum, Cataria (Catnip), and Symplocarpus (Skunk Cabbage). The actions of *musk* have been studied by Y. Takayama, 1930. They are so slight that they would not produce any therapeutic effects.

MUSTARD OIL GROUP

The sharp taste and irritant action which *black mustard seed* develops on contact with water are due to the formation of the *volatile mustard oil, allyl isothiocyanate,* C_3H_5NCS, by the action of the enzyme *myrosin* on the glucoside *sinigrin* (potassium myronate), which by itself is not irritant. The ferment action is favored by warmth, but arrested by boiling water. *White mustard* contains a similar ferment and glucoside, *sinalbin,* which yields an analogous volatile oil, acrinyl isothiocyanate, in much smaller quantity. Mustard seed also contains about 25 per cent of bland fixed oil. Similar sulfur-containing volatile oils are formed in other cruciferous plants, such as radish, horseradish, cress, shepherd's purse; and in onion and garlic. Dichlordiethyl sulfide, "*mustard gas*" (see Index) is a much more violent irritant belonging to the same group.

Externally, mustard oil produces more prompt, more violent and more penetrating irritation than the other volatile oils. Mustard preparations are used for counterirritation, in neuralgia, rheumatism and pleurisy, generally as "mustard plaster," mustard poultice or alcoholic solution of mustard oil. They cause rubefaction if the application is stopped as soon as marked tingling is felt. Longer contact may result in vesication and slow-healing ulcers. Since the oil is absorbed into the skin, its action progresses somewhat after the mustard is withdrawn.

Black Mustard, U.S.P. (Sinapis Nigra), consists of the dried ripe seeds of Brassica nigra, B. juncea, or varieties of these species, yielding not less than 0.6 per cent of allyl isothiocyanate. Dose, emetic, 10 Gm., 2½ drachms. **Mustard Plaster,* U.S.P. (Emplastrum Sinapis, Charta Sinapis, Mustard Paper), is a mixture of defatted black mustard and an adhesive, spread on paper or cotton cloth. When it is moistened thoroughly with warm (not hot) water, and applied to the skin, it produces redness and a decided sensation of warmth within a few minutes. It may be left on for fifteen to thirty minutes; or five to ten minutes if the skin is sensitive. Powdered mustard is applied as a *poultice,* mixed with 1 to 10 parts of flour and enough tepid water to make a paste; it may also be sprinkled on the surface of the ordinary linseed poultice. It is used in *foot baths* for preventing colds (1 to 2 ounces to a gallon); and in general baths for infantile coma (large tablespoonful to small bath). *Allyl Isothiocyanate,* U.S.P., C_3H_5NCS, is the *volatile oil of mustard,* distilled from macerated mustard seeds or prepared synthetically. It is a pale yellow liquid, having a pungent odor and taste. It should not be smelled or tasted unless it is highly diluted. It may be used as a counterirritant in $\frac{1}{10}$ to 2 per cent solution in 50 per cent alcohol (Herzfeld, 1909). Mustard oil is more irritant in aqueous than in oily vehicles (Sollmann). A 2 per cent suspension in 3 per cent tragacanth paste represents an effective counterirritant, equal to a 3 per cent ointment (Ewe, 1920).

Mucous Membranes.—Mustard oil in vapor as well as in substance or solution causes strong irritation of the conjunctival, nasal and bronchial mucosae.

A 15 per cent solution of mustard oil in liquid petrolatum produces marked *chemosis* if a single drop is applied to the conjunctiva of a rabbit. The edema begins in a few minutes and becomes maximal in half an hour, and then fades slowly, with complete recovery in one to two weeks, so that the experiment may be repeated a number of times, with fairly similar results. This has been used to study modification of inflammatory phenomena by analgetics and anesthetics (Chiari and Januschke, 1911; Hirschhorn and Mulinos, 1930); but the results are too variable to be conclusive.

Digestive Tract.—Internally, mustard is used as a *condiment;* larger doses (1 to 4 teaspoonfuls of powdered mustard in a tumbler of warm water) produce *vomiting;* still larger doses cause violent gastro-intestinal irritation. *White mustard seeds* (Sinapis Alba) have a cathartic action, due to the liberation of H_2S on contact with water. Large doses may produce sulfide poisoning, with cyanosis, etc. (van Leersum, 1916). It may be used as emetic similarly to black mustard. Plants containing mustard oil (*Bursa pastoris*) stimulate the contractions of the excised uterus (Groeber, 1915).

ONION AND GARLIC

Plants of the genus Allium owe their odor, flavor and irritant action to volatile oils containing organic sulfides and allyl aldehyde. Their effects are similar to those of mustard. They were used in folk-medicine as counterirritants, especially in pneumonia.

Systemic Actions.—Oral administration of extracts of onion or garlic lower the *blood sugar level* of rabbits (Laland and Havrevold, 1933). *Smooth muscle* responds with brief stimulation, followed by depression (Lio and Agnoli, 1927). The effects on *frog heart* have been studied by Agnoli and Lio, 1927. Garlic vapor is somewhat *bactericidal*, due to its allyl aldehyde (Vollrath *et al.*, 1937).

The persistent odor of garlic in the expired air is due partly to fragments adhering to the structures of the mouth (Haggard and Greenberg, 1935), but chiefly to the pulmonary excretion of the absorbed sulfides which circulate in the blood stream (Blankenhorn and Richards, 1936). A mouthwash of chloramine (0.3 Gm. in 30 cc. of water) destroys the odor arising from the mouth, but not that from the lungs. A similar odor is conferred by tellurium and some arsenical compounds. *Milk of cows which have eaten wild garlic* is tainted with garlic odor. This is due partly to pulmonary absorption of the volatile oil (Babcock, 1925).

Thiosinamine, *allyl-sulfocarbamide*, was introduced by Hebra and Unna, 1892, and has been credited with causing the absorption of exudates, lymphatic swellings, scar tissue, etc.; and with the cure of lupus. It is usually administered by hypodermic injection (which need not be made at the site of the lesion) (Mendel, 1905). The administration must be continued for weeks and combined with massage and other adjuvant measures. It is therefore difficult to judge whether it has any value. It probably does little if any good, and it may produce toxic systemic effects, although it is usually well borne, except for the bitter taste and garlic eructations. Thiosinamine has been injected intravenously in arsphenamine dermatitis, in place of sodium thiosulfate (Greenbaum, 1924), but has not found favor.

Toxic Effects.—In man, 1 Gm., or 0.2 Gm. on repeated use, have caused headache, nausea, vomiting, lassitude and fever (J.A.M.A., *56:* 835, 1911; Charteris, 1910). These may set in suddenly after it has been used for a time uneventfully. In animals, Tyrode, 1909, found impaired respiration, eventually cessation and death, sometimes pulmonary edema and hyperemia (Lange, 1892). The circulation is not affected in mammals, but high concentrations paralyze the frog's heart. Smaller doses produce severe changes in metabolism, with loss of nitrogen and rapid emaciation; and fatty degeneration of parenchymatous organs, especially the heart and kidneys. Normal connective tissue showed no changes.

Other Allyl Compounds.—Allyl acetic acid, allyl urea and dimethylallylamine are indifferent; allyl iodide is strongly irritant; allyl formate produces necrosis of the liver and kidneys; allyl amine is highly toxic (Piazza, 1915).

OIL OF TURPENTINE

This produces simple reddening and burning when applied to the skin, is used as a counterirritant; undiluted, or mixed with 1 to 5 parts of oil in liniments. It is often employed as "stupe," *i. e.*, flannel wrung out of hot water, and then out of turpentine, and applied for ten to thirty minutes. In susceptible individuals it may cause severe eruptions and blistering if left on for several hours, but this is exceptional. Few painters develop dermatitis even from its daily use to cleanse the hands, if this is followed by soap and water. Hypersensitiveness may appear after many years of safe handling (L. Schwartz, 1939). Oil of turpentine is *used externally* in bronchitis, neuralgic and rheumatic pains, and to telieve meteorism. It causes more severe irritation on mucous membranes.

Inhaled or taken internally, it diminishes bronchial secretions (Rossbach and Fleischmann). It was used for this purpose (a teaspoonful inhaled from a pint of hot water) in chronic bronchitis, but has been displaced by the more pleasant terpin hydrate by mouth, and pineneedle or eucalyptus oil for inhalation. For the relief of *flatulence*, half to one teaspoonful of oil of turpentine, emulsified with the yolk of an egg, may be added to a soapsuds enema. Its use as anthelmintic (2 to 15 cc. followed by a saline purge) and as diuretic and urinary antiseptic have also been discontinued.

Various "expectorant" volatile oils increase the output of respiratory tract fluid when administered to animals by stomach tube, 50 mg. per Kg. (E. M. Boyd and Pearson, 1946).

Turpentine Abscess.—The injection of oil of turpentine produces localized aseptic abscess.

Absorption, Fate and Excretion.—Oil of turpentine is readily absorbed from the skin, lungs and intestines. It circulates for a time unchanged in the blood, and is excreted mainly in the urine as terpenals, paired with glycuronic acid. The urine has the odor of violets. Neither turpentine, nor eucalyptol nor menthol is excreted by the lungs or sputum (Falk, Hofbauer, 1915).

Systemic actions do not occur with small doses.

Toxicology.—Turpentine oil is easily accessible from its use in paints and varnishes and may give rise to accidental poisoning or be taken as abortifacient. Half an ounce has been fatal to children, 6 ounces to adults. The symptoms in man are those of gastro-intestinal irritation; nausea and vomiting, colic and diarrhea, wild excitement and delirium, ataxia, painful micturition, hematuria, albuminuria, glycosuria, skin eruptions, coma. The *treatment* comprises evacuation, demulcents and coffee.

Inhalation.—Fatal poisoning has been reported from inhalation of varnish in a confined space (Drescher, 1906), largely by exclusion of air (Wolf, 1911). There are rapid breathing, palpitations, vertigo, stupor, convulsions and other nervous disturbances; pain in the chest, bronchitis and nephritis. The latter may also occur on chronic exposure.

PREPARATIONS.—*Oil of Turpentine*, U.S.P. (Spirits of Turpentine), is the volatile oil distilled from the oleoresin (Turpentine) of various pine species. Distillation of this oil over sodium hydroxide yields ***Rectified Oil of Turpentine,** U.S.P. It consists chiefly of pinene and is the preparation for internal use. A thin, colorless liquid of characteristic odor and taste; practically insol. in water, sol. in 5 vol. of alc., and in all proportions of oils. Dose, 0.3 cc., 5 minims; as anthelmintic, 8 to 16 cc., 2 to 4 drachms, B.P. The U.S.P. *Emulsion* contains 15 per cent. Dose, 2 cc.

Terpin hydrate is used to diminish cough and expectoration in phthisis and chronic bronchitis, acting similarly to oil of turpentine, but is less irritant, less disagreeable and less toxic. It is sometimes employed as diuretic and urinary antiseptic, but is not very effective.

Lepine, 1887, claimed a diuretic effect from 0.2 to 0.4 Gm. Matzel, 1905, took 4 Gm. daily without any effect; the urine was not albuminous. It was excreted as paired glycuronic acid.

PREPARATIONS.—*Terpin Hydrate*, U.S.P. (Terpini Hydras), is prepared by hydrating oil of turpentine with alc. and nitric acid. Colorless crystalline powder, odorless, slightly arom. and bitter taste; sparingly sol. in water (1:200), sol. in alc. (1:13). Dose, 0.25 Gm., 4 grains, in powders and capsules. The *Terpin Hydrate Elixir*, N.F., contains 1 grain to the drachm. **Terebene** consists of dipentene and other terpene hydrocarbons, obtained by the action of sulfuric acid on oil of turpentine. Colorless, thin liquid of agreeable arom. odor and terebinthinate taste. Slightly sol. in water, sol. in alc. (1:3). Dose, 0.25 cc., 4 minims, on sugar or by inhalation.

Pine Needle Oil, U.S.P. (Ol. Pini Pumilionis; Oil of Dwarf Pine Needles), resembles oil of turpentine, but has a more agreeable odor, and is employed as an inhalant in bronchial affections. Steam distilled from fresh leaves of Pinus montana (Abies sibirica, Siberian Fir, Oleum Abietis, B.P.), a colorless or faintly yellow volatile oil.

EUCALYPTOL

Eucalyptol (Cineol, Cajeputol) is obtained chiefly from oil of eucalyptus, but occurs also in other volatile oils, such as cajuput. It is a mild local irritant, used especially in bronchitis, as inhalation (teaspoonful in hot water), or internally (5 to 10 drops on sugar); and in coryza (spraying with 3 to 5 per cent solution in liquid petrolatum). The oil of eucalyptus may be substituted. "*Nose drops,*" *i. e.*, solutions in olive oil or liquid petrolatum for instillation into the nares, should not contain more than 1 per cent of eucalyptol or camphor, or 0.3 per cent of menthol or thymol. Their prolonged use may lead to lipid pneumonia.

Toxicity.—Large doses of eucalyptol or the related *myrtol* produce excitement, rapid pulse, nausea, vomiting, dilatation of the pupils and fatal collapse. Death occurred in about one-third of the human subjects who had taken between 10 and 30 cc. Idiosyncrasy toward small doses is manifested by skin eruptions (L. F. Barker and Rowntree, 1918; experimental and clinical bibliography).

***Eucalyptus Oil,** U.S.P., is a colorless or pale yellow vol. oil steam distilled from the fresh leaves of Eucalyptus species, yielding not less than 70 per cent of eucalyptol. *Eucalyptol*, U.S.P., is a colorless liquid, sol. in alc. and oils, and practically insol. in water. Dose, 0.3 cc., 5 minims. *Cajuput Oil* is distilled from the fresh leaves and twigs of Melaleuca leucadendron. It is used mainly as a counterirritant.

RUBEFACIENT VOLATILE OILS

Many drugs containing volatile oils have been used as ingredients of liniments. With some of the tinctures (arnica, witch hazel) used in domestic medicine, the alcohol is perhaps the main active ingredient. Thymol, menthol, camphor and some of the volatile oils that are discussed in other connections could be classed with the rubefacients. The oils of clove, cinnamon and creosote are employed in *dentistry* to destroy the nerves and disinfect the cavities of carious teeth and to deaden the pain of toothache, a small drop of clove oil being introduced in the cavity.

Skin Pigmentation by Perfume Oils.—Oils of bergamot and of cedrus produce local sensitization of the skin to the actinic rays of the sun, resulting in irritation and pigmentation after the use of perfume ("cologne"), which contains these oils (del Vivo, 1930; Szanto, 1929). Tar causes similar sensitization (Herxheimer and Nathan, 1917). *Citrus fruit oils* in general are very irritant to the skin, due chiefly to the terpene, d-limonene, of which they contain about 90 per cent.

Liniments.—Cutaneous irritants are usually employed in the form of liniments, *i. e.*, in solution or suspension in oil or alcohol. The proportions in which they are used are about the following—20 per cent: Ammonia Water; Tr. Aconite, Belladonna, Iodine or Opium; Spirits Camphor, Chloroform or Ether; 10 per cent: Tr. Cantharides or Capsicum; Turpentine Oil; Sp. Sinapis; Essential Oils.

Clove Oil, U.S.P. (Oleum Caryophylli), is distilled from *Cloves*, U.S.P., the dried flower buds of Eugenia caryophyllata. It contains not less than 82 per cent of *Eugenol*, U.S.P., an unsaturated aromatic phenol obtained from oil of cloves and other sources. Dose, 0.1 cc., 1½ minims. Similar counterirritant properties are exerted by the volatile oils of *Amber*, *Cedarwood*, *Origanum*, *Pimenta* (Allspice), *Rosemary*, *Sassafras* and *Thyme*.

Arnica consists of the dried flower heads of Arnica montana and contains a volatile oil. Used externally; intravenous injections tend to produce lasting rise of blood pressure (E. D. Brown *et al.*, 1918). *Hamamelis Water* ("Witch Hazel Extract") is a saturated aqueous distillate from the twigs and leaves of Hamamelis virginiana to which about 15 per cent alcohol is added.

BALSAMS AND AROMATIC RESINS

Balsams (Peru, benzoin, tolu, storax) are oleoresins containing cinnamic and benzoic acids. The oils are antiseptic; the oils and resins, mildly irritant, stimulating repair; the resins furnish local protection and so allay inflammation. The balsams are applied in chronic inflammations of mucous membranes (bronchitis) and of the skin (eczema and pruritus); and to promote the healing of ulcers and wounds. Myrrh acts similarly. The balsams are also used locally against scabies, destroying the acarus and their ova. Peru balsam is employed locally and internally for tuberculosis (for intravenous use, see "Cinnamic Acid"). Its internal administration is of doubtful utility, as is also the internal use of other balsams in bronchitis. Even large doses of the balsams do not produce albuminuria (Stockman, 1890).

Benzoin, U.S.P. (Gum Benjamin), is a balsamic resin obtained from Styrax Benzoin (Sumatra Benzoin), S. tonkinensis and other species of Siam Benzoin. The *Tincture,* U.S.P., contains 20 per cent. The ***Compound Tincture of Benzoin,** U.S.P. (Tr. Benzoini Composita; Friars' Balsam, Turlington's Balsam), is representative of the old "balsamic tinctures." It contains benzoin (10 per cent), aloe, storax and tolu in alcohol. Dose, 2 to 4 cc., ½ to 1 drachm, as stimulant expectorant; as inhalant, teaspoonful to cup of boiling water; externally, mixed with glycerin or water, as lotion for chapped hands. The original formula was much more complex; the present formula is still needlessly complicated and expensive. When used as inhalant, the steam contains a trace of oil and benzoic acid (Peacock and Deg, 1919), which would be deposited on the mucous membranes. The same results would probably be secured more simply by substituting the official Tr. Balsam. Tolu.

Peruvian Balsam, U.S.P., is obtained from Toluifera Pereirae. Dark brown, viscid liquid of agreeable vanilla odor; freely sol. in alc. Externally on lint; in scabies, inunction of 2 to 3 Gm., four to six times a day; as a stimulant in indolent ulcers and bed sores, diluted with two parts of castor oil. It is said to promote healing without stimulating granulation; but it is sometimes irritating. It prevents adherence of dressings, but leaves an indelible stain on fabrics. The odor may become objectionable on continued use. *Storax,* U.S.P. (Styrax), is a similar balsam. Dose, 1 Gm. (0.6 to 2 Gm.), 15 grains (10 to 30 grains), in bronchitis. *Tolu Balsam,* U.S.P. (Balsamum Tolutanum), obtained from Toluifera Balsamum, has a pleasing odor resembling vanilla. The *Syrup,* U.S.P., is used as a vehicle.

Myrrh, U.S.P. (Myrrha), a gum resin from Commiphora species, was used by the ancients as incense in religious ceremonies, and by the Egyptians in embalming, in combination with spices. The *Tincture,* U.S.P., 20 per cent, is carminative (dose, 1 cc., 15 minims); it is used especially as a mouth wash (1:25) in stomatitis, pharyngitis, and as a lotion 1:5 or 10. *Mastic* (Mastiche) is a similar resinous exudation from Pistacia Lentiscus. *Mastic Varnishes* have been used in surgery to fix the skin bacteria on the hands and operative area. They are brushed on and allowed to dry. The skin may first be treated with iodine. Various formulae have been published; Borchardt's consists of mastic, 40 Gm.; benzene, 60 Gm.; castor oil, 20 drops, filter. *Galbanum* is a gum resin from Ferula galbaniflua.

Echinacea, the root of Echinacea angustifolia (Purple Cone Flower), contains resins and no alkaloids (Heyl and Staley, 1914). Several proprietary preparations have been praised for sialagogue, diaphoretic, stimulant and general alterative effects; but no good evidence of its value has been published and the claims appear extravagant (J.A.M.A., Nov. 27, 1909). Dose, 1 to 2 Gm., 15 to 30 grains. *Grindelia,* the dried leaves and flowering tops of Grindelia camporum, contains an amorphous resin (probably the active principle) and a very small quantity of volatile oil, no saponin or alkaloid (Power and Tutin, 1905). It is said to relax the muscular coats of the bronchi and diminish the excretion of mucus. It is therefore used in asthma and bronchitis. *Pellitory* (*Pyrethri Radix*), the root of Anacyclus pyrethrum, is chewed as a sialagogue and against tootache.

DIURETIC VOLATILE OILS

Volatile oils tend to increase the urine flow by irritating the kidneys. Larger doses produce nephritis and anuria. Turpentine and juniper oil were used as diuretics, but the possibility of harmful irritation has restricted their employment.

The oxygen consumption of the kidneys is increased by turpentine or sandalwood oil, regardless of whether there is diuresis (Kaburaki, 1927). These oils also produce histologic abnormalities of the renal epithelium (Tukioka, 1927).

Juniper Oil, U.S.P., is distilled from the ripe fruit of Juniperus communis. It is closely allied to turpentine (containing pinene, $C_{10}H_{16}$, and cadinene, $C_{15}H_{24}$); but it has a more agreeable flavor. In the form of "*Holland Gin,*" it was employed as diuretic (Cow, 1912) in cardiac and hepatic dropsies. It is supposed to act by mild irritation of the kidneys. Its use in nephritis requires caution It also had some reputation as emmenagogue. Overdoses produce poisoning, similar to savin (see below).

VOLATILE OILS AND OLEORESINS EMPLOYED IN URETHRITIS AND CYSTITIS

Oil of Sandalwood and the oleoresins of Copaiba, Cubeb and Matico were administered as urinary antiseptics in subacute and chronic urethritis, as adjuvants to local treatment, to diminish the pain and the discharge, and to hasten healing, but they are not curative. Their use has greatly diminished, as the beneficial results appear too uncertain to offset the side effects. Santal oil is generally preferred. It is best administered in capsules, on a full stomach, to minimize gastric irritation. Buchu is used as a diuretic in catarrhal cystitis; cubeb is sometimes employed in bronchitis.

The oleoresins are natural mixtures of resins and volatile oils rich in terpenes and terpene alcohols. The terpenes are excreted as glycuronic compounds, which have a slight antiseptic action on the urine. This is much less than that of methenamine, but it has the advantage that it is not affected by the reaction of the urine (Jordan, 1911); probably they are specifically more effective for certain bacteria. The gonococci are not killed (Bruck, 1913), but the control of the putrefactive bacteria presumably puts the mucous membrane in a better position for resistance. The terpenes and resin acids are mildly irritant. The urinary passages are thus kept under the continuous influence of the antiseptic terpenes, and stimulated to repair by the irritation. Winternitz, 1901, and Pohl, 1912, found that the oral administration of various balsams, santal oil, etc., appeared to have favorable effects on *experimental aseptic pleurisy* (aleuronat, etc.) in rabbits. However, their doses were much larger than the clinical.

Side Actions.—The gastro-intestinal tract is also irritated, resulting in anorexia, colic, eructations and diarrhea. These unpleasant effects are less with santal oil, and may be minimized by the use of the santalol esters, which are only dissolved in the intestines. Skin eruptions, scarlatinal rashes, etc., occur in some patients, either directly or from the digestive disturbance. Excessive doses of the oils produce more pronounced irritation of the entire urinary tract, with kidney pain, albuminuria and vesical tenesmus. Albuminuria may be simulated by the precipitation of the resin acids with nitric acid: to be distinguished by the addition of alcohol, which dissolves the resins. Glycosuria may also be simulated by the glycuronic acid.

Santal Oil, N.F. (Ol. Santali; Sandalwood Oil), is distilled from the heartwood of Santalum album; a pale yellow, viscid, oily liquid; peculiar aromatic odor, spicy taste; sol. in alc. It often disturbs the stomach, and sometimes causes vesical and renal irritation. Dose, 0.3 to 1 cc., 5 to 15 minims. It consists chiefly of *santalol,* a mixture of two sesquiterpene alcohols.

Copaiba, N.F. (Balsam of Copaiba), is an oleoresin obtained from South America species of Copaiba. A pale yellow or brownish yellow, viscid liquid; peculiar aromatic odor and persistent, bitter acrid taste; insol. in water, partly sol. in alc., freely sol. in oils. Dose, 1 cc., 15 minims. The various "Lafayette," "Chapman" and similar mixtures are undesirable.

Cubeb Oleoresin is an evaporated alcoholic extract of the dried, full grown, unripe fruits of Piper Cubeba. Dose, 0.5 Gm., 8 grains. *Matico* consists of the leaves of Piper angustifolium. *Buchu* is the dried leaves of various species of Barosma. Contains vol. oil, glucoside, bitter principle, etc.; best as infusion.

Sabal (Saw Palmetto) is the partially dried, ripe fruit of Serenoa serrulata. Statements as to presence of alkaloids and vol. oils are contradictory. Has been used as nutritive tonic, alterative, in respiratory diseases, digestive disturbances, as aphrodisiac, etc. Of doubtful value. Dose, 1 Gm., 15 grains.

ECBOLIC AND TOXIC VOLATILE OILS

Several volatile oils are employed in folk medicine as emmenagogues and ecbolics; especially apiol, savin, pennyroyal, tansy, rue, turpentine and juniper. They may produce pelvic congestion through intestinal irritation. A mild degree of this action was supposed to be useful in delayed and painful menstruation, as after exposure to cold, but it is doubtful whether safe doses are effective. Abortion occurs only with toxic doses (Datnow, 1928); indeed, fatal doses are not always ecbolic. Fatty degeneration of the liver and other organs results from large doses of these oils, especially from pennyroyal (pulegone), and also from nutmeg, sassafras, rosemary and thyme (Heffter, 1895; Lindemann, 1899).

Excised uterus gives variable responses to the different drugs. Prochnow, 1911, reported slight stimulation; Macht, 1913, invariably obtained depression. Apiol appears to be somewhat stimulant (see below). Excised human uterus is not stimulated by the oils of juniper, pennyroyal, rice, savin or tansy. Low concentrations have no effect; active doses produce relaxation and inhibition (Gunn, 1921).

Apiol.—Two drugs are known under this name: "Green Apiol," or Oleoresin of Parsley Seed, a green oily liquid; dose, 0.3 to 1 cc., 5 to 15 minims; and "Apiol" proper, "Crystallized Apiol," "Parsley Camphor," a crystalline aromatic derivative extracted from the oleoresin; dose, 0.1 to 0.3 Gm., 2 to 5 grains. The apiols are administered in capsules, as emmenagogue and antipyretic. Their usefulness is doubtful. Overdoses produce arrhythmia, incoordination, digestive disturbances and fever. Fatal poisoning with intestinal irritation, icterus and uremia was reported by Brenot, 1916. Dogs and rabbits poisoned with apiol and related drugs show visceral fatty degenerative lesions, especially in the liver and kidneys. Individual tolerance varies widely. Excised uterus, intestines and ganglion-free leech muscle are stimulated (Heffter, 1895; Patoir *et al.,* 1935; Lutz, 1920). Adulteration of green apiol with ortho tricresyl phosphate (see Index) has given rise to serious neuritis.

Savin (*Sabina*) and **Arbor Vitae** (*Thuja*) contain volatile oils (Cedar Leaf Oil, U.S.P.) similar to turpentine but much more toxic. Thuja contains pinene, fenchon and thujone (isomers of camphor, having similar actions) (Hildebrandt, 1902; Matzel, 1905). Poisoning has often occurred from their use as abortifacients. Six drops of oil of savin are said to have produced toxic effects: burning, nausea, vomiting, colic and diarrhea, sometimes bloody; severe congestion of the pelvic organs, increased menstrual flow and sometimes abortion; hematuria and painful micturition; unconsciousness, convulsions and coma. Death may occur in a few hours, but more often after several days (Lewin). The chief effect in animals is intestinal irritation (Kagaya, 1927).

Tansy.—The leaves and tops of Tanacetum vulgare have been used as anthelmintic against Ascaris and Oxyuris, internally, 0.5 to 2.5 Gm. as infusion, twice a day; or as enema of 15:200. Half an ounce to an ounce of the oil (which contains thujon) has produced death after two to four hours, with convulsions and unconsciousness.

Pennyroyal.—The leaves and tops of Hedeoma pulegioides are used as carminative, 5 to 10 Gm., 1 to 2 ounces, as infusion. *Ol. Hedeomae,* 0.2 cc., 3 minims; a teaspoonful has produced convulsions. Its active constituent, *pulegone,* has been studied by Matzel, 1905.

Nutmeg Poisoning.—In man severe symptoms have occurred from one to one and one-half nutmegs, or from a teaspoonful of powdered mace. The effects appear in one to six hours, and are mainly narcotic, varied by excitement and delirium, with some motor stimulation and local irritation; they usually end in recovery in twenty-four hours. Nutmeg is also ecbolic. Similar effects occur in animals. Hepatic necrosis has been demonstrated in cats (Dale, 1909). Cushny and Wallace, 1908, showed that the narcotic effect is produced by "*myristicin*," the high boiling portion of the volatile oil. The oil has been investigated chemically by Power and Salway, 1908. *Myristica*, U.S.P. (Nutmeg), is the ripe seeds of Myristica fragrans. Dose, 0.3 to 0.6 Gm., 5 to 10 grains. The dose of Myristica Oil, U.S.P., is 0.06 to 0.2 cc., 1 to 3 minims.

Senecio.—The alkaloids (*senecine, senicionine, seneciophylline, riddeline* and others) of S. Jacobea and vulgaris and other species produce toxic effects in cattle resembling those of volatile oils; hemorrhages in abdominal organs, especially the liver; fatty change, necrosis, congestion and hepatic cirrhosis, leading to ascites and terminating in coma (Cushny, 1911). Prothrombine time is prolonged, but may be restored by feeding of vitamin K (C. L. Rose *et al.*, 1945). The primary effect appears to be vascular (J. Davidson, 1935). The renal tubules and glomeruli are also injured. Intravenous injection of the alkaloids causes rise of blood pressure, convulsions, uterine contractions and intestinal relaxation. Excised intestine is relaxed; uterus of guinea pigs and rabbits is contracted. Another senecio alkaloid, *platyphylline*, when injected by vein, causes convulsions, probably medullary, but no renal or hepatic damage (Chen *et al.*, 1940; Harris *et al.*, 1943). *Lasiocarpine*, the alkaloid of a *heliotrope*, has similar effects (K. K. Chen, Harris and Rose, 1939). The fluidextract of senecio (10 to 20 drops) has been used as emmenagogue. It has a slight depressant effect on the excised uterus (Pilcher, 1916).

Helenium autumnale contains a neutral bitter principle (Reeb, 1910) which is strongly irritant to mucous membranes. Systemically, it stimulates respiration and directly paralyzes cardiac and other muscle. It is not hemolytic (Lamson, 1913).

Spewing sickness, a sheep disease of Utah, is due to the eating of *Dugaldia* hoopesii, a composite plant allied to Helenium and probably containing similar active principles. It produces similar gastro-intestinal and cardiac symptoms (D. D. Marsh, 1916).

Eupatorium Urticifolium (*Ageratoides*).—Feeding on the green plant is said to be the cause of one form of "trembles" or "milk sickness" of sheep; the symptoms consist in weakness and ataxia, ending in death (Marsh and Clawson, 1917). The toxic principle is extracted by 95 per cent alcohol (Sackett, 1919). *Other species of Eupatorium* (Boneset) are used as diaphoretic tea.

Hypericum.—Ray, 1914, stated that cattle feeding on a Tunisian species (H. crispum) develop dermatitis of nonpigmented portions of the skin, and inflammation of the mucous membranes exposed to light. The phenomena are due to a *fluorescent substance*. Rogers, 1914, claims analogous effects for the common St. John's wort, Hypericum perforatum.

Buckweat Photosensitization.—Feeding with the flowers or seedhusks or hay of buckwheat (Fagopyrum esculentum) renders guinea pigs, white rats and mice sensitive to light of wave lengths 540 to 610, resulting in the syndrome of *fagopyrism:* inflammation of the skin, especially about the eyes, ears, nose and tail, and of mucous membranes (conjunctivitis, diarrhea); and convulsions. With a single dose of 0.25 Gm. per 100 Gm. the effects occur in twenty-four hours and persist some days (Chick and Ellinger, 1941). Photosensitization by handling of *parsnips* has been reported (V. Starck, 1944),

◆

GASEOUS IRRITANTS AND "WAR GASES"

Irritant gases are important chiefly as industrial poisons and in chemical warfare. The former include ammonia, chlorine, bromine, the fuming mineral acids, the gaseous acids, such as sulfurous, nitrous, etc.; the volatile organic acids—acetic, formic, etc., and formaldehyde. *Warfare "Gases"* include not only true gases and liquids with sufficiently high vapor tension, but all other forms that may be diffused through the air as smokes, sprays and dusts, by the heat or force of the explosion of the shell.

Available Substances.—Practically every substance of sufficient toxicity and heat stability may thus become an implement of "gas warfare." The choice of the substances is limited by the fact that they must be effective even when highly diluted. In practice, this requirement is best met by irritants. Curiously, it has excluded hydrocyanic acid, arsine, phosphine and hydrogen sulfide, substances that owe their sinister reputation mainly to rapidity of action, but which apparently can not be used with sufficient concentration in ordinary military operations. Dense liquids and solids have an advantage in that they are not so rapidly dissipated by the wind.

The military effectiveness of poison gas is due to the morbidity rather than to the mortality; 98.3 per cent of the gas casualties of the first World War recovered completely. Popular ideas of fatalities do not correspond to field conditions (A. L. Kibler, 1935). In a confined space a man could probably be killed by 20 mg. of mustard gas; in the war, however, one and one-half tons were expended for each fatality, and seventy-five pounds for every casualty (G. E. Miller, 1937). Hysterical manifestations, such as persistent vomiting, aphonia, blepharospasm, and other psychosomatic reactions are more common sequels than physical disabilities (Rennie and Small, 1943). The experiences of the war are described in "Vol. XIV, Medical Aspects of Gas Warfare," of "The Medical Dept. of the U. S. Army in the World War," 1926. War gases offer some danger of *accidental water contamination*, especially by the arsenical smokes and, to some extent, mustard gas; phosgene does not. In any case, water contamination can be fairly easily prevented or removed.

Classification of Substances Used in Chemical Warfare.—These may be grouped, chiefly by the usual location of the irritation, as (*a*) *pulmonary irritants*, chlorine, phosgene, palite, chloropicrin (nitric vapors, sulfur dioxide and ammonia belong to this class, but are not used in warfare); (*b*) *vesicants*, mustard gas and Lewisite; (*c*) *lachrymators* ("tear gases"), often contain halogen groups. The most important are chloroacetophenone and brombenzylcyanide; (*d*) *irritant smokes*, chiefly diphenylamine chlorarsine and diphenyl chlorarsine (G. E. Miller, 1937). The actions are not sharply localized, but differ according to circumstances, especially the concentration and duration of exposure. However, the effects adhere pretty closely to the type classification under ordinary conditions.

Other purposes of warfare served with relatively nontoxic agents are (*e*) *screening smokes*, titanium tetrachloride, chlorsulfonic acid, sulfur trioxide, white phosphorus; (*f*) *incendiary agents*, white phosphorus, thermite, solidified oils.

Effective Concentrations of Irritant Gases.—The following data, adapted from Henderson and Haggard's "Noxious Gases," expressed as parts per million (by volume) of air, apply to man. They are arranged in descending sequence: *Lowest concentration detectable by odor:* NH_3 = 53; $COCl_2$ = 5.6; SO_2 = 3 to 5; Cl = 3.5. *Lowest concentration producing immediate irritation of the eyes:* NH_3 = 698; SO_2 = 20; $COCl_2$ = 4.0. *Lowest concentration producing immediate irritation of the throat:* NH_3 = 408; NO_2 = 62; Cl = SO_2 = 8 to 12; $COCl_2$ = 3.1. *Least concentration for coughing:* NH_3 = 1720; NO_2 = 101; Cl = 30; SO_2 = 20; $COCl_2$ = 5. (In general, it requires about one and one-half times as much to irritate the eyes, and about twice as much to produce coughing, as suffices to irritate the throat.) *Maximal concentration allowable for prolonged exposure:* NH_3 = 100; NO_2 = 39; HCl and SO_2 = 10; HF = 3; Cl and $COCl_2$ = 1; *maximum allowable for one-half to one hour exposure:* NH_3 = 300 to 500; NO_2 = 115 to 155; SO_2 = 50 to 100; HCl = 50; HF = 10; Cl = 4. *Dangerous even within half an hour:* NH_3 = 2500 to 4500; HCl = 1000 to 2000; NO_2 = 240 to 775; SO_2 = 400 to 500; HF = 50 to 250; Cl = 40 to 60; $COCl_2$ = 25. *Rapidly fatal with short exposure:* NH_3 = 5000 to 6000; Cl = 1000; $COCl_2$ = more than 25. (In general, the concentrations allowable for an hour are about four times, and those dangerous within half an hour are about fifty times, the maximum allowable for prolonged exposure.)

The concentration ppm by volume (at 25° C., 760 mm. pressure) **may be transposed** to mg. per liter by multiplying by the molecular weight and dividing by 24,450. Conversely, mg. per liter is transposed to ppm (vol.) by multiplying by 24,450 and dividing by the molecular weight.

The Phenomena of Gas Irritation.—When swallowed, the volatile irritants produce the ordinary phenomena of gastro-intestinal irritation. When inhaled, they irritate the respiratory passages and other exposed mucous membranes, causing conjunctivitis, rhinitis, bronchitis, pulmonary edema and pneumonia. The phenomena are essential uniform for man and other mammals, for all volatile irritants, but differ in the relative intensity of the effects on the upper and deeper respiratory passages, and in the sensory irritation and reflexes, which arise only above the bronchioles. Generally, the more soluble gases act high, the less soluble gases prolong their action in the lungs; but there are exceptions. The gases that act directly, as does chlorine, also begin their effect in the pharynx; while those which act only after decomposition by moisture, such as phosgene and palite, cause chiefly alveolar irritation.

Ammonia, hydrochloric, sulfuric and hydrofluoric acid and formaldehyde act mainly on the *upper portion;* chlorine, bromine, sulfur dioxide, hydrogen sulfide and acrolein act on *all portions;* nitrous fumes, phosgene, ozone, phosphorus trichloride and pentachloride and arsenic trichloride act chiefly on the *alveoli.*

Acutely Lethal Concentrations.—Prompt death occurs especially with high concentrations of the direct irritants (for example, 1 to 5 per cent of **chlorine**), through reflex spasm or acute edema of the glottis, or by obstruction of the pulmonary irritation. The symptoms are those of violent respiratory irritation and rapid asphyxial syncope.

The experiments of Schaefer, 1915, showed that *1 per cent of chlorine* in the air may be ineffective for several minutes; then, often suddenly, the respiration becomes deep, convulsive and arrested. The blood pressure falls. Rapid recovery occurs in fresh air. With *5 per cent,* death is rapid and inevitable. The respiration becomes slowed and is arrested in one to three minutes. The blood pressure falls to zero in three to four minutes, the heart still beating well. Artificial respiration does not cause recovery. The *bronchioles* are not constricted, air passing at least as well as normally. Secretion of mucus is also unimportant, for the course is not modified by atropine. The *systemic circulation* is also unaffected directly, the changes being secondary to the asphyxia. Even the right heart is not especially congested.

The essential changes are in the *pulmonary circulation.* The lungs are intensly hyperemic, microscopic examination showing engorgement of the capillaries and edema of the intestinal tissue and alveoli. The epithelium proper is normal. Perfusion of the pulmonary vessels with Ringer's solution shows marked obstruction of the flow when chlorine is injected into the trachea or perfusion fluid. Schaefer assumed that this phenomenon occurs during life and that this obstruction is the cause of all the symptoms. (It is probable that chlorine coagulates the endothelium, as do other astringents.) **Bromine vapor is more irritant, but less fatal.**

Respiration.—Inhalation of high concentration of chlorine (admitted directly into the trachea) arrests the respiration completely, for twenty seconds or longer. This is followed by peculiar, abortive abdominal movements, and these by restoration of practically normal respiration. Further chlorine does not again arrest the respiration (Schultz, 1918). Inhalation of air containing chlorine 1:5000 to 1:1000 produces quickening of the respiration and transient broncho-constriction, due partly to edema of the bronchial mucosa (Azzi, 1918). There may also be a direct action on the bronchial musculature; for excised rings are strongly contracted when placed in Ringer's solution containing fairly high concentrations of chlorine. Low concentrations relax. Rings of *pulmonary artery and vein* behave similarly; but it is doubtful whether they are exposed sufficiently in life.

Heart.—In mammals, inhalation of concentrated chlorine often produces prompt temporary arrest of the heart. If the heart resumes, the pulse and respiration remain greatly slowed. These effects are absent if the vagi have been divided. The exposed frog or terrapin's heart and especially the mammalian heart are immediately depressed by chlorine in Ringer's fluid or in the air (Schultz, 1918).

Subacutely Toxic Concentrations of Volatile Irritants.—The greater number of accidental intoxications and practically all war gas casualties belong to this group. The distinguishing feature is the occurrence of profuse pulmonary edema. With direct irritants, this may be preceded and accompanied by sensory phenomena, reflexes and inflammation of the respiratory passages.

Most of the irritant gases are not absorbed as such from the lungs. They therefore do not have direct systemic actions. All their effects are explainable as direct or indirect results of the local irritation. The indirect effects are produced by asphyxia or by reflexes.

The fatigue and exhaustion of the mild cases and the loss of consciousness in severe cases are asphyxial. Retching and vomiting result from pharyngeal irritation and from the cough. Diarrhea is emotional. The kidneys are practically unaffected.

The results of the German experiments with war gases are described in the thirteenth volume of the Zeitschrift für die gesammte experimental Medizin.

Sensory phenomena and reflexes are conspicuous with direct irritants, such as chlorine; delayed or absent with the slower acting poisons (phosgene). They begin with the characteristic *odor* of the gas. Dogs with their keen scent note the presence of gas much earlier than does man, and run away from it. The *irritation* starts with the first two or three inspirations of the directly irritant gases; for instance, chlorine 1:1000 to 1:10,000, or with ammonia vapor, etc. There is a sensation of pain and choking, which causes a reflex temporary arrest of the respiration, in expiration, spasmodic closure of the glottis, and bronchial constriction and reflex inhibition of the heart. These are conservative reactions, which temporarily exclude the poisonous gas and prompt the subject to seek pure air. They explain why fatal effects are relatively rare; but if the respiratory arrest exceeds 70 to 80 seconds, the subjects generally do not recover (Fabroni, 1929). Excessive spasm or edema of the glottis may be directly fatal. The protection can only be temporary if exposure to the gas continues. The air hunger leads to dyspneic, spasmodic and painful respiration, resembling asthma, although the bronchi may not be constricted. Asthmatic individuals are indeed especially sensitive to direct respiratory irritants. There may be violent coughing, with frothy expectoration. Acute asphyxia develops, with cyanosis and great anxiety, then mental confusion and lethargy, and finally unconsciousness. Eventually the condition passes into pulmonary edema and circulatory collapse. These, rather than the immediate phenomena of irritation, are the fatal features of the intoxication (L. Lewin, 1908). The irritation also affects the conjunctiva, resulting in lachrymation and congestion. Swallowing of the irritant with the saliva may inflame the esophagus and stomach, with protracted hemorrhagic gastritis (Loper *et al.*, 1915).

Acute epithelial injury by gases increases progressively in inverse ratio to the robustness of the cells, from the trachea to the alveolar endothelium. The functional injury may be much greater than the histologic changes. In acute gas cases, particularly, severe edema may occur before the cells present any morphologic abnormalities.

Lesions of Upper Respiratory Tract.—Chlorine and other direct irritants, including "mustard gas," produce more or less violent inflammation of the larynx, trachea and bronchi. In case of survival these are likely to lead to secondary infections: laryngitis, tracheitis, bronchitis and lobular pneumonia. Those gases which liberate chlorine only on contact with water (phosgene, palite, superpalite, etc.) cause little or no inflammation of the upper respiratory tract. They are also somewhat less productive of secondary pneumonia.

Irritative pulmonary edema is the essential danger factor with all the volatile pulmonary irritants; its mechanism, phenomena and treatment being essentially the same for all.

Other Forms of Experimental Pulmonary Edema.—The methods employed, reviewed by Schlomovitz, 1920, may be arranged into the following groups:

1. Embolism of artery by fat, lycopodium, etc.; intravenous collargol. 2. Injury to pulmonary capillaries by excessive hydremia; excessive blood concentration and anoxemia. 3. Injury to pulmonary capillaries by intravenous acetic ether, or ammonia. 4. Injury to respiratory epithelium; irritant gases. 5. Clinical inflammatory type, mainly by vascular injury. 6. Disproportion in the work of the right and left ventricles; compression of the left ventricle (Welch); epinephrine injection; muscarine asphyxia. 7. Combinations.

The pre-edemic stage (*first stage of phosgene poisoning*) is characterized by congestion and stasis in the pulmonary circulation; dilatation of the right heart, dilution and increased volume of the blood.

Thrombosis of the pulmonary vessels is especially prominent in chlorine poisoning. Many of the pulmonary capillaries are occluded by agglutinated red cells. This process reaches its maximum rapidly, in one or two hours at the latest, and then gradually diminishes. The thrombosis may be partly the result of the usual inflammatory stasis; but probably is largely due to the direct action of the acid gases on the blood corpuscles; for agglutination may be produced *in vitro* by dilute chlorine, phosgene or hydrochloric acid.

The oxygen content of the blood decreases considerably, nearly parallel to the deficiency of the hemoglobin. This, together with the obstruction in the pulmonary circulation and the venous stasis, produces some asphyxia and dyspnea; but the respiratory symptoms in this stage of phosgene poisoning are not severe.

Chlorine poisoning is always accompanied by *acidosis*. In case of survival the blood recovers its normal values rapidly, often in a few hours. The alkali reserve of the tissues was therefore not seriously depleted. In fatal cases, however, the reserve alkali of the blood continues to fall progressively. This is of prognostic importance.

In *phosgene poisoning*, acidosis occurs only shortly before death; *i. e.*, there is only the terminal acidosis that is likely to precede death from any cause.

Stage of Pulmonary Edema (*Second Stage of Phosgene Poisoning*).—The pulmonary capillaries, which were irritated and obstructed in the first stage, become gradually permeable, leading to pulmonary edema. Heubner, 1919, believes that the pulmonary stasis plays a greater part than the direct irritation of the endothelium. The edema results in diminished blood volume, concentration of the hemoglobin and decreased size of the heart. This is liable to develop quite rapidly, especially in chlorine poisoning, and may reach extreme degrees. Most of the fatalities occur in this stage, from anoxemia and decreased blood volume (Meek and Eyster, 1920).

Blood concentration, with increase of blood count, hemoglobin and viscosity, occurs rapidly with chlorine, slowly with phosgene, reaching its maximum about the fifth to eighth hour. It may then remain stationary for some time. The rapidity and degree of the concentration are proportioned to the severity of the intoxication and are therefore of prognostic importance.

Circulatory Collapse.—Severely gassed patients suffer more or less from circulatory collapse, as shown by a gray pallor, by rapid and feeble pulse and by venous congestion and dilatation of the right heart (never of the left). The collapse is often the immediate cause of death. The circulatory collapse is due mainly to the asphyxia, but is aided by the local conditions in the lungs, by the increased viscosity and thrombosis, and by the compression of the capillaries and veins through the edema.

Development of the Pulmonary Edema.—The fluid exudes first into the air sacs and from there overflows into the bronchioles and bronchi. Here it is churned into foam by the tidal air. As this foam mounts toward the larger air tubes, it provokes the cough reflex, and is more or less effectively expelled, until the exudate and foam become so excessive that they produce fatal asphyxia. The edema compresses the pulmonary capillaries, another factor in the impeded pulmonary circulation. Some of the exudate may also form in the pleural cavity, but usually in scanty amount.

Respiration.—The minute-volume of respiration is always increased after the symptoms of gassing develop. With chlorine, the sensory phenomena dominate the respiration. With phosgene, the increase of respiration is asphyxial and therefore increases with the edemal stage.

Disruptive emphysema is especially serious in *chlorine* gassing because of the violent coughing and inspiratory efforts provoked by the irritation of the gas. These efforts tend to tear the partitions between the alveoli. The pulmonary tissue may be ruptured so extensively that air escapes even into the subcutaneous tissue of the neck. The much milder sensory irritation of *phosgene* poisoning leads to less violent muscular efforts, and emphysema is therefore less prominent. Disruptive emphysema diminishes permanently the breathing area, so that survived piatients are apt to suffer indefinitely from shortness of breath.

Gas Exchange in Irritative Pulmonary Edema.—In chlorine poisoning, air hunger sets in rapidly, but soldiers gassed with phosgene do not complain of air hunger for some time, although they may show intense grayish cyanosis and may even die. This is a condition of anoxemia analogous to mountain sickness. If the patient survives, the cyanosis gradually changes to the ordinary blue tint, and he develops air hunger and intense hyperpnea. These are the phenomena of carbon dioxide poisoning. In other words, the patient passes first through a condition of pure anoxemia; this is then complicated by the accumulation of CO_2, which develops much more slowly.

Haldane explained the early dissociation of the oxygen and carbon dioxide factors of asphyxia by the relative solubility of the two gases. CO_2 is twenty-five times more soluble in water than is oxygen. Consequently, when the exudate begins to form, it interposes a much greater obstacle to the passage of oxygen than to the passage of CO_2. This would result in the anoxemia without carbon dioxide accumulation, as noted clinically. These conditions change, however, when the edema fills the alveoli, and its foam mounts more and more into the bronchioles and bronchi. When this happens, the air is totally prevented from reaching the alveoli. The respiratory exchange stops in that part of the lung, and CO_2 accumulates. This produces more or less hyperpnea, and this in turn produces overventilation of functionating portions of the lung. Their CO_2 therefore falls below the normal level. The blood returning to the left heart is a mixture derived from the overventilated and the unventilated parts of the lung—the first with a deficiency of CO_2, the second with an excess of CO_2. These two factors tend to balance each other, so that the CO_2 excess of the mixed blood is not at first very great. It increases as more and more of the lung is thrown out of function. On the other hand, overventilation does not increase the oxygen of the blood anywhere, since the hemoglobin in the functional part of the lung is practically saturated with oxygen by ordinary ventilation. The overventilated portions of the lung do not compensate for the asphyxiated portions. The uncompensated oxygen deficit therefore continues greater than the more or less compensated CO_2 excess.

The administration of oxygen reverses these conditions: oxygen diffuses gradually through the foam, and thus the foam near the alveoli becomes so much enriched in oxygen that a sufficient quantity can diffuse into the alveolar exudate. The CO_2 excess is not lowered by this, so that oxygen inhalation abolishes the cyanosis and diminishes the danger of asphyxial death; but it does not diminish the hyperpnea. The air hunger, the amplitude and rate of respiration are not changed by the oxygen. Since the oxygen must diffuse through the foam before it can be effective, the relief is rather slow, coming on only after about five minutes. This contrasts with the instantaneous response to oxygen in ordinary obstructions.

Postmortem findings differ somewhat for chlorine and phosgene (Winternitz, 1919):

Chlorine Followed by Acute Death (Inside of Twenty-Four Hours).—The trachea and bronchi are red and congested, edematous and may be more or less filled with serous exudate. The lumen of the bronchioles may be filled with debris. The lungs are heavy and edematous with overdistended, emphysematous areas scattered through the purplish collapsed and depressed structures. On section, serous fluid flows abundantly.

Postmortem Findings for Phosgene.—When death has occurred within two hours after exposure, the lungs are uniformly edematous, airless and purple. There is little or no emphysema. The lungs exude abundant fluid on section. There is also considerable fluid in the pleural cavities. When death occurs later (second or third day), the pulmonary edema is less, the lung containing some aerated areas. This may be because all the cases of severe edema die early. However, it is conceivable that in nonfatal cases a reabsorption of the edema occurs from the second day, since even deeply cyanosed patients may ultimately recover.

The degree of the pulmonary edema may be determined post mortem by the water content of the lungs, or by the ratio of their weight to that of the heart.

Prognosis in the Edema Stage.—Experience with animals indicates that the severity of the intoxication and the direct fatality in phosgene poisoning may be judged with fair certainty by the course of the blood concentration and by the temperature. The more rapidly the blood concentration sets in, and the higher its degree, the more grave is the danger. The temperature does not change in light cases. In severe cases, there is a preliminary rise, followed by a later fall. This fall is rapid in fatal cases, gradual in those that survive.

Phenomena of Restoration (*Third Stage of Phosgene Poisoning*).—If the patient does not succumb to the pulmonary edema, the excessive concentration of the blood gradually disappears, so that it finally becomes slightly more dilute than normal. The edema is slowly reabsorbed; and there is a fairly rapid readjustment and eventual return to a practically normal condition. The stage of restoration is often complicated, however, by secondary respiratory infectional pneumonia or bronchitis, which may run a fatal course.

Late Effects of Irritant Gases.—Inhalation of phosgene, dichlorethyl sulfide, and especially of chlorine may be followed by chronic respiratory lesions. However, even heavily gassed dogs are essentially normal after two to twelve months; only a small minority show unimportant focal fibrosis (Koontz, 1925). Similarly favorable results are reported for soldiers. Four months after miscellaneous "gassing," the physical findings were normal in about 50 per cent of the patients; chronic bronchitis was present in 30 per cent, emphysema in 2 per cent (Berghoff, 1920). Exceptional cases develop persistent gastro-intestinal or nervous changes, due to hemorrhages into these situations.

The treatment of poisoning by pulmonary irritants may be directed against the immediate local irritation and bronchial spasm; the anoxemia and acidosis; the abnormal blood volume; the circulatory collapse; and the later bronchitis and secondary infections. Since these factors vary in importance and urgency at different stages of the intoxication, and in different patients, the treatment should also vary; but the pulmonary edema and the consequent asphyxia and circulatory collapse dominate all other indications.

In the following discussion the individual measures are arranged generally in the order of their application.

Protection is the first and most important measure. For military personnel this is secured mainly by appropriate masks and clothing. Civilians should speedily leave the gas area, walking against the wind or, if necessary, across the wind, and go upstairs, never into the basement.

If the *clothing* has been contaminated it should be removed, placed in a covered pail outdoors, and later washed with kerosene, then with water. If the *skin* has been wetted with liquid "gas", this should be blotted off, not rubbed, taking care that it does not touch the fingers. If the agent is "mustard gas", a chlorinated solution (household "bleach") should be applied. Hydrogen sulfide or "BAL" destroys lewisite. If the *eyes* have been exposed they should be rinsed thoroughly with sodium bicarbonate, a tablespoon of the powder to a quart of water. This may also be used for the nose if it feels irritated. A shower bath should be taken, with plenty of soap.

After exposure to asphyxiant gases, absolute rest is the important indication. Oxygen should be given to relieve cyanosis. Pain may be controlled with 10 to 15 mg. of morphine.

The usefulness of venesection and intravenous fluid is now doubted.

More or less asphyxia is always present. Every exertion, even standing, means a more rapid exhaustion of the difficultly obtainable oxygen; a more rapid accumulation of the difficulty excretable CO_2; and an added mechanical and chemical strain on the overloaded heart, which may easily bring on acute decompensation. The rest must be as absolute as circumstances permit. Sleep generally brings improvement. Restless and excited cases must have morphine. The indication of rest must be observed as long as the patient reacts to exertion by cyanosis, dyspnea or extra rapid pulse. Usually, if the rest is thorough in the start, the patient can return to light duties in a few weeks.

Warmth is a useful precaution against collapse. Severe cases should therefore be heated. Ordinary cases should at least be protected against chill, but should at the same time receive the benefit of fresh air.

Morphine is used as a sedative, to secure rest and to check spasmodic cough and mechanical trauma. It should be employed only when these indications exist and should be avoided when there is deep cyanosis. However, if the patient is very restless, he may receive morphine even though he be deeply cyanosed. The objection to morphine lies in the fear that it would depress the respiration at a time when the maximum respiratory ventilation is needed to offset the diminished lung area. This is largely obviated by employing rather small doses, not to exceed 0.015 to 0.02 Gm. The characteristic effect of therapeutic doses consists in a slowing but deepening of the respiration. This would counteract the rapid and shallow respiration that follows as a vicious circle on oxygen deficiency (Haldane and Meakins, 1918).

Ammonia inhalation, a few whiffs at intervals, during the first day, acts as respiratory stimulant, usually making breathing less exhausting. A few patients are made more uncomfortable by it, and in these it is not continued. Some early attempts were made to neutralize the inhaled chlorine by the continuous inhalation of ammonia. They were entirely unsuccessful, since the ammonia could only reach the chlorine excess in the upper air passages. These would not require the neutralizant, since they are quickly flushed by fresh air. The irritant action of the ammonia, if unskillfully used, may add to that of the chlorine so as to increase the local injury.

Analeptics: Brandy (small sips) is rather useful, until collapse becomes established. *Camphor* and *ether* have been used hypodermically, against the later collapse, with the usual discordant opinions as to their efficiency. *Pituitary solutions*, 0.5 cc. every three hours, intramuscularly, and *strychnine* are useless.

Atropine was proposed originally with the object of diminishing "pulmonary secretion." It proved entirely useless, since the exudate of pulmonary edema is of inflammatory origin and is not affected by atropine. It might be of advantage against *bronchial spasm* (Symes, 1915; Cow, 1915), but this is not a serious feature of gassing; and besides, the ordinary doses of atropine are apparently not sufficient to relieve it. In animals gassed with chlorine, Barbour, 1919, found the fatality unchanged by atropine.

Epinephrine was tried especially to relax bronchial spasm. It is efficient, although the relief is only temporary (1 cc. of 1:1000, hypodermically). It is not employed extensively, probably because the bronchial spasm is not an important factor in gassing. Barbour, 1919, found it inefficient in animals.]

Oxygen Inhalation.—The dominant indication, with the onset of edema, is to facilitate the access of oxygen, and later the elimination of carbon dioxide. The control of the carbon dioxide is difficult; but the anoxemia can be relieved considerably by efficient oxygen inhalation. This diminishes the cyanosis and increases the chances of survival. By its persistent use, patients may recover after being cyanosed and unconscious for two days.

Venesection was introduced early in the gas war, and maintained itself for all forms of irritant gases. Neither the clinical nor the experimental data are quite conclusive as to its efficiency for saving life, but the balance of the evidence is in its favor. The clinical relief is often striking, especially in the early severe cases, with deep-blue cyanosis and full pulse corresponding to acute asphyxial dilatation of the heart. The relief, however, may be only temporary. Bleeding must *not* be used when collapse has started, as indicated by a poor pulse; or when the condition of the patient is in any way immediately dangerous. This confines the usefulness of bleeding to the pre-edemic stage.

Saline Infusion.—During the stage of pulmonary edema, the blood becomes markedly concentrated, more viscid, and diminished in volume. Injection of normal saline (1 per cent of the body weight; *i.e.*, equal to the quantity of blood withdrawn at the venesection) has been tried to relieve this condition, but with doubtful benefit. Simple saline remains in the circulation at most half an hour and generally less, so that the benefit would at best be temporary; and the use of hypertonic salt or glucose solutions was found rather to increase the fatality.

Alkaline Treatment.—The most hopeless element in the treatment of the severe cases is acidosis, due to the inability of the edematous lung to eliminate carbon dioxide. Some good may be accomplished by introducing alkali into the blood; but the efficiency of this is limited when carbonic acid is not being excreted. This is an essential difference from other forms of acidosis.

Digitalis and ouabain were tried against the cardiac dilatation, but Barbour, 1919, found them useless with chlorine gassing. *Acetphenetidin and acetyl-salicylic acid* were tried against the headache, but are not advised, for fear of aiding the tendency to collapse.

Discharge of the Exudate from the Lungs.—Attempts to remove the exudate from the air passages mechanically are not promising. Coughing is a natural device for this purpose, but tends to become so violent as to threaten mechanical injury to the lung, and therefore generally rather needs to be allayed. Something can be accomplished by *position*. The head is turned to the side, and the foot of the bed raised 2 or 3 feet or higher, for a few minutes at a time. *Schaefer's method of artificial respiration* has been applied. It is not likely to do good, and may do harm. *Emetics* were used with the hope that the movements of vomiting would also expel some of the contents of the lungs. They appear to be ineffective for this purpose; and in the later stages the depression is certainly detrimental.

Expectorants.—On the first day ordinary expectorants are useless, and may indeed be harmful by exaggerating the tendency to nausea. An exception may be made for demulcents. *On the second day,* if the general condition is good, treatment of the bronchitis may be begun, with ammonium carbonate, 0.3 Gm., or ipeac tincture, 0.5 cc. every six hours. *Later,* the treatment of the bronchitis should be continued by the ordinary methods. Steam inhalation charged with Eucalyptus oil or Comp. Tr. Benzoin is used extensively.

Protection against poison gases is provided by masks covering the eyes, nose and mouth, and communicating with the air through layers of adsorbent and neutralizing chemicals. Those used in warfare (charcoal, permanganate and soda lime) are intended to protect at once against all the gases so far used, in their ordinary concentrations. This is a great advantage under field conditions. *The British type* contained essentially active charcoal and alkaline permanganate. *The German type* contained three layers: the inside layer, pumice with methenamine, which protects against phosgene; the middle layer, active charcoal; the outer layer, a mixture of baked earth, potassium carbonate and fine charcoal.

When only one gas need be considered, as under industrial conditions, more specialized absorbents may be preferred. *Chlorine* is so highly reactive that it can be easily neutralized. Even water is fairly effective. Thiosulfate and alkalis are the special absorbents. Soda lime is used against all *acid vapors;* cupric sulfate and activated charcoal against *ammonia;* charcoal against *organic vapors* (aniline, gasoline); catalytic metallic oxides against *carbon monoxide;* filter pads against *smokes* (Henderson and Haggard). *The detection and identification* of war gases are described in the Chemical Warfare Bulletin, 1940, *26:* 86.

Chronic poisoning by irritant gases has industrial importance, in view of their escape from chemical factories, etc. Even a small proportion tends to produce bronchitis and to diminish the resistance to infections (Ronzani, 1908: low concentrations of Cl, SO_2, NO_2). They may possibly cause cachectic conditions; but it is difficult to assign the limits between which these poisons are harmless, objectionable and dangerous.

CHLORINE GAS

The effects of inhaling toxic concentrations of chlorine gas were described in the general discussion of pulmonary irritants (see above).

Use in "Gas Clouds."—Chlorine was the first gas used in the war, being the sole constituent of the "gas-cloud" attacks of Ypres in April of 1915. It was effective, but because of the ease of protecting against it, was replaced almost entirely by phosgene mixtures, which were used almost exclusively in the gas clouds of 1916. *The concentration in cloud attacks* probably never rises above 1:1000, and more commonly is nearer 1:10,000. These are effective concentrations. With concentrations below 1:100,000, chlorine gas is practically ineffective under military conditions, although long exposure is followed by bronchitis.

Minor toxic effects of chlorine arise mainly in industry. Air contaminated with chlorine produces irritation of the conjunctiva and respiratory mucous membranes; 0.001 to 0.002 per thousand of air (volume) is harmless, although even 0.001 produces slight conjunctival irritation (Buergi in Heffter's Handbuch, 3, 1*:* 888); 0.003 is disagreeable, and 0.004 irrespirable (Matt, 1889). The foliage of plants is destroyed by concentrations which are not noticeable for man. The odor is recognizable in dilutions of one per million of air.

Habitual exposure to chlorine causes rhinitis with anosmia, conjunctivitis, bronchitis and stomatitis; anorexia, chronic gastritis, loss of weight, anemia, cachexia; insomnia. "Chlorine acne" is not due to chlorine as such, but to products of its action on tar lining of electrolytic tanks.

The mechanism of action of chlorine probably involves abstraction of hydrogen with liberation of nascent oxygen; and formation of hydrochloric acid. Chlorine is nearly twenty times more toxic than HCl gas, partly because of its relatively low solubility so that the action extends further down the respiratory tract.

Fate of the Inhaled Chlorine.—Chlorine is not absorbed as such. The chloride content of the plasma increases for a few hours after gassing, and the chloride excretion by the urine is raised on the second day following severe gassing. Presumably, chlorine-protein compounds are formed in the lungs and are absorbed, especially by the corroded tissue. These would break down in the tissues, liberating chloride ions, which would then appear in the urine.

Chlorine against Colds.—The inhalation of diluted chloride has been suggested as a treatment of acute respiratory affections. Vedder and Sawyer state that the concentration must be exactly 0.013 to 0.015 mg. per liter for an hour. The clinical results do not appear convincing. The chlorine can not exert any antiseptic actions under these conditions; and while it is conceivable that the irritation may sometimes produce a beneficial degree of hypermia, it is more probable that it would lower the resistance of the tissues.

Iodine and bromine are also local irritants, corrosives and antiseptics, but it seems more convenient to consider iodine with the iodides (see Index). Freshly made aqueous *bromine solution,* 1:1000 to 2000, applied on compresses to odorous wounds and fistulas, destroys the odor and produces little or no irritation (W. W. Babcock, 1945).

CHLORINE ANTISEPTICS

Strong and prompt germicidal effects are produced by chlorine as gas or in solution, and by substances capable of yielding "active" chlorine, such as the hypochlorites and chloramines (*i. e.,* compounds containing NCl groups). Toxins are also destroyed. Active chlorine compounds attack all organic matter, and are thus likely to be corrosive and to become inactive. These objections can be largely overcome by proper technic and selection of the preparations. *Inhalation of chlor-*

amine T or halazone dust in industries may sensitize to the production of asthma and rhinitis (S. M. Feinberg and Watrous, 1945).

Mechanism of Action.—Chlorine itself acts partly by oxidation, partly by chlorination of the organic matter. With the hypochlorites the chlorination appears to be the chief element. It is supposed to occur in the amino acid groups of the proteins, yielding chloramines. In chloramine-sulfonetoluene derivatives, the chlorine of the chloramine is still "active;" for instance, it liberates iodine from iodides. It is readily transferred to proteins, so that it acts essentially like hypochlorite, and is at least equally germicidal. The germicidal potency of sodium hypochlorite is about equal to that of free chlorine; the *hypobromite* has only about a hundredth of the activity of bromine, and *hypoiodites* react feebly with proteins and amino acids (Dakin, 1916).

Hypochlorites are available as *Chlorinated Lime* (*Calx Chlorinata, "Bleaching Powder,"* popularly misnamed *"Chloride of Lime"*), which consists mainly of a mixture or weak compound of calcium hypochlorite and calcium chloride, yielding 30 per cent of available chlorine. It occurs as a grayish-white granular powder of chlorine odor, partially soluble in water. It is an effective and cheap disinfectant, used largely as a disinfectant for excreta, but too irritant for application to the tissues. High dilutions are employed to sterilize water, especially for temporary emergencies. When swallowed, bleaching powder produces gastro-intestinal irritation. The treatment would be by evacuation and demulcents.

Disinfection of Excreta.—Six ounces of chlorinated lime are mixed with a gallon of water; a quart of this is added to each discharge and allowed to stand an hour.

Sterilization of Water.—Five to 15 pounds of chlorinated lime are used per million gallons according to the impurities and other conditions. This imparts a slight taste, but no other bad effects have been demonstrated. On a small scale a level teaspoonful is rubbed with 4 cups of water, and a teaspoon of this solution is added to 2 gallons of the drinking water, and left for at least ten minutes.

For Disinfection of the Hands.—These are moistened and rubbed with a little dry chlorinated lime and washing soda. If the powder or paste is left on the skin it causes burning, then rubefaction or mild dermatitis (Lebduska *et al.*, 1939). *Fetid wounds and ulcers* may be deodorized by washing twice daily with a solution of two tablespoonfuls in a basin of warm water (Muench, 1915). *For snake bites,* 10 cc. of a 1 per cent solution is injected hypodermically about the wound (Calmette, 1907).

Hypochlorite footbaths have been proposed for prophylaxis against *fungus infections,* but are useless, as it would require hours to kill the organisms (L. Schwartz, 1947).

Sodium Hypochlorite Solution, U.S.P. ("Labarraque's Solution"), contains about 5 per cent of NaOCl. *This solution is not suitable for application to wounds,* as it is too strongly alkaline; but when diluted with ten or twenty parts of water, it may be used as deodorant on ulcers; *Javelle Water* is a similar preparation of chlorinated potash.

Surgical Solutions of Hypochlorites (Dakin-Carrel Solution).—Continuous saturation of wounds with dilute, buffered hypochlorite solutions practically abolishes sepsis, dissolves dead tissue and promotes healing. The skin must be protected by petrolatum gauze, since it is often irritated even by the correct solution.

The solution is merely a tool in a specially developed surgical technic (Carrel and Dehelly, 1918), and its success depends on the care with which the principles of the technic are followed. To be effective, the solutions must contain between 0.43 and 0.48 per cent of available chlorine. Higher percentages are too irritant. The alkalinity must be adjusted to *p*H 9–10, for the tissues are more irritated on either side of this range (Cullen and Austin, 1918; Cullen and Taylor, 1918). The preparation and titration of the solution are fairly simple. It must be protected from light and kept not longer than a week. More permanent solutions can be prepared by electrolysis and the addition of a trace of permanganate or sodium silicate.

Solvent Action.—Hypochlorite solution is markedly solvent for necrotic tissues, even when the reaction is strictly neutral (Taylor and Austin, 1917). This helps to give better access to the bacteria. At best, however, the action is superficial, and damaged tissues must be promptly excised. Chloramine and Dichloramine T are without solvent action (Taylor and Austin, 1917). There is also a fibrinsolvent action on *living tissue cultures* (Lambert, 1916). The injury, however, to the phagocytes and other living cells is distinctly less serious than with most antiseptics. Silk *ligatures* are soluble in hypochlorite, and can therefore not be used with it. Catgut ligatures tend to slip, and thus incline to secondary hemorrhage (K. Taylor, 1917).

Intraperitoneal injection into dogs produces marked irritation, corrosion, collapse and death, or pericardial effusions and adhesions (C. S. Beck, 1929). *Intravenous injection* is relatively less toxic, but larger doses cause laking and delay the coagulation time (Mann and Crumley, 1918). The hypochlorite is rapidly destroyed by the blood serum, which partly accounts for the low toxicity (Dakin, 1916). *Blood Coagulation.*—The addition of Dakin's solution to blood (1:10) prevents clotting by interfering with the thrombin. Clotting occurs if tissue extract is added, so that the interference would not be important in wounds (Githens and Meltzer, 1918).

Dilution Solution of Sodium Hypochlorite, N.F. (Surgical Solution of Chlorinated Soda; Modified Dakin's Solution), is prepared by the dilution of the solution of Sodium Hypochlorite and addition of Sodium Bicarbonate, or by the interaction of sodium carbonate and assayed for chlorinated lime. It must not be confused with the stronger solution of Sodium Hypochlorite.

Chloramine T, *sodium para-toluene sulfonchloramide* (also called *chlorazene*), may be used in place of Dakin's solution and has the advantage that its watery solutions are practically stable. In equimolecular solution it is somewhat more germicidal than NaClO. This may perhaps be explained by less side reactions with nonbacterial proteins. Weight for weight, the germicidal power is somewhat weaker. It is less irritating and has but little solvent action on necrosed tissue. It is decomposed by oils.

It is employed in wounds as 1 to 2 per cent solution by the saturation technic. Strengths of solutions for eye, 0.1 per cent; nose and throat, 0.2 per cent; bladder and urethra, 0.25 per cent (Dakin, 1916; Eicher, 1917).

Chloramine T, U.S.P. (Sodium Paratoluenesulfonchloramide), contains about 12 per cent of active chlorine. White or faintly yellow crystals or crystalline powder having a slight chlorine odor; slowly decomposes on exposure to air, losing chlorine. Sol. in water (1:7) with alkaline reaction. Insol. in benzene, chloroform and ether. Decomposed by alcohol.

Dichloramine T, *toluene parasulfondichloramide*, is much more germicidal than chloramine T, but only traces dissolve in water. It is readily soluble in most organic solvents and oils, sparingly in paraffin and petrolatum. When such solutions are applied to the tissues, they give up the drug slowly and exert a continuous antiseptic action, until all the dichloramine T has been used up. A single application lasts for hours, or even a day, according to the strength of the solution (Dakin, Estell, 1917). There is little irritation of the skin. Catgut is not affected, so that the danger of secondary hemorrhage is avoided (Lee and Furness, 1918). The solution causes rather painful though short smarting of sensitive wounds; is more or less irritant to granulations and is said to retard epithelization; the dressings adhere to the wound, causing mechanical injury (Morrison *et al.*, 1918). The solvent action on dead tissue is less marked than with Dakin's solution (Taylor and Austin, 1917). Application to the peritoneum produces inflammation (Reismann and Magoun, 1918). Injection into the gallbladder is followed by induration. Introduction into the pleura is followed by rapid death (reflex?) (Grey, 1918). Dichloramine T is generally applied as solution in chlorinated paraffin. These solutions deteriorate rather rapidly, but retain considerable activity for a week or longer. The usual concentrations are: for *open wounds*, 2 to 10 per cent; sterilization of the *nasopharynx*, 2 per cent spray for fifteen minutes, several times daily (Dakin and Dunham, 1917); for *eye infections*, 0.5 to 1 per cent every four hours (Green and Green, 1918). Contact with yellow petrolatum destroys dichloramine T rapidly.

Chlorinated Paraffin, N.F. (*Chlorosane*), is a liquid paraffin treated with chlorine; used as a solvent for Dichloramine. A light yellow, clear, thick oily liquid; odorless; stable in air. Its chlorine is not "active" or antiseptic, but serves merely to protect the dichloramine.

Halazone, para-sulfondichloraminobenzoic acid, N.N.R., was introduced by Dakin and Dunham, 1917, for the extemporaneous purification of drinking water (one or two tablets of 4 mg. per liter). It sterilizes in about thirty minutes, and has little taste.

Succinchlorimide, N.N.R., (N-chlorosuccinimide,) yielding about twenty-six parts of active chlorine, is used for rapid disinfection of drinking water: 11.6 mg. per liter of water is reported to be effective in twenty minutes.

Chloroazodin, U.S.P., *azochloramid*, dichloroazodicarbonamide, yields about 38 per cent of active chlorine. It has the actions of chloramine and hypochlorite, but reacts less with organic matter and therefore has greater stability and higher bactericidal power in the presence of organic material. It is but little soluble in water, but an aqueous solution of 1:3500 to 1:1500, or an oil solution of 1:2000, may be used on infected wounds. *Solution of Chloroazodin*, U.S.P., a 2.6 per cent solution in glyceryl triacetate ("triacetin") deserves preference. It is more stable and can be diluted with three to eight volumes of water or with four of oil, for application to mucous membranes, or used undiluted on cuts, bruises and on dressings.

Dermatitis from "cutting oils."—Mechanics exposed to these oils tend to develop acne, folliculitis, comedones and keratoses, attributable to chlorine and sulfur compounds present in these preparations (Schamberg, 1920; S. M. Peck, 1944).

Chloracne.—Dermal cysts appear in nearly all electrical workers who are sufficiently exposed to electric insulating compounds. These dielectrics generally contain chlorodiphenyloxides, chloronaphthalenes, chlorodiphenyls, chlorophenols and chlorobenzenes; but the lesions are said to be purely mechanical, by obstruction of the pores by these agents, resulting in local keratinization (S. M. Peck, 1944).

PHOSGENE; CARBONYL CHLORIDE; $COCl_2$

Phosgene in itself is fairly indifferent; but in the presence of moisture it decomposes with the production of hydrochloric acid: $COCl_2 + H_2O = CO_2 + 2HCl$. Its effects are therefore relatively slight in the upper air passages, where the moisture is relatively small, and reach their maximum in the alveoli, where the air is saturated with water. With prolonged inhalation, however, enough is decomposed in the bronchi and trachea to produce corrosion. The site of action, as determined by the decomposition, explains the greater toxicity of phosgene as compared with chlorine. The slight degree of irritation of the sensory nerves in the upper air passages does not warn sufficiently against inhalation of the gas, so that the patient is likely to inhale it more deeply than he would equivalent concentrations of chlorine or other directly irritant vapors. Moreover, the reactive chlorine would be partly neutralized and bound in the upper air passages, while the indifferent phosgene would escape this destruction.

History and Use.—Before the first World War, this substance was known in toxicology mainly as the irritant product of the combustion of chloroform and carbon tetrachloride (which is used in fire extinguishers). Its use in gas clouds followed soon after that of chlorine. It incapacitates more slowly than chlorine, but is more dangerous in the end. For physical reasons, it was generally mixed with some chlorine when used as clouds. It was also employed extensively in shells.

Properties.—Phosgene liquefies at 8.2° C. The gas is about three times heavier than air.

Limits of Toleration.—The highest concentrations that can be breathed without prompt distress are 1:50,000 to 1:500,000; generally about 1:125,000. Even this, however, produces definite eye irritation. Gas clouds generally contain about 1:10,000. The high mortality may be judged by the result of animal experiments: of dogs exposed for half an hour to concentrations of 1:17,000 to 13,000, about 42 per cent died within two days; with concentrations 1:13,000 to 1:10,000, the deaths were 62 to 69 per cent. The concentrations for cats are reported by W. Wirth, 1936.

Differences in Symptoms from Chlorine.—The eye irritation is stronger than with chlorine. The sensory irritation of the respiratory passages is much less than with chlorine; for the irritation begins in the finer bronchial division, beyond the sensory nerves. Consequently there are generally no acute symptoms or cough. If cough occurs, it is less violent than with chlorine, so that there is much less emphysema. Although cyanosis and asphyxia may develop promptly, the ordinary onset is slow and insidious. The soldiers usually felt little inconvenience for an hour or two except some weakness; and then developed progressive pulmonary edema, with "grayish-white" collapse, that may soon terminate in death. Phosgene gas is much more likely to be followed by circulatory collapse; *i. e.*, it is much more likely than chlorine to develop irrecoverable pulmonary edema.

Superpalite, diphosgene, trichloromethyl-chloroformate (Cl COOC Cl_3), was the chief constituent of the "Green cross" shells, where it was usually mixed with some chloropicrin ("vomiting gas") or diphenyl chlorarsine ("sneezing gas"). It was perhaps the principal "killing" gas for shells, and is highly effective, acting essentially like phosgene, *i.e.*, by the liberation of hydrochloric acid on contact with water. The pathology and treatment are identical with those of phosgene. It is an oily liquid, of disagreeable, suffocating odor.

Palite, chloromethyl-chloroformate (Cl $COOCH_2$ Cl), is a liquid which was also used extensively in shells. It belongs to the same class as superpalite and phosgene.

NITRIC VAPORS

These constitute the brown vapors produced by the partial reduction of nitric acid or nitrates; when nitric acid acts on metals, as in etching, or on organic materials, as in the nitration processes of chemical industry, especially in the manufacture of nitrocellulose and picric acid; or by the accidental spilling of nitric acid on organic material, such as sawdust; or by the combustion of organic materials containing nitrates, in the combustion (not in the explosion) of nitroglycerin and of nitrocelluslose; the latter as "gun cotton," or "smokeless powder" in ammunition, or as "pyroxylin," the chief component of "celluloid," and of the highly inflammable nitrocellulose "films" used in photograph, cinema and radiography. The fatal catastrophes resulting from these combustions have led to the substitution of cellulose-acetate films, which do not form nitric vapors, and which have only a fire hazard, little greater than that of the combustion of paper. Many celluloid articles are still made of nitrocellulose, but they are not usually stored in large quantities in dangerous situations. Nitric vapor poisoning is quite common in the industries (review, von Oettingen, 1941).

Composition.—Nitric vapors consist chiefly of nitrogen dioxide, NO, and nitrogen tetroxide or peroxide, NO_2 (colorless) and N_2O_4 (dark brown). The last two, which are the more important, change readily into each other so that the end effects are virtually identical. The ratio of the peroxide increases with the temperature. The amounts produced from gun cotton, celluloid and photographic film vary with conditions. The smoke from these also contains carbon monoxide, cyanogen compounds and toxic tars (Proc. U.S.A. Chem. Warfare Service, 1929).

The effects consist in immediate irritation and delayed progressive inflammation of the exposed mucous membranes, especially of the respiratory organs. During exposure, there is some irritation of the eyes and the respiratory mucosae; but this subsides promptly when the exposure ceases, and the patient may feel practically normal for four to eight hours, but during this time fluid is accumulating in the pulmonary alveoli. When the edema has reached a sufficient degree, and especially when some slight exertion calls for extra oxygen, asphyxia sets in, with dyspnea, cyanosis, cardiac dilation and collapse. Death occurs in most cases in eight to forty-eight hours. The amount of pulmonary fluid is often profuse, and the blood becomes correspondingly concentrated and viscous; the hemoglobin is reduced, but there is no methemoglobin (E. Muntwyler *et al.*, 1929). If patients are not killed directly by the pulmonary edema, this often passes into secondary infective pneumonia, with death after several weeks; light cases may escape with laryngitis and bronchitis (Lehmann, 1913).

The *toxic concentrations* have been determined by K. B. Lehmann and Hasegawa, 1913. Some nitrite is formed after absorption, but the amounts and effects of this are insignificant in comparison with the irritant actions. *Film-combustion poisoning* involves also other gases. The acute deaths, which occur immediately or within a few minutes, are due to carbon monoxide, possibly with the admixture of cyanide, which is also formed. The later fatalities take the ordinary course of the nitric patients. The smoke also contains a toxic tar, which produces methemoglobin (Sollmann, Ray and Hambourger, 1931); but this does not appear to be concerned in the acute fume poisoning.

The treatment should consist in absolute rest for twenty-four to forty-eight hours after the exposure, to minimize the need of oxygen (Walton, 1925). Oxygen inhalation may be begun with the first sign of edema. Chemical antidotes (thiosulfate injection, etc.) are useless after the gas has been inhaled. The treatment of the developed edema is that of other acute pulmonary edema (glucose injection, etc.); but the prognosis is bad. Sedative doses of morphine may be administered without hesitation, to diminish anxiety and dyspnea. Larger doses may be dangerous. Emetics, atropine, epinephrine and pituitary injections are useless and possibly harmful. The mucous membranes may be treated with boric acid lotions and protected by demulcents.

Protection.—The fumes are freely soluble in water, and a damp cloth furnishes considerable protection. A sponge wetted with sodium carbonate or, better, sodium thiosulfate solution, or the army gas masks, are more effective. Industrial fumes should be removed by adequate ventilation. Film fires should be flushed with water; chemical extinguishers are useless.

Dimethyl sulfate $(CH_3)_2SO_4$, produces corrosion of the respiratory mucosae, probably by hydrolysis into sulfuric acid (Strothmann, 1929).

Sulfur dioxide is discussed under sulfur compounds (see Index).

Chloropicrin, "vomiting gas," *nitro-trichloro-methane, nitrochloroform* $(C\,Cl_3{\cdot}NO_2)$.—All irritants, even the asphyxiants, may provoke vomiting; but chloropicrin was used in the war particularly for this purpose. It is a neutral, colorless fluid, noninflammable, boiling at 113° C. It was therefore used in shells, but may be used in gas clouds if mixed with more volatile substances. It was intended partly to induce the men to remove their masks, and thus inhale the more toxic substances (diphosgene, diphenyl chlorarsine) with which it was generally mixed. It is itself a potent pulmonary irritant, however, intermediate between chlorine and phosgene. It is an effective insecticide fumigant (Chapman and Johnson, 1925).

Effects.—Chloropicrin irritates all surfaces. It therefore produces lacrimation, bronchitis and pulmonary edema, as well as vomiting. It also irritates the skin. Dilutions of 1:1,000,000 are detected by the *eyes* of most subjects. Concentrations of 1:200,000 would incapacitate victims within ten minutes. The eyes smart and pain, as with all lacrimators. There is considerable irritation of the *throat*, cough, etc. Exposure is generally followed by *bronchitis* and asthmatic attacks. Death may follow from the pulmonary complications. In experimental exposures of dogs to moderate concentrations the *blood picture* is that of phosgene poisoning, *i. e.*, a pre-edemic fall in hemoglobin, followed by a rise as edema develops. With high concentrations, the edema may set in so rapidly that the hemoglobin appears increased almost from the start. The *emetic effect* is presumably due to direct gastric irritation from swallowing saliva impregnated with the poison. Contact with the liquid causes severe *burns*, usually with blistering, and may lead to ulceration. Abrasions, if exposed to the vapors, tend to become septic. The *kidneys* appear to be injured more frequently than with any of the other "gases." For this reason prolonged exposure is dangerous even in low concentrations.

After-Effects.—Chloropicrin poisoning is likely to be followed by serious sequels: severe anemia, with general asthenia; weak and irregular heart, sometimes cardiac dilation; the patient ages rapidly. There is a liability to recurrent asthmatic attacks, leading to emphysema. (These are treated like ordinary asthma, by epinephrine, morphine and atropine.) Those who have been poisoned appear to be hypersensitive to the poison. This is also observed in animals.

Chloracetophenone, $C_6H_5.CO.CH_2Cl$, a white crystalline solid, produces irritation of the mucous membranes, the conjunctiva being especially susceptible. Very small quantities cause the eyes to water, smart and pain so as to put men out of action, without any permanent harm resulting from these concentrations. Higher concentrations irritate the nose, pharynx and skin. It is the principal "*tear gas*" or lacrimator used in grenades, for protection and in civil riots as well as in warfare.

Effective Concentrations.—Lacrimation begins with 0.3 to 0.5 mg. per cubic meter, nasal irritation with 1 mg.; 2 mg. makes seeing impossible; 4 to 5 mg. is the highest concentration that can be tolerated for one minute. The pain protects against exposure to higher concentrations which would otherwise cause pulmonary edema. Ordinarily, the symptoms go no further, and recede rapidly after exposure ceases. Within an hour or two the patient is practically normal, except for slight hyperemia of the eyes, which may last twelve hours. There are no toxic after-effects, and men are fit for duty as soon as the eye irritation lets up; but the conjunctival irritation is sometimes followed by secondary bacterial invasion. Direct contact with the cornea may produce permanent opacity.

Treatment.—Washing with sodium sulfite solution gives prompt relief; for the eyes, 0.4 Gm. in 25 cc. of water and 75 cc. of glycerin; for the skin, 4 per cent in 50 per cent alcohol. If sodium sulfite is not available, the surface should be washed with glycerin, 50 per cent alcohol or with whiskey (W. D. McNally, 1931). The substance is but little soluble in water. Its odor is similar to that of locust blossoms.

Other lacrimators are numerous, but generally less specific and more harmful. They include phenylcarbylamine chloride $(C_6H_5NCCl_2)$, used chiefly by the Germans in the first World War; benzyl and xylyl bromide, chloride and bromcyanide; bromated and chlorinated ketone and acetone; chlorosulfonates, bromacetic and iodacetic ether; acrolein; stannic chloride.

CHLORARSINES

Diphenylchlorarsine, $(C_6H_5)_2AsCl$ and diphenylaminechlorarsine, $(C_6H_5)_2NAsCl_2$ (*adamsite*) were used as "*irritant smokes*," chiefly to enforce the inconvenience of masking. They cause extreme distress, immediate or delayed for half an hour, likened to extreme seasickness, together with acute sinusitis and toothache! They irritate the eyes, nose and throat, with copious watery nasal discharge; characteristic severe pain beginning at the base of the nose and spreading through the sinuses, sneezing and coughing with pain in the chest; nausea and vomiting; marked mental depression and muscular weakness. Sensory disturbances, generally temporary, set in later, sometimes not till the third or fourth day (S. A. White, 1938).

Diphenylchlorarsine is used as a very fine powder. Diffused in the air in the proportion of 1:1,000,000, it produces intolerably violent sneezing for some fifteen minutes. Even more dilute mixtures are effective sneezing agents. *Higher concentrations* act as respiratory irritants. With animals, fatal concentrations produce inflammation of the whole respiratory tract; fibrinous bronchitis, pulmonary edema or pneumonia. The toxicity is as great as that of phosgene (Underhill, 1918). Intraperitoneal injections also produce pulmonary congestion. There is a conspicuous absence of the intestinal and renal changes produced by ordinary arsenicals.

Treatment.—Inhalation of chlorine was reported to relieve the symptoms by forming nonirritant compounds with these arsines (Walton and Eldridge, 1929).

Chlorvinyldichlorarsine, $ClCH{:}CH.AsCl_2$, "*Lewisite,*" a liquid with rose-geranium odor, which penetrates through rubber, acts as a vesicant, somewhat like "mustard gas," but with quicker absorption and with some systemic arsenical actions, especially on the kidneys. Severe illness results if 0.3 cc. is left on the skin; 1.4 cc. may produce death in three hours to five days. Its effects on the skin were studied by Rovida, 1929. It produces large blisters, but not surrounded by erythema. It may penetrate to the bone. The blisters should be evacuated (in contrast to mustard gas burns) to diminish the systemic arsenic effects. Sorbitol-gelatin film furnishes some protection (C. J. Carr, 1943). Eye burns under field conditions produce superficial irritation of the cornea, usually without permanent damage (D. G. Cogan, 1943). They may be treated with prompt application of hydrogen peroxide solution diluted with three parts of water, but the most effective antidote against all arsenial agents is 2-3 dithiolpropanol "BAL," Dimercaprol (British Anti-Lewisite) (see Index).

Ethyldichlorarsine acts similarly to lewisite, but is milder. It was proposed as a "sneezing gas."

DICHLORDIETHYLSULFIDE
(DICHLORETHYLSULFIDE)
"MUSTARD GAS"
CHLOROETHYLAMINES
"NITROGEN MUSTARDS"

Dichlorethylsulfide $(C_2H_4Cl)_2S$, acquired great importance as the "*blistering gas*" of gas warfare. It was also known as "*Yperite,*" "yellow cross shells" and thiodiglycol chloride. It is an oily fluid of sharp odor, but not chemically related to "mustard oil" It differs from the older war "gases" in that its serious effects are not confined to the respiratory tract. Pulmonary lesions, when they occur, are indeed the most fatal manifestations; but there are important actions on the eyes and skin, and sometimes fairly severe gastric disturbances. Direct systemic effects are only faintly indicated in field or factory intoxications.

It penetrates deeply, injures the blood vessels and blocks the circulation, resulting in severe inflammation and tissue necrosis. Contact with the fluid or its vapor does not produce any immediate effect whatever; but after a latent period of some hours, intense inflammation develops at the site of contact, even with minute traces. This leads to vesication, followed by local necrosis with slow healing. The lesions are superficial and extend but little beyond the actual contact. It produces marked leukopenia, with involution of the lymph nodes and aplasia of the bone marrow (O. Bodansky, 1945). Secondary infections are common, as the resistance is lowered. The intoxication is usually strictly local, involving the skin, the eyes, the respiratory and sometimes the alimentary mucosae, according to the method of application. Systemic intoxication usually occurs only by intravenous injection. The treatment of the local lesions is mainly by cleanliness and emollients, similar to that of burns. Oils protect the skin only slightly. If the patient is seen immediately after exposure, the poison may be partly removed by scrubbing with kerosene; but the penetration is so rapid that this treatment is not successful if delayed for fifteen or thirty minutes.

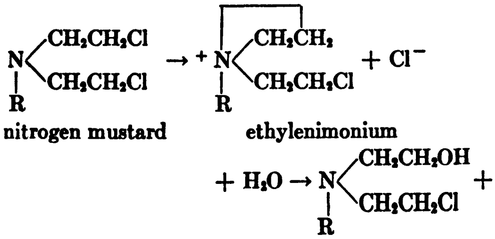
Nitrogen mustards are analogous compounds of nitrogen, chloroethyls (C_2H_4Cl) taking two (bis) or three (tris), more commonly two (bis), valences of nitrogen. The third valence of the bis compounds is taken by an alkyl group; this furnishes a large series of compounds differing in degree of reactivity and therefore capable of biologic adaptations. Nitrogen mustards are also casualty-producing vesicants, but their chief interest lies in their systemic actions, especially their toxicity to lymphoid tissue, suggesting possibilities in the treatment of leukemic conditions. The effects on cells resemble those of x-ray irradiation. Dichlordiethylsulfide produces the same actions, but the amines are more adaptable (reviews, A. Gilman, 1946; Gilman and Philips, 1946). At present, the therapeutic usefulness of nitrogen mustards appears to be limited to widely disseminated, rapidly growing neoplasm, but the improvement is only temporary (C. P. Rhoads, 1946).

Chemical Properties.—The toxic action of dichlorethylsulfide is intimately connected with its constitution, particularly with the presence of the two chlorine atoms. If these are either diminished or increased, the activity is destroyed. This may be accomplished, and the "mustard gas" may be "killed" by hydrolysis, chlorination and by reducing agents evolving nascent hydrogen; less efficiently by oxidizing substances.

Hydrolysis.—Dichlorethylsulfide is hydrolyzed by water, probably mainly according to the equation: $S(C_2H_4Cl)_2 + 2H_2O = S(C_2H_4OH)_2 + 2HCl$. The hydrolysis starts promptly and proceeds fairly rapidly for the dissolved substance, but proceeds slowly for the undissolved excess.

Hydrolysis Theory of Toxic Action.—It has been suggested that the dichlorethylsulfide penetrates as such into the cells, where it is slowly hydrolyzed, resulting in a liberation of free acid within the cells; and that in this free acid is the toxic agent (Lynch, Smith and Marshall, 1918). It is established that the substance is hydrolyzed before it is excreted; and there is proof that this hydrolysis may occur within the cells at the place of application, at least in starfish ova (Lillie, Clewes *et al.*, 1918, 1919). The proof, however, is not conclusive. Related substances, such as dichlordiethylsulfone, which practically do not produce acid, are nevertheless vesicant; while dichlordimethylsulfide, which produces acid more readily than the "mustard gas," is not vesicant (Flury and Wieland, 1921; Peters and Walker, 1923).

Current Theories of Mechanism.—Gilman and Philips, 1946, attribute the toxic effects, local and systemic, to the formation of highly reactive *cyclic onium* cation, ethylene sulfonium or ethylene imoniums. These act on the carboxyl, amino and perhaps other groups in proteins and are thereby cytotoxic, apparently through inactivation of essential cellular enzymes, especially phosphokinases, concerned with the transfer of PO_4 to and from adenylic compounds. The sequence of reaction of the nitrogen mustards may be represented as:



$$\underset{\substack{|\\R}}{N}\left\langle\begin{matrix}CH_2CH_2Cl\\CH_2CH_2Cl\end{matrix}\right. \rightarrow {}^{+}\underset{\substack{|\\R}}{N}\left\langle\begin{matrix}CH_2CH_2\\CH_2CH_2Cl\end{matrix}\right. + Cl^-$$

$$+ H_2O \rightarrow \underset{\substack{|\\R}}{N}\left\langle\begin{matrix}CH_2CH_2OH\\CH_2CH_2Cl\end{matrix}\right. + H^+.$$

Sulfur mustard depresses oxygen consumption, aerobic and anaerobic glycolysis and pyruvate oxidation in minced brain, mammalian skin, avian erthrocytes and other tissues, but this requires higher concentrations than exist in living animals. Most enzymes are resistant or only moderately sensitive.

The cytotoxic action appears analogous to irradiation in many ways. The *mitotic* activity of a wide variety of cells is susceptible to inhibition by minimal doses. Somewhat higher concentrations produce *nuclear fragmentation*. Threshhold doses act on *chromosomes* in Drosophila, resulting in inheritable abnormalities.

Systemic effects, obtainable most conveniently by intravenous injection of sublethal doses of nitrogen mustards, involve especially the *blood-forming organs*. The lymphoid tissue throughout the body is fragmented and atrophied; the bone marrow shows swelling of the cells, disappearance of mitotic activity, and aplasia. There is marked decrease of lymphocytes, granulocytes and thrombocytes, and moderate decrease of erythrocytes. These effects are in direct ratio to the dosage. The *gastrointestinal epithelium* is also markedly affected, with vacuolization, nuclear swelling, desquamation and hemorrhage.

Therapeutic applications of the high toxicity for lymphoid tissue are under trial, by intravenous injection of saline solutions of the crystalline hydrochlorides of the nitrogen mustards, especially methyl-bis (-chloroethyl) amine ("Dema"), 0.1 mg. per Kg., in courses of one to 7 daily injections. Experimentally, they lead to rapid dissolution of transplanted lymphosarcoma of mice, but the dose borders on the toxic and the tumors return. Hodgkin's disease responds with remission of the same kind and degree as with x-ray therapy, rapid alleviation of symptoms and of the lymphadenopathy. The administration must be repeated in one to eight months. The results are less favorable in lymphosarcoma, and disappointing in lymphogenous and myelogenous leukemias. The dosage must be limited to avoid hematopoietic damage. The margin of safety is small, but *untoward symptoms* are generally less severe than with irradiation. At present the superiority over this is questionable, but it is hoped that better results may be secured by more favorable derivatives (Gilman and Philips, 1946).

The systemic toxic symptoms begin in a few hours with nausea and vomiting. Diarrhea starts within a day and becomes severe. Vomitus and stools may show blood. Loss of fluid and electrolytes by these actions results in marked anhydremia, with decrease of intracellular water and potassium, ending in prostration and fatal shock. With smaller doses the changes set in later, the intestinal symptoms in one or two days, the leukopenia in three to six days. Survivors recover completely (Graef *et al.*, 1946; L. S. Goodman, Wintrobe *et al.*, 1946; L. O. Jacobson, Spurr *et al.*, 1946).

Acute effects are seen only with supralethal doses. Central nervous excitation leads to convulsions and acute death; the parasympathetic stimulation, to salivation and miosis, followed by parasympathetic paralysis. *Subconvulsive doses* of nitrogen mustards produce progressive muscular paralysis, finally including the respiratory muscles and producing death (Gilman and Philips, 1946).

Historical.—Dichlordiethylsulfide and its toxic effects were discovered by Victor Meyer in 1886 (Ber. deut. chem. Gesell., v. 19, p. 3259; v. 20, p. 1729). Its military use as a war gas was apparently first suggested by J S. Haldane in 1915, but the Allies turned it down as not being sufficiently fatal (J. B. S. Haldane, 1938). It was first used on a large scale by the Germans at Ypres, July 12 and 13, 1917, and scored heavily, since its peculiar properties were not at once appreciated. It differs from the other gases in two essential respects: (1) its effects are delayed several hours, so that effective protection is apt to be neglected; and (2) it is very persistent, so that areas that have been shelled with it are infective for several days. This persistence is due to the limited volatility of the liquid at ordinary temperatures. When atomized by the explosion of the shell, it spreads as a mist, which condenses as a liquid film on any solid substance, leaves, cannon, the ground, etc.; and thus forms deposits that are dangerous both by direct contact, and because their slow evaporation keeps up a prolonged saturation in the air with the poison. This holds especially for valleys, trenches, etc., where the air is stagnant. *Nitrogen mustards* were developed during the second World War, but were not used.

Other Skin Irritants.—Hanzlik *et al.*, 1919, give a survey of the results from a large number of substances.

Physical Properties.—Dichlordiethylsulfide is a colorless or pale yellow, heavy, oily liquid of neutral reaction. When pure, it has a faint but penetrating odor, reminiscent of stale ether. The odor of the crude product is more pronounced and similar to that of garlic. It is due mainly to contamination with ethyl sulfide. This is the source of its popular name, "Mustard Gas," for it is not derived from true mustard oil. Toxic concentrations of mustard gas can generally be smelled in the air. *Nitrogen mustards* are liquid, or solid of low melting point; odorless or of a slight fishy odor. They hydrolyze fairly rapidly, forming toxic products.

Solubility.—Dichlorethylsulfide is soluble in fats, fat solvents and alcohol, but is only slightly soluble in water. Its solubility increases with the temperature, but it is rapidly hydrolyzed.

The cause of the delayed action of dichlordiethylsulfide has been attributed to gradual hydrolysis. This could scarcely explain the delay of over a day. More likely it is merely the expression of the sluggish character of the inflammation.

Destruction of mustard gas may be accomplished by chlorination or dechlorination; or less efficiently by other chemical changes. Free chlorine, as gas or dissolved in carbon tetrachloride, introduces a third chlorine atom into the dichlorethylsulfide, forming "monochloro-mustard gas," which is nonirritating. Sulfur dichloride, pure or dissolved in carbon tetrachloride, is also highly effective, and is used to "kill" the gas. It is, however, corrosive to organic matter. BAL does *not* detoxicate the mustard.

The development of symptoms under field conditions without protection is usually in the following order: No effects are felt *immediately* on exposure, except in high concentrations, when there may be tendency to sneeze, with or without smarting of the eyes. Hemorrhage, especially from the nose, is a common early symptom (Berghoff, 1919). The first definite symptoms are generally from the eye, starting *two or three hours after exposure,* with smarting and watering, proceeding to reddening, pain, edema and all the phenomena of acute conjunctivitis. The nose also reacts early with increased secretion and sneezing. The throat likewise becomes sore. *In four to sixteen hours after exposure,* these symptoms have become much more marked and distressing. The eyes are discharging and very painful; the nasal discharge is more purulent; the voice is husky or suppressed. Nausea, retching and vomiting, associated with epigastric pains, occur in a large proportion of cases and may recur at frequent intervals for several hours. In severe cases, they may become intense and prolonged. Diarrhea may set in, but is rather exceptional. Skin rashes also show in this period, as a dusky erythema of the exposed parts of the body, and in the axilla, crotch and genitals. *At the end of twenty-four hours,* the eye symptoms have assumed a characteristic form in the severer cases. They are very painful, with the lids swollen almost shut, and oozing tears. There are photophobia and blepharospasm, and generally frontal headache. The exposed skin is further reddened and swollen and may be itching. The nose discharges freely. The throat feels raw and burning. Aphonia may be complete. A dry harsh cough may develop. The respiration is fairly normal. Death practically never occurs during the first day. *During the second day,* the skin erythema may have developed into blisters, sometimes of large size, with the scrotum and penis especially painfully swollen. (The future course of the skin lesions will be discussed later). The eyes become somewhat less painful, although the acute inflammation may persist for several days. This is also the time when the inflammation of the respiratory tract becomes conspicuous in severe cases. The expectoration becomes abundant, mucopurulent, sometimes with large sloughs of tracheal mucosa. This is complicated by secondary infection of the necrotic respiratory membranes. Fever sets in, with rapid pulse and respiration. The infection may terminate in bronchopneumonia, with death anywhere between the second day to the fourth week. Most cases are of a milder type; especially as troops acquire familiarity with the gas and apply the protective measures more stringently. In the opening of the 1918 campaign, the mustard mortality was slight. There were few actual blisters, although minor rashes were common. The conjunctivites were less severe; the laryngites fairly mild, but almost universal. Most mustard field cases have only slight respiratory catarrh. Only about 10 per cent are burns (Underhill, 1918). During the hot months, there is an increase of the pulmonary lesions, perhaps because of the greater volatilization.

The toxicity for animals is fairly uniform, with less variation for species than there is for individuals (Lynch, Smith and Marshall, 1918; Reed, 1918, 1920). Air saturated with dichlorethylsulfide at ordinary temperatures would hold about 0.5 mg. per liter. This would be fatal if breathed for seven minutes. Concentrations of 0.01 to 0.02 mg. per liter have a 50 per cent mortality with a two-hour exposure, and 60 per cent with four hours. Less than 0.01 mg. per liter (1:700,000 by volume) is not fatal even with eight hours' exposure, but produces slight symptoms from the mucosae (conjunctiva, nose), and loss of appetite.

Lesions in Upper Respiratory Tract.—The corrosive effects on the epithelium are identical with the corrosion of other epithelial surfaces. Their intensity diminishes from the mouth and nose toward the lungs. The bronchi are involved only in the severest cases. Subepithelial edema is much less than in the skin or conjunctiva. The primary action is followed by local catarrh or diphtheritic lesions from the nose to the bronchi, even in the mildest cases. In the more severe, there is a marked pseudomembrane formation, secondary purulent bronchitis and bronchopneumonia (Warthin and Weller, 1919). The rhinitis, laryngitis, tracheitis and bronchitis play a conspicuous part in the minor as well as in the severe intoxication of mustard gas. The *alveoli* are but little affected directly, presumably because most of the substance is bound and absorbed before it can reach them. Consequently there is no acute pulmonary edema, in the early stages, and no fluid or froth in the air tube; although there may be considerable congestion and some epithelial desquamation. The serious cases become infected by bacteria, and then change to an intensive bronchopneumonia, with its ordinary phenomena, which may bring about a secondary edema. In case of *recovery,* the ulcers of the mucosae heal slowly. Ulceration of the trachea may be followed by constriction of its lumen.

Eye Lesions from Mustard Gas.—The cornea and conjunctiva are highly sensitive to the "mustard" irritation, and present the earliest and often the most serious symptoms after unprotected exposure to the vapor. Identical effects are produced by contact with the liquid poison. A previous eye burn increases the susceptibility. Light cases may heal in two or three days. In severe poisoning the inflammation is intensely painful for several days, and ocular symptoms may persist for several weeks. The deeper structures of the eye are not affected, except under extreme conditions. Nearly all cases recover without permanent injury, except at most some reduction of vision from cicatrization of the cornea. Severe eye injuries resulted in only about 1½ per cent of the gassed (Tenlieres, 1918). The course and pathology of the lesions have been studied in detail on rabbits (Warthin and Weller, 1918). The effective concentrations for man are reported by Reed, 1920; for animals, by Marshall *et al.*, 1918.

Treatment of the Eye Lesions.—The conjunctiva should be kept clean by frequent irrigation with saturated boric acid, or with 1 per cent sodium bicarbonate, followed by a few drops of oil. Continuous mydriasis and exclusion of light are advised (S. A. White, 1938). Lightweight cold compresses of saturated boric solution should be applied continuously for twelve to twenty-four hours, or longer if needed, to relieve the pain and discomfort, reduce the congestion and protect the eyes against light. Pressure on the eyelids must be avoided. This treatment tends to prevent adhesion of the eyelids. If they do become glued together, they must be soaked in boric or bicarbonate solution until they can be opened without force.

If liquid "mustard" is splashed into the eyes, this should be washed at once with the 1 per cent dichloramine solution.

Skin burns differ from the course of ordinary toxic dermatites: in the length of the latent period and in the absence of pain until the ulceration stage has set in. Not only are mustard burns imperceptible when first received, but they remain painless until the blisters break, about the third or fourth day. This is not due to anesthesia. In the mild rashes, the skin edema causes intense itching about the same time.

The tedious and slow healing of the necrotic lesions is due to injury of their blood vessels. They generally become somewhat infected, but only superficially. There is little or no fever. The lymph nodes are swollen and painful quite early.

Dichlorethylsulfide penetrates the skin very rapidly. The effects of the liquid or vapor are identical, differing only in extent and intensity, vapor burns being usually more extensive but less severe. The susceptibility varies considerably in different individuals, and is also influenced by temporary conditions. The burns range in intensity from simple rubefaction, through edema, vesication and necrosis. Although severe, the inflammation remains confined to the skin, perhaps because the circulation prevents its accumulation in the deeper structures (Warthin and Weller, 1918; Marshall, Smith and Lynch, 1918; Sollmann, 1919.)

Course.—The inflammation has a rather striking course. There is a latent period of a half hour to two days, before any inflammation can be seen or felt. The inflammation gradually increases, then remains stationary, and slowly heals. The duration of these stages depends on the severity of the exposure. Light burns appear late and heal early; severe lesions appear early and heal late

Skin Rashes.—Erythema occurs as the first stage of all "mustard" lesions. Vapor burns and dilute solutions (*f. i.*, saturated watery solution) do not usually progress beyond this stage. Practically everyone who works with or around mustard gas is liable to the frequent occurrence of these rashes, which are probably the most common form of "burns" in the field. Rashes also commonly surround the blister burns for considerable distance, but the excess of the dichlorethylsulfide evaporates from the cloth, and the vapor spreads. The axilla and groins are especially affected. Severe grades may develop minute miliary blisters. These may give the skin the appearance and feel of pebbled oilcloth. The edema is confined to the epidermis and papillary layer. The inflammatory phenomena persist for several days, and then gradually subside, within a week or two, leaving generally some pigmentation, and hypersusceptibility to irritation.

Pigmentation may take various forms. It may have the red appearance of weather exposure, or be more or less "tanned" as by the sun. In severe burns, the pigmentation is sometimes almost black, but confined to the superficial desquamating epidermis.

Erythema Preliminary to Vesication.—Erythema also constitutes the first stage of the blister burns. In that case it appears much earlier, is more sharply localized, and undergoes vesication after one or two days.

Prognostic Significance.—The time when the erythema first becomes noticeable is of prognostic value: If the skin shows pink or livid spots within one and one-half hours after exposure, the burn will develop into a deep blister, and probably undergo ulceration and scarring. If the pink spots start between two and three hours after exposure, the blisters will be superficial and will probably heal without ulceration, and without real scarring. If the rash is delayed for twelve to forty-eight hours, it will not develop into blisters.

Blister Burns.—When strong vapor or especially when liquid dichlorethylsulfide comes in contact with the skin, the erythema passes into vesication. The first noticeable change is a silvery appearance of the skin, produced by loosening of the epidermis. This is then raised by the accumulation of fluid; the blister is usually well developed in twelve hours, and reaches its maximum size in about twenty-four hours. The blisters at first are very tense, often an inch or more high, and may be up to 3 or 4 inches in diameter. They are filled with a transparent gelatinous material, *i. e.*, practically coagulated plasma. If they are opened at this time, the contents stand up like a jelly, and require to be pushed or scooped away.

Between the second and third days the serum begins to separate from the clot. The "skin" of the blister becomes thin and wrinkles as the serum is absorbed, and opaque balls or shreds of the fibrin are seen within the blister. Generally the blister breaks, and the serum, as it separates, drips in a continuous slow stream from the wound. This gives the patient a distressing and uncomfortable appearance, especially if the genitalia are involved. In fact, however, the process is painless up to this time. If the blister is undisturbed, it may be a week before it is fully collapsed.

About three days after exposure, the blister begins to become painful, especially on exposure to air, on mechanical contact, or when treated with chemicals. This sensitiveness increases rapidly to the fifth or sixth day, and the pain becomes severe. This hypersensitiveness lasts for two or three weeks, or even longer if ulceration develops. However, the lesions become painless long before the ulcers are healed.

The size of the blisters is not an indication of the severity of the lesions: the largest blisters may be healed in two or three weeks, while another smaller blister, nearby, goes through a tedious ulceration that is healed only by scarring after six or eight weeks. The severest lesions (the gangrenous form) do not blister at all. The process apparently involves the corium more or less, although it does not often destroy the epithelium so deeply that it can not re-cover the wound. Statements that it "corrodes to the bone" have no foundation.

This condition of the wound remains practically stationary for two to four weeks. Then further necrosis ceases quite noticeably, about the same time that the hypersensitiveness diminishes. A pale pink ring of epithelium starts from the periphery to cover the wound, which meanwhile may form exuberant granulations. Toward the end of the fifth or sixth week, practically all wounds are essentially healed, with or without cicatrization. The new skin over the burned areas appears shiny and often pigmented, as in x-ray burns.

Burns of the genitalia differ somewhat from the type. When the scrotum is involved, the testicles become sensitive. The condition clears about the same time as the skin lesions. Blisters of the penis may come on quite slowly, and turn into tedious ulcers, which heal much more slowly than other lesions. Infection of the meatus may cause a urethral discharge.

The most severe burns (the gangrenous type) differ from the blister type from the start. Smarting and burning are felt within an hour after receiving the burn. The skin at that time is intensely blanched. By the next day, the burn proper is of a livid, cadaveric color. It does not vesicate, but forms a depression, surrounded by a continuous ring of blister. After a week or so it breaks down into an ulcer, and the entire thickness of the skin may be removed in a mass. The wound remains painful for three or four weeks. Healing occurs after five to seven weeks by cicatrization.

Systemic Reactions of Mustard Burns.—Dichlorethylsulfide applied to the skin does not reach the circulation in sufficient amount to produce systemic lesions; nor are the mustard burns, even when extensive and deep, accompanied by the acute toxic phenomena of fire burns. The temperature remains practically normal. Extensive burns may produce temporary collapse, mainly if not entirely of psychic origin. Later on, the pain is likely to interfere with sleep. The urine should be watched.

Secondary Furunculosis.—Mustard burns lower the resistance of the skin to infection. The blisters are usually followed by a crop of furuncles or pustules, generally on and around the burned area. Men who work with mustard commonly have this complaint even when they have had only superficial rashes.

Increased Susceptibility of the Skin.—Healed mustard burns are hypersusceptible to the poison, and also to mechanical injury. A light contusion may result in a blister. This hypersensitivity is confined to the burned areas and does not extend to the remainder of the skin.

Microscopic changes in mustard burns have been described in detail by Warthin and Weller. The epithelium shows hydropic and other degenerative and necrotic changes within two hours. The edema in the early stages is confined to the epidermis and papillary layer, and does not extend much more deeply. In severe burns, the vessels in the affected area are greatly damaged and collapsed. This results in local anemia in the earlier stages, with marked exudation and leukocyte migration.

Skin Lesions in Animals.—Blistering does not usually occur in the customary experimental animals, including monkeys. Otherwise the lesions are essentially the same as in man (Marshall and Williams, 1918). Horses are said to be about five times more sensitive to vesicants than is man. Ducks respond with large blisters to mustard gas and to lewisite (L. Goldman *et al.*, 1944).

Susceptibility to Skin Burns.—A visible reaction requires, in a "tolerant" individual, a concentration more than a hundred times greater than will produce results in a hypersensitive. Negroes are notably tolerant. The tolerance for a given person does not change greatly with time, if other conditions are uniform. It is also fairly alike for the skin of the entire body, with the exception of a few special regions. The axilla and crotch are hypersusceptible (largely because of their moisture), but the thick-skin palmar surface of the hand and fingers is relatively insusceptible. The area of a previous burn is hypersusceptible; but hypersusceptibility appears not to be especially frequent among those who have worked constantly with "mustard" and have received severe and extensive burns (Sollmann, 1919).

Moisture of the skin and perspiration definitely increase the susceptibility. The presence of moisture also increases the susceptibility to other irritants that are more soluble in oil than in water, *f. i.*, phenol or true mustard oil. In all these cases, the insolubility in water would favor the penetration into the more solvent skin. Marshall, Lynch and Smith, 1918, explain susceptibility along similar lines.

"Nitrogen Mustards" are somewhat less persistent than mustard gas, have about a fifth its potency, but are somewhat more rapid in action. The blisters heal in two to four weeks. All exposed tissues are killed. The eyes are especially sensitive. The inflammation may extend below Bowman's membrane and result in permanent blindness. The effects on the upper respiratory tract are similar to those of mustard gas, but there may be absorption from the lungs, and systemic effects: abrupt decrease of lymphocytes, agranulocytosis, necrosis of lymphoid tissue, destruction of the bone marrow, hemorrhagic lesions in the basal ganglia, miosis, flaccid paralysis of skeletal muscles, especially of the head and neck. The *treatment* is as for mustard gas.

Anticarcinogenetic Action.—It was feared that mustard gas burns of the skin would be followed by the development of carcinoma. This has not been so. To the contrary, the local application of 0.5 per cent in acetone checks the development of mouse and rat carcinoma and the tumors become necrotic (Berenblum, 1929, 1931; Visser and Vos, 1935).

Direct gastro-intestinal lesions occur by ingestion of the substance with the food or saliva. Animals that survive several days after being "gassed" in chambers generally have acute gastro-intestinal catarrh. The lesions are similar to those produced by local contact in other locations: superficial necrosis, followed by ulceration of the mucosa (Warthin and Weller, 1919). The gastro-intestinal symptoms in man are probably chiefly reflex, from respiratory irritation and shock.

The *kidneys* do not show direct changes, even with intravenous injection. Secondary involvement (cloudy swelling and hyaline casts) may occur during infection or extensive necrosis in severe local lesions. (Warthin and Weller, 1919). Such cases have diminished urine output, increased concentration, diminished urea and chloride. The condition improves on forced liquid regimen. Mild skin burns show no changes in the urine or blood (Hermann, 1918).

Fate.—The urine contains products of hydrolysis, probably dihydroxyethylsulfide, with all methods of administration. This is not irritant (Lynch *et al.*).

Destruction of Mustard Gas.—Dry hypochlorites chlorinate and destroy the substance readily, with evolution of heat "Bleaching powder" is useful as a "kill." Chloramine and dichloramine also react vigorously with "mustard." With these, the reaction appears to be more complicated, but the irritative qualities are destroyed. All chlorinating agents must be applied as concentrated and especially as dry as possible; else the immiscibility of "mustard" with water prevents intimate access of the chemicals.

Protection of the Skin against Mustard Gas.—The limited success of treatment makes prophylaxis especially important. The poison, like other fat-soluble irritants, is more injurious when the skin is moist; while oiling of the skin confers a certain degree of protection. Unfortunately, this protection is quite limited. It may be fairly complete for short exposure to low concentrations; with high concentrations it at least increases the efficiency of removal treatment. For long exposures, however, there is practically no protection by oils. Extensive experiments with different oils, ointments and admixtures revealed quantitative differences; but they are not sufficiently great to affect the practical results materially (Sollmann, 1919).

Removal of Mustard Gas from the Skin.—When the dichlorethylsulfide has penetrated the cells of the skin, the damage has been done, and treatment is only palliative. It is therefore imperative to remove the poison as completely as possible before it has penetrated and combined. The penetration is rapid and the fixation within the skin is almost as rapid, so that the efficiency of removal treatment is limited within five minutes, and almost nil after ten to twenty minutes. This, combined with the fact that most burns are not noticed until several hours after they were received, emphasizes the desirability of protection against exposure and contact.

The first step in the treatment of a mustard burn is the removal of the contaminated clothing. The removal from the skin may be attempted by chemical means or by solvents. The solvents have given better results, presumably because of their better penetration. Any convenient solvent may be used with almost equal results: alcohol, acetone, gasoline, kerosene, turpentine, oils or grease, petrolatum and somewhat less efficiently, soap. For practical reasons, chiefly economical, kerosene is generally preferred. The solvent treatment is materially more efficient if it is combined with rubbing, because this presses some of the poison out of the gland ducts.

Chemical Removal.—Chlorinated lime and the chloramines neutralize the poison if they are applied immediately; but they fail to reach any that has penetrated. This renders them inferior to the kerosene treatment. They would be useless five or ten minutes after exposure.

Treatment of Mustard Burns.—The various treatments that have been proposed involve mainly three principles:

1. *Attempts at chemical destruction of the poison within the skin* have been uniformly unsuccessful, since the poison is rapidly fixed within the cells and is out of reach of most, if not all, of the chemical antidotes.

2. *Protective measures* at least add considerably to the comfort of the patient, and may indirectly hasten healing somewhat. It is doubtful whether the natural course and healing of the burns can be materially influenced for the better by any treatment so far tried; but it can be materially influenced for the worse by irritation. Protective measures eliminate this additional injury. The patient should be removed from all chances of exposure to the poison, even to the dilute vapor, or other irritant vapors, until the burns are healed. Irritant dressings must be avoided.

3. *Antiseptics.*—The extensive raw surface, the lowered vitality and the presence of necrotic tissue in the blistered burns offer opportunity for infections; but the infection remains superficial and is easily kept in bounds by ordinary cleanliness. Most burns probably heal about the same whether antiseptics are used or not, but these should be given the benefit of the doubt. Antiseptics of the chlorine group have been found most serviceable, and should be used whenever possible (Warthin *et al.*, 1918). They are especially useful toward the end of the necrotic stage. Perhaps their benefit here may be referred partly to the solution of the necrotic tissue.

The comparison of different methods of treating the burns is not easy, partly because it is difficult to judge the severity of a burn and its presumptive course, especially if it was not followed through all its stages. Several adjacent blisters that look practically alike at the height of vesication may really be of a different depth; one may heal smoothly within two weeks, the other may undergo necrosis and require four weeks. Another source of error is the rather abrupt turning point when spontaneous improvement sets in. A necrotic surface that has been practically stationary for a week or more, starts to improve overnight, almost visibly. If treatment has been instituted within a few days of this turning point, it would naturally, but erroneously, receive the credit (Sollmann, 1919).

Treatment of Gastric Symptoms.—Nausea and vomiting are seen in a proportion of the intoxications by inhalation. Recovery generally follows without other treatment than a light diet. Occasionally the vomiting is very severe and prolonged. Such cases should be treated with alkalis, bismuth and milk diet, essentially like gastric ulcer.

There seems to be a general *lowering of resistance* after mustard gas poisoning, and therefore increased susceptibility to infections; influenza, bronchitis, pneumonia and tuberculosis (Warthin and Weller, 1919).

PHOTODYNAMIC ACTIONS

These interlock mutually with pharmacodynamic actions, since some chemical substances sensitize to actinic or ultraviolet light, especially through fluorescence, or light sensitizes toward these substances. Ultraviolet light also produces D vitamins from the cholesterol of the skin, and thereby acts on the calcium and phosphate metabolism. This effect is discussed under "Vitamin D" (see Index).

Dermal irritation begins to appear a few hours after exposure to the ordinary doses of actinic rays. It consists in hyperemia, followed by pigmentation, almost exclusively in the basal cells. These are stimulated to increased activity and quickened metabolism (review, H. Laurens, 1938). The amount of pigment formation is directly proportional to the preceding erythema in a given individual, but not in different patients (Rogin and Sheard, 1934). The erythemal sensitivity of the untanned skin differs not only for different persons, but for the same individual at different times. Erythema occurs in summer with one-half to two-thirds of the exposure required in winter, due probably to different moisture of the skin (review, W. W Coblentz, 1932). The sensitivity is increased by acid-producing food and diminished by alkali (Kittel and Stahl, 1933). The outer horny layer of the skin protects the true skin against ultraviolet rays by reflecting or absorbing them in great part, transmitting chiefly the other light rays (Laurens, 1936). Exposure of the *eyes* to ultraviolet radiation ordinarily causes conjunctivitis and blepharitis, but if excessive, the damage may progress to corneal erosion and, if long continued, to scotoma (Laurens, 1938).

Therapeutic Uses.—The stimulation and hyperemia of the skin by ultraviolet irradiation are utilized in dermatology, especially against psoriasis, superficially situated bacterial infection, sluggish ulcers and lupus vulgaris. Skin tumors have been produced in rats and mice by prolonged exposure, but far beyond the amount used therapeutically (Luce and Clausen, 1938, review).

Protection against ultraviolet radiation and sunburn has been investigated by Luckiesh *et al.*, 1946. They found dark red petrolatum the most effective agent for excluding the ultraviolet rays of natural sunlight which are chiefly responsible for the erythema. Addition of 10 per cent of phenyl salicylate would render this even more effective, and is harmless. Of insoluble powders, titanium dioxide gives the best protection; calamine is fairly efficient.

Distant Effects.—Zedda, 1933, reported that ultraviolet irradiation increases the *urine flow* and sodium chloride output, sometimes to three times the normal control period. It has also been reported that it raises the platelet count in idiopathic hemorrhagic *purpura.*

Bacteria may be killed or attenuated, but their susceptibility varies. Actinic rays are effective only through thin layers. Good results are reported for droplet disinfection of operating rooms (D. Hart, 1937). *Ferments* may be stimulated, inhibited or destroyed.

Photodynamic Sensitization.—Living cells may be sensitized by certain chemical substances so that they react to the luminous rays of the spectrum as to the ultraviolet. Most sensitizers are fluorescent, but sensitization is not due to fluorescence as such. Photodynamic effects require the presence of oxygen, which is not necessary for direct ultraviolet reactions (review, F. H. Blum, 1945). The photodynamic sensitizers include erythrosin, rose bengal, rhodamin, anthracene, acridine dyes, methylene blue, quinine, chlorophyll, hypericin, buckwheat, porphyrins (Laurens, 1938; F. P. Mathews, 1937). Photodynamic dyes also sensitize to heat (A. C. Giese and Crossman, 1946). Porphyrin sensitizations have clinical significance (see Index).

Paramecia are not harmed by the acridine 1:20,000 if kept in the dark, but die in an hour in diffuse daylight, and in six minutes if exposed to direct sunlight.

Frog's sartorius muscle suspended in Tyrode solution contracts when exposed to ultraviolet light; after a few minutes this is followed by relaxation and finally by rigor. The effects require the presence of calcium (Azuma, 1927). The contraction occurs in ordinary light if the muscle has been immersed for two hours in 0.004 per cent of hematoporphyrin, or in eosin or rose bengal (Lippay, 1927).

Perfused turtle heart is arrested by hematoporphyrin if exposed to light. This is not due to the formation of a toxic substance, for a second heart perfused in the dark with the perfusate of the first heart is not affected (Rask and Howell, 1928). The effect of porphyrins on *excised intestines* was investigated by Reitlinger and Klee, 1928.

◆

STOMACHICS

This term is applied to remedies intended to improve the functions of the stomach: either to increase appetite, especially by bitters and condiments, or to decrease gastric distress of various kinds, chiefly by carminatives. These also secure the expulsion of gas from the alimentary canal. *Simple bitters* generally contain some "*bitter principle*"—neutral substances, often crystalline, non-nitrogenous, sometimes glucosidal, and without pronounced systemic actions. In *aromatic bitters* these are mixed with volatile oils. The *astringent bitters* contain tannin. *Condiments,* which also contain aromatic oils or other sharp principles, form the transition to *carminatives.* Bitter, aromatic and "*sharp*" drugs have been used since antiquity as "tonics," and in functional dyspepsias. About a tenth of the medicines mentioned by Hippocrates belong to this class, and they have played a prominent role in folk medicine.

CARMINATIVES

These are aromatic and pungent drugs, used in flatulence and colic, to expel gas from the stomach and intestines, and to diminish the "griping" pains. Given by mouth or by enema, according to the situation of the gas, they may be promptly effective; in other cases they fail. They have a "warm" taste, and exert a mild irritant action on the digestive tract. The most useful carminatives are mints, fennel and anise; ginger; and capsicum.

Gastric Motility.—In normal human subjects peppermint oil or spirit temporarily inhibits the *hunger contractions*, but inhibition is followed by stimulation and regularization of the peristalsis, with slow and deep waves (Todd, 1930). The emptying time after meals is materially shortened, especially after fats (Sapoznik *et al.*, 1935). The acid secretion of the stomach in response to alcohol and histamine and in gastric ulcer is decreased by peppermint (J. Meyer *et al.*, 1935).

In unanesthetized trained dogs, carminatives relax the gastric tonus for five to thirty minutes, while the tonus and peristalsis of the intestines and colon are increased (Plant and Miller, 1926). With laparotomized animals the movements may be either increased or decreased (Gunn). The excised stomach is also relaxed. Relaxation of the cardial sphincter may be an important factor in the relief of gastric flatulence. "*Heartburn*" and retrosternal pain is associated with continuous stretching of the lower esophagus. It is overcome by the passage of peristaltic waves over this region, and may become more intense during the relaxation that follows the contraction wave (Payne and Poulton, 1928). The pain of gastric and duodenal ulcer is due partly to direct irritation of the denuded nerves, but largely to pyloric or duodenal contractions which may be excessively strong, or act on hyperexcitable pain endings.

Intestinal Motility.—Dilute suspensions or saline solutions of the carminative oils increase the tonus, rhythm and peristalsis if they are injected into the intestines of unanesthetized dogs, by a long Thiry-Vella loop. This would result in the propulsion of any gas. Occasionally the stimulation is followed by decrease of movement, which may be helpful in relaxing spasms, and explains the clinical use of carminatives to diminish the griping of irritant cathartics.

The carminative stimulation is abolished by cocainization, so that it is perhaps a sensory reflex (Plant, 1920). Excised intestines and those of laparotomized animals are relaxed (Gunn, 1921).

The antiseptic action of aromatic oils may be useful in gastric dilatation and intestinal putrefaction. The effects of peppermint, fennel and chamomile on the course of *inflammations* have been studied by W. Arnold, 1927.

Menthol and Peppermint Oil on Bronchial Foam.—McGuigan, 1921, found that these diminish the foaming of blood, saponin, etc., and suggests that their mechanism in catarrhs consists in breaking down foam in the air passages, and thus enlarging the effective lumen. However, the mucus of catarrh is not always foamy, especially not in rhinitis or pharyngitis, in which menthol gives most relief. The benefits are probably due to detachment of adherent mucus by the fresh secretion which follows the counterirritation.

PREPARATIONS.—***Peppermint Spirit,** U.S.P. (Spt. Menthae Piperitae; Peppermint Essence), is a 10 per cent solution (in alcohol) of *Peppermint Oil*, the vol. oil distilled from the fresh overground parts of the flowering plant of *Mentha piperita*, macerated with 1 per cent of peppermint leaves. The dose of the spirit is 0.3 to 2 cc., 5 to 30 minims. Analogous preparations are made from *Spearmint*, U.S.P., Mentha Viridis (Mentha spicata). Spearmint Oil contains not less than 50 per cent of carvone. The dose of *Spearmint Water*, U.S.P. (Aq. Menthae Viridis), a sat. watery solution of the oil, is 15 cc., 4 drachms; the *dose of the oil* is 0.1 cc., 1½ minims, on sugar.

Fennel Water, U.S.P., a saturated watery solution of *Fennel Oil*, U.S.P., distilled from the dried ripe fruit of Foeniculum vulgare. The dose of Fennel Water is 15 cc., 4 drachms.

Ginger, U.S.P. (Zingiber), is the dried rhizome, with outer cortical layer removed, of Zingiber officinale (*Jamaica Ginger*). Dose, 0.3 to 1 Gm., 5 to 15 grains, as powder or *Fluidextract*.—*Asarum* (Wild Ginger), *Galanga* and *Zedoaria* are similar to ginger.

BITTER STOMACHICS

Bitter substances when taken in moderate amount shortly before eating may improve deficient appetite, and the flow and quality (acidity) of the gastric juice, in conditions of poor health (anemia); although they have no effect on normal individuals (Carlson and coworkers, 1914 and 1915). The *mechanism of the action* of the "bitters" has not been demonstrated. It is conceivable that they act as a "chemical dinner bell," setting up a "conditioned reflex" of appetite. The aromatics and condiments probably act by mild direct irritation of the gastric mucosa, the beneficial effects being due to the hyperemia and motor stimulation.

Effect in Experimental Cachexia.—In dogs provided with a Pavlov gastric pouch, and rendered cachectic by repeated large hemorrhages, Moorhead, 1915, found that the administration of bitters improved the appetite and the gastric deficiency, although not quite to normal. The animals consumed more food and the gastric juice became more abundant and more acid. The increase of appetite occurred whether the bitters were given by mouth or by stomach; the increase of secretion was confined to oral use. The improvement occurred with the first administration, so that it was not due to the establishment of a habit. Possibly the bitter taste enhances the taste of foods, by contrast.

Experiments on Normal Individuals.—Ivancevic and Kadruka, 1938, report from roentgenologic observations on man that gentian causes swelling of the gastric mucosa and increased secretion, similar to normal digestive hyperemia. The effects are maximal in twenty to thirty-five minutes. Carlson and co-workers, 1914 and

1915, could find no beneficial effects in normal men or dogs. Therapeutic doses of bitters, however given, had no immediate or delayed effect on gastric secretion. When taken by mouth (or large doses introduced directly into the stomach) they inhibit the normal hunger contractions and the sensations of hunger, just as do other irritant or disagreeable substances.

Gastric Secretion.—Carlson, 1915, tested the effects on a man with gastric fistula, and on dogs with Pavlov miniature stomachs. The bitters were placed in the mouth, or directly in the stomach, before, with, or without food, etc. However the experiments were varied, the results were uniformly negative. This disposes of the rather contradictory results of older investigators as to direct secretion and "psychic juice." The introduction of irritant substances into the mouth also fails to provoke gastric secretion in man (Carlson, 1915).

Absence of "Taste" in the Stomach.—Albertoni and Tullio, 1912, found on a human subject that the direct introduction, through a gastric fistula, of bitter or sweet substances or bouillon, produced only the same immediate sensation as saline; but bouillon, bread or alcohol provoked speedier secretion of acid and, taken with food, afforded a more satisfactory sensation.

Pancreatic secretion and bile flow are not increased by bitters. Intestinal juice is first diminished, then increased (Reichmann, 1888; Jodlbauer).

Effect on Absorption.—Bitters are claimed to hasten the absorption of sugar and peptone from the stomach (Brandl, 1893), but seem to delay it somewhat from the intestine (Rieder, 1910).

Sojourn of the Food in the Stomach.—According to Heubner, this is shortened by small, delayed by large, doses. W. E. Morse found that *tabasco sauce* does not modify the discharge of water from the stomach.

Effect on Digestive Ferments.—Most of the bitters have no effect on digestion *in vitro*.

Antiseptic Action.—Bitters and aromatics are antiseptic and may influence digestion favorably by limiting putrefaction and abnormal fermentation.

Leukocytosis.—Bitters and aromatics *increase the leukocytes* of the blood (Hirt, 1856; Binz, 1875; Pohl, 1888). It has been claimed that these play a role in intestinal absorption (Hofmeister, 1887).

Therapeutic Uses of Stomachics.—These are employed: (1) To increase appetite, from whatever cause this be deficient. (2) To improve digestion in all kinds of "atonic" dyspepsias, with motor or secretory deficiency. They tend to remove the anorexia, oppression, constipation and hypochondria. The astringent bitters may be more useful in subacute or chronic gastritis, otherwise they are rather objectionable. Tannic acid must be especially avoided when the bitter is to be prescribed with iron, since this makes an unsightly mixture. The simple bitters and the majority of the aromatic bitters are tannin-free. (3) As tonics in anemia, convalescence, phthisis, to hasten reconstruction. (4) As antemetics. (5) To modify or improve the taste of food or medicines; and to obscure any "bad taste in the mouth."

Administration.—Stomachics should be taken within a half an hour, preferably five or ten minutes, before meals. They are generally more pleasant, and therefore more effective, if they are judiciously blended, as in the aromatic and compound bitters such as Compound Tincture of Gentian or of Cardamom. Overdoses produce nausea and so defeat their object. Since the effects of bitters involve the taste, it is probably useless to administer them in the form of pills and tablets, although this is often done.

SIMPLE BITTERS

These are practically free from aromatic oils or tannin, and can therefore be mixed with water. The tinctures are strongly alcoholic. Gentian is perhaps the most agreeable of the simple bitters. The Compound Tincture of Gentian is an aromatic bitter. Strychnine and quinine are often used in small doses for their bitter effect.

Gentian, U.S.P., the dried rhizome and roots of Gentiana lutea, is one of the most useful simple bitters. It is mentioned by Pliny. The bitter principles are glucosides Tannin is present in small amount—not astringent, but incompatible with iron. It is generally prescribed as the ***Compound Tincture of Gentian**, containing 10 per cent of gentian, aromatized with bitter orange and cardamom, in 45 per cent alcohol. Dose, 4 cc., 1 drachm. *Quassia*, the wood of Picrasma excelsa, or of Quassia amara, has an intense and disagreeable bitter taste. Dose, 0.1 to 0.5 Gm., as infusion or *Tincture*, 10 per cent. A 1 to 5 per cent infusion is used by enema (to ½ pint, retained as long as possible) against oxyuris. It is a rather ineffective insecticide (McIndoo and Sievers, 1917). The systemic effects of quassin have been studied by Antonibon, 1927.

Other Simple Bitters include: *Berberis*, the dried rhizome and roots of species of the section of Mahonia of the genus Berberis (pharmacology studied by Hilderbrandt, 1907); *Calumba* (Colombo), the dried root of Jateorrhiza palmata (pharmacology studied by Biberfeld, 1909); *Xanthoxylum*, the dried bark of Xanthoxylum americanum, or of X. Clava-Herculis; and *Pareira*, the root of a Chondodendron species. Commercial "Bebeerine sulfate cryst." is isobebeerine, obtained from Pareira. It is isomeric with codeine, and like this has narcotic actions (Scholtz and Koch, 1915). *Taraxacum* (Dandelion) consists of the dried rhizome and roots. Its composition was investigated by Power and Browning, 1912. The extract was reported to stimulate the bile flow in rats (Bussemaker, 1936).

ASTRINGENT BITTERS

With these, tannic acid is a prominent ingredient, whilst volatile oils are present only in small quantity, if at all. The preparations can be mixed with water.

Cimicifuga (Black Cohosh, Black Snakeroot, Macrotys), the dried rhizome and roots of Cimicifuga racemosa. Dose, 1 Gm., 15 grains. The constituents were investigated by Finnemore, 1910. It contains a resin, cimicifugin or macrotin. It has been employed as stomachic, against chorea, and as "uterine tonic." Extensive pharmacologic study failed to reveal any distinctive effects, except some depression of excised intestine and uterus, probably by the volatile oil (D. I. Macht and Cook, 1932)—*Condurango,* the dried bark of Marsdenia Cundurango. Dose (of the fluidextract), 1 to 4 cc.—*Cusparia* (Angostura Bark), the dried bark of Cusparia febrifuga. Dose, 0.6 to 2.5 Gm.—*Serpentaria* (Virginia or Texas Snakeroot), the dried rhizome and roots of Aristolochia Serpentaria, or A. reticulata. Dose, 1 Gm.

AROMATIC BITTERS

These contain both aromatic oils and bitter principles, but no tannin. Their alcoholic preparations turn turbid when mixed with water.

Aromatic bitters include: *Bitter Orange Peel,* U.S.P. (Aurantii Amari Cortex), the dried rind of the unripe fruit of Citrus Aurantium; used as the *Tincture,* U.S.P. (20 per cent), and in Compound Tincture of Gentian. Grapefruit contains a bitter glucoside *narginin.* Oranges contain the practically tasteless glucoside *hesperidin.* Addition of 1 per cent of these to the diet of rats produces no effect of any kind (R. H. Wilson and de Eds, 1940). *German Chamomile,* the dried flower heads of Matricaria Chamomilla (used as infusion, internally as stomachic, carminative and diaphoretic; externally as counterirritant in contusions and other local inflammations. The antiphlogistic constituent of chamomile oil is a blue hydrocarbon, *azulon,* $C_{15}H_{18}$ [Heubner and Grabe, 1933]. Dose, 15 Gm., 4 drachms). *English or Roman Chamomile,* the dried flower heads of Anthemis nobilis; *Calamus* (Sweet Flag), the peeled dried rhizome of Acorus Calamus; and *Ginseng,* the dried root of Panax quinquefolium, highly valued by the Chinese. Korean ginseng contains a glucoside said to lower blood sugar in various hyperglycemias (Abe and Saito). Other species of Panax and Aralia are also aromatic bitters. Numerous other bitters are used in domestic medicine.

◆

CATHARTICS

Cathartics, purgatives or evacuants are drugs which induce defecation They may do so by increasing the bulk of the intestinal contents (petrolatum, agar, etc.), by preventing the absorption of water (salines), or by irritating the small or large intestine, as most of the vegetable cathartics. Their irritation is is relatively mild and is confined more specifically to the intestines, by selective action, or because the alkaline reaction or bile of the intestines favors their solution or decomposition. This solution should not be too rapid or the drugs will be largely absorbed or decomposed before reaching the lower intestine. The isolated principles are therefore less useful, and sometimes less effective than the galenic preparations in which they are masked as compounds or by the extractives of the drug

Liberation and Solution of the Cathartic Constituents.—Castor oil and croton oil become active only when their fatty acids are liberated; croton oil contains some free acid and is, therefore, pustulant also on the skin. The emodin cathartics often contain glucosidal compounds, which must be split before the action occurs. The "resins" are insoluble in water, but are decomposed and dissolved by alkalis and bile.

Influence of the Bile on Cathartics.—The *bile* seems to be necessary for the activation of many of the resinous cathartics, the following being relatively or quite ineffective in its absence: gamboge, podophyllum, convolvulin, jalap, and scammonium (Buchheim and Stadelmann). The bile acts presumably by increasing the solubility. Rhubarb, senna and calomel are active in the absence of bile (Valeri, 1910). Aloe seems to act quite well without bile in animal experiments; but clinically it has been claimed that it is ineffective in biliary obstruction.

Toxic Effects.—The vegetable cathartics are not corrosive. Even the drastic cathartics do not ordinarily produce inflammation, because they are expelled rapidly; but if their propulsion is prevented by obstruction, or slowed as by opiates, they may lead to enteritis, especially colitis, and to nephritis. The intestinal irritation may also become cumulatively harmful if the irritant cathartics are used habitually.

The *location of action* may determine the choice of the cathartic. The emodin cathartics (senna, etc.) act mainly on the colon. Castor oil stimulates peristalsis in the small intestine. Colocynth increases the movements of the small intestine and leads to intestinal effusion. Magnesium sulfate quickens the passage through the small intestine, and prevents the absorption of fluid and the concentration of the contents of the large intestine. Calomel increases peristalsis both in the small and large intestines.

The older investigations have only a limited value, because they generally involved operative procedures which are likely to render the intestinal movements abnormal or to arrest them altogether. Cannon's method of observing these movements in intact animals by means of the roentgen rays opened the way for more reliable observations. This method was first applied to pharmacologic problems especially by Magnus, 1902, and by his pupils. Their results have been confirmed in man (*f. i.*, Meyer-Betz and Gebhardt, 1912). Another fruitful method, which has been applied especially by Lenz, 1923, consists in replacing a part of the abdominal wall by a plate of transparent celluloid, which heals into the wound and serves as a window. This has been modified by Barcroft and Robinson, 1929, into "exteriorization" of the intestines. Thiry-Vella fistulas permit recording of observations by sounds (the optimal conditions are described by C. M. Gruber and Anthony, 1935) and by bolus-progression (Quigley and others). The phenomena in animals correspond in general to those in man (Alvarez, 1929).

The *defecation reflex* is started by the arrival of the mass in the rectum. It is greatly influenced, however, by the sensitiveness of the rectum and by the habits of the patient. It is here that the delay in constipation mainly occurs.

A tonic mechanism for the rectum is located in the midbrain, and the rectal stretch reflexes are lost after low section of the medulla (O. R. Langworthy and Rosenberg, 1939). Defecation usually involves a reflex through the spinal cord; but destruction of the lumbar and sacral cord results in diarrhea, lasting several days, followed by normal evacuation of the large intestine at the customary interval (Goltz and Ewald, 1896). The intra-intestinal mechanism can therefore control defecation, if necessary (Schüller, 1911). (Review of defecation reactions, Lehmann, 1912.)

The anthracene and resinous cathartics and the phenolphthaleins also increase peristalsis if they are injected *subcutaneously or intravenously;* the resin group is even more active by this channel. The action may even then be local, the constituents being excreted into the intestine by bile. The cathartics are not administered in this manner, in practice, since the injection would be painfully irritant; the effects are also more easily controlled when the drugs are given by mouth.

The *effectiveness of cathartics for animals* differs materially from that in man. The relations are discussed by Fuehner, 1925; as also the evaluation on mice. The response of dogs and cats is much more closely akin to the human than is that of rabbits. The small crustacean *Daphnia* has been proposed for the essay of cathartics; its suitability appears inherently doubtful; the technic is described by Tinsley, 1938.

Cathartics on Excised Intestines.—The effects are not related to those produced in life. For instance, the addition of aloin to the bath is inactive; cascara and castor oil inhibit the contractions; saponified croton oil stimulates (Meissner, 1916). Alvarez and Taylor, 1917, obtained more positive results by giving cathartics to living rabbits, then excising the intestines. The segments showed irregular irritability. The doses were so high, however, that the significance of the results is doubtful. The reactions of *inflamed intestines* are described by Tsurumaki, 1928.

Time of Action.—A cathartic which acts on the large intestine can not produce the effect until it reaches this place. Even then the response depends on the habits of the patient. These become less important with the more irritant cathartics. The usual time of response, for the more important cathartics, is as follows: *Salines*, one-half to one hour on empty stomach; two to four hours if in bed. *Castor oil*, one to two hours on empty stomach. *Jalap*, three hours or less. *Senna*, four to five hours. *Rhubarb* or *Phenolphthalein*, four to eight hours. *Cascara* or *Aloes*, eight to twelve hours. *Podophyllum*, ten to sixteen hours.

Colic or *"griping"* is proportional to the severity of the irritation and is due partly to direct irritation, as evidenced by abdominal tenderness, but chiefly to strong and spasmodic peristalsis, especially without preceding relaxation wave and therefore against excessive resistance, resulting in forcible distention. It may also result from interference with the blood supply through vascular spasm, arteriosclerosis or embolism. It is essentially similar for all smooth muscle, as in the labor-pains of the uterus, overdistention of the urinary bladder, and renal or biliary colic. Gastro-intestinal colic may be mitigated by carminatives, amyl nitrite, atropine or heat externally or internally. Colics may be completely inhibited by ether or chloroform anesthesia. Tonic spastic contraction without distention, such as occurs under morphine and in the spastic colon of nervous constipation, generally does not give rise to pain.

Consistency of the stools varies from the soft but formed stools of the milder laxatives, to the watery stools of the "hydragogue" cathartics, the salines and drastics. The more rapid passage of the intestinal contents leaves less time for the *absorption of fluid*, so that the stools contain more water. Some of the cathartics also prevent the absorption of fluid by osmosis (salines); or by imbibition (agar); and some perhaps by inhibiting the absorbing power of the epithelium (castor oil, calomel). The fluid in these cases comes really from the food rather than from the body. Even large doses of the anthracene cathartics (senna, cascara, etc.) do not increase the secretion of intestinal fluid (Thiry, Brieger, Flemming). On the other hand, the irritant cathartics (colocynth, jalap, etc.) actually produce *effusion* into the small intestine. The tissue dehydration is the same, whether they are deprived of fluid by effusion or by nonabsorption.

Catharsis is likely to be accompanied by some *intestinal hyperemia*, were it only by the increased intestinal movement. The irritant cathartics produce more violent intestinal congestion, which extends also to the pelvic organs, and may perhaps increase the menstrual flow. *The systemic circulation* is affected indirectly by the splanchnic dilatation and by the withdrawal of fluid from the blood. Both factors tend to lower the blood pressure moderately. The heart rate is slowed reflexly (C. H. Neilson and Hyland, 1913).

The following gives a useful **clinical classification**; but the effects vary with the dose. The more important agents are in italics.

1. **Laxatives or aperients** increase peristalsis only moderately, producing somewhat more frequent stools, of almost normal consistency, and this without causing notable irritation. They are active in *doses* of 10 Gm. or over.

Fruits, Manna, Agar, etc.; mechanical means (massage, *enemas*, etc.); Sulfur, *Magnesia*, Carminatives, Bile, Bland Oils (*Olive*, Cottonseed, *Liquid Petrolatum*, etc.). Small doses of Cascara, Senna, Castor Oil, Rhubarb, and Ipecac are also laxative.

2. **Purgatives** increase peristaltic activity, causing more frequent soft or semifluid stools.

(*A*) *Simple Purgatives.*—Active in *doses* of 0.2 to 1 Gm. Full doses may cause more or less colic and irritation: Aloes, Rhubarb, Senna, *Cascara*, *Phenolphthalein*, *Castor Oil*, *Calomel*, small doses of drastics.

(*B*) *Saline Purgatives.*—Active in doses of about 10 Gm. Rather profuse, watery stools, with practically no irritation or griping: *Sulfate of Magnesium* or Sodium Phosphate, Magnesium Citrate, Potassium Bitartrate, Rochelle Salt, etc.

3. **Drastics** produce watery stools, with much irritation. Large doses are liable to set up an enteritis: Elaterium, Colocynth, *Jalap*, Scammony, Gamboge, *Podophyllum*, Croton Oil, the stronger Mercurials and Antimony Sulfide.

4. **Hydragogues** are all which produce watery stools, *i. e.*, the salines and drastics.

5. **Cholagogues** were supposed to increase the bile flow: *Aloes*, Rhubarb, Mercurials, Podophyllum, Euonymin, Sod. Salicylate or Phosphate, Acid. Nitrohydrochlor. Dilut., Bile.

Therapeutic Indications.—Cathartics are used chiefly for the following indications: (1) *To relieve constipation*—cascara, rhubarb, phenolphthalein, small doses of salts. (2) *To soften the stools*, in hemorrhoidal and other rectal diseases, and to prevent straining in aneurysm, hernia and apoplexy—petrolatum, cascara, agar, mucilaginous drugs. (3) *To cleanse the intestines* in digestive disturbances, diarrheas and other intestinal putrefactions—calomel, castor oil, rhubarb, cascara, aloes. (4) *To facilitate the absorption of dropsies; to relieve the kidneys in nephritis; to relieve internal congestions*, especially of the brain—calomel, large doses of salines, compound jalap powder.

Cathartics are among the most ancient methods of internal medication, and were for a long time practically the only method. The Greeks used the same word, *φαρμακειν*, both for intestinal medication in general and for the use of cathartics in particular. The present English word *physic* is similarly applied.

The annual consumption of cathartics in the United States was reported (1933) as twenty million pounds.

Contraindications.—All inflammatory conditions of the abdominal organs (appendicitis, peritonitis, gastro-enteritis, etc.) contraindicate intestinal irritants. Pregnancy and menstruation are contraindications to the use of the stronger cathartics, since the hyperemia may lead to abortion or excessive menstrual flow. General debility, tendency to collapse, threatened intestinal hemorrhage and toxic spasm of the intestine are further contraindications. Cathartics must not be used in intestinal obstruction or intussusception.

Cathartics should be used rather sparingly in the chronic intestinal stasis of *habitual constipation*, the condition being treated most effectively by the removal of the cause and the cultivation of proper hygienic and dietetic habits, aided by the mechanical laxatives, liquid petrolatum, agar or enemas. Small doses of salts, cascara or similar aperients may be needed. The irritant cathartics should be avoided. The fatality rate of appendicitis is much higher for patients who have been in the habit of taking laxatives (J. O. Bower).

Pharmacologic Classification.—From the standpoint of the mechanism of action, cathartic agents may be grouped as: (1) *Parasympathetic stimulants*, pilocarpine, physostigmine, choline, etc. These produce toxic side actions and intestinal spasm, so that they are not used as cathartic therapy; but physostigmine and prostigmine are employed against postoperative intestinal gas distention. (2) *Muscular stimulants,* acting more directly on smooth muscle. Barium is effective but too dangerous; histamine and extract of posterior pituitary gland are of inconstant efficiency; but posterior pituitary is employed in gas distention. (3) *Capillary poisons* are concerned in gastro-enteritis, and violent catharsis of specific bacterial toxins, toadstools, anaphylaxis, and in the toxic effects of certain drugs, colchicum, arsenic, mercury and other metals. The agents of these three groups are discussed under the individual drugs (see Index). (4) *Mechanical distention by retention of intestinal fluid* produces softened stools to copious watery evacuations, without inflammatory injury. The degree of distention may be graded by the choice of the agents and by the dosage.

(a) **Saline cathartics** are easily soluble but difficultly absorable salts, which retain fluid in the intestines by their osmotic pressure. The distention of the duodenum and upper ileum arouses increased motor activity throughout the intestines, resulting in a prompt laxative effect. When the unabsorbed salt solution itself reaches the colon, it may cause purgation by direct distention, or smaller quantities may be merely laxative by hindering inspissation of the contents. Saline cathartics are used to evacuate fluid in dropsy; they have occasional use in constipation; but the intestinal movements which they induce are not of the normal type of peristalsis and they should not be used habitually. Intestinal colic, as that of lead poisoning, offers a special indication for magensium salts, for these resolve the spasm by direct depressive action on the intestinal muscle. Magnesium oxide and carbonate are also used to neutralize gastric hyperchlorhydria, which may be a cause of constipation. Further details are considered under the individual salts (see Saline Cathartics in Index).

(b) **Mucilaginous drugs, agar, psyllium seeds, bran and prunes** are also unabsorbable and retain moderate quantities of fluid by imbibition, thus modifying the bulk and consistence of the feces, so that these are more easily expelled. They are useful in habitual constipation, especially if aided by the occasional administration of cascara. They have some advantage over mineral oil in that they do not interfere with the absorption of vitamins and do not cause leakage, but they are less convenient to regulate.

***Agar,** U.S.P. (Agar-Agar), is a dried mucilaginous substance extracted from marine algae growing along the eastern cost of Asia. It consists mainly of the hemicellulose "gelose," which gelatinizes with water. It is tasteless and has been used for culinary jellies, but is not digested (8 to 27 per cent is utilized in man; Swartz, 1911; herbivorae utilize about 50 per cent; Lohrisch, 1908). It was introduced as a laxative by A. Schmidt, 1905. The dose is 4 to 15 Gm., 1 to 4 drachms, of the chopped shreds or powder, with breakfast cereal. It may also be boiled with the cereal or made into a jelly (1:200 boiling water). The effect is usually not noticeable for nearly a week. The efficiency is not great, and it usually requires the addition of cascara or phenolphthalein.

Psyllium consists of the seeds of a plantain, Plantago Psyllium and related species, of Southern Europe. Its hull contains a mucilaginous substance which swells to a jelly in water. The laxative dose is a teaspoonful to a tablespoonful of the seeds. It may cause fecal impaction and lesions in the lower intestines. In rats and dogs it may produce a peculiar pigmentation of the kidneys, but this does not appear to interfere with renal function (Thienes and Hall, 1939). Its dose is 4 to 15 Gm., one to three times daily. It may be administered in orange juice. *Bran* probably owes its laxative action to water-imbibition, not to mechanical irritation or to any soluble constituent (M. B. Davis, 1931). Its richness in vitamin B complex is useful when this is deficient (Report. Council on Foods, 1936, J.A.M.A., *107:* 874). In many individuals it irritates the intestinal mucosa, and in spastic constipation it may increase the spasticity and lead to obstruction, especially if the dosage is increased when small doses are not effective (Davis, 1931). Roentgenoscopic studies show little effect on the normal events in the intestines except that the emptying time is shortened by its daily use in about a fourth of normal individuals. It relaxes haustral hypertonus (Fantus, Kopstein and Schmidt, 1940). *Prunes* act partly by imbibition, but they also contain a directly laxative constituent, apparently related to dihydroxy phenyl isatin (G. A. Emerson, 1933). *Other fruits* act as laxatives chiefly by their organic acids and sugars. *Tamarind,* the fruit of Tamarindus indicus, owes its activity to organic acids, especially citric. It is used as a laxative, in doses of 4 to 30 Gm. (1 to 8 drachms). *Manna,* the dried saccharine exudation of an ash tree, Fraxinus ornus, contains about 90 per cent of mannite, a difficultly absorbable sugar, which is laxative by osmosis. Its dose is 15 Gm., 4 drachms, to 60 Gm., 2 ounces, as infusion. *Karaya gum* produces serious intestinal lesions when fed to rats in large quantity for long periods (Hoelzel *et al.,* 1941). Rats receiving more than 20 per cent of *inulin* with their diet develop severe diarrhea (Hodge, 1944).

Methylcellulose ("*Methocel*") has been suggested as a synthetic hydrophilic laxative. It is a white fibrous material, dissolving in cold water to a clear jelly which coagulates on heating and redissolves on cooling. It is insoluble in most organic solvents. It is nontoxic by mouth, is not absorbed from the digestive tract, and does not interfere with the absorption of fat-soluble vitamins. Five grams twice daily increase the water content and bulk of the stools by about ten times the weight of the drug (M. L. Tainter, 1943). It is not metabolised and does not increase the methanol or formic acid content of the urine (Machle *et al.*, 1944). Large amounts fed to rats over long periods have no deleterious effects on the normal growth curve (Lehman and Yonkman, 1944). **Ethylcellulose** ("*Ethocel*"), which is insoluble in water and soluble in organic solvents, is also innocuous (Deichmann and Wintherup, 1943). **Cellulose acetate phthalate** likewise appears inert. Growth curves of rats remain normal when 20 per cent is added to the diet; above this there is some mechanical interference with food disposal, without other symptoms or lesions. Dogs remain in good health when fed 16 Gm. daily (Hodge, 1944). The substance appears promising for "enteric" capsules or coatings, as it is insoluble in acid fluids, and quickly soluble in alkaline. Roentgen studies on normal men indicate that the capsules disintegrate within eight hours, generally in the intestines, exceptionally in the stomach (Hodge *et al.*, 1944).

(c) **Mineral Oil,** which is not absorbed from the intestines (except minimal quantities, Channon and Collinson, 1929), prevents inspissation in the colon and is therefore used as laxative, especially in habitual, nervous and spastic constipation, and to prevent straining at stool in cardiac decompensation, and in hemorrhoids, where it also protects against irritation. It hinders the absorption of lipo-soluble drugs, bile and vitamins, such as carotene, especially if taken at meal time. Ordinary doses consumed at other times do not interfere materially with the absorption of vitamin A (Dutcher, 1934; R. W. Jackson, 1934). Interference with absorption of vitamin A is much less than for carotene (Dutcher, Harris *et al.*, 1934); but addition of 5 per cent to the diet of rats raises their codliver oil requirement to three times (M. O. Smith and Spector, 1940). Excessive quantities of the oils which are not thoroughly incorporated in the feces are likely to leak insensibly from the anus. Emulsified oil is less liable to this and is more easily taken. The leakage and flatulence diminish with habitual use (F. T. Jung and Isaacs, 1939) (see Index, Petrolatum).

Evacuant Enemas.—Rectal injections or clysters increase the peristalsis of the large and small intestines in response to the mechanical distention. The effect is enhanced by the addition of irritants. Enemas have an *advantage* over cathartics taken by mouth, in that they may be made absolutely nonirritant, and may therefore be used in conditions in which the other cathartics are contraindicated. If the purpose of the enema be merely to *soften hardened scybala,* they would be used warm, in copious quantities, or as decoctions of mucilaginous substances. Olive oil is sometimes employed; it is less solvent, but if it is administered carefully in amounts of 70 to 500 cc., it can be retained several hours. To secure the maximum motor effect, the injection must be used cold, and in fairly large quantity: adults a pint, quart, or more; children according to age (at a year, an ounce, and about ½ ounce more for each year). *Irritants* may be added to enemas to secure immediate expulsion: soap, even a small quantity; molasses, 1:8; salt, 1:16; turpentine, 1:20 (emulsified with egg yolk), especially against flatulence; bile 1:50.

Enemas also have other uses: For *local effects* on the rectal mucous membrane (astringents, etc.); for the *removal of parasites;* and as a method of *introducing medicine and nourishment.* Irritant injections into the colon may either inhibit the emptying of the stomach, by pyloric spasm, or may shorten the gastric sojourn by increased peristalsis (F. W. White, 1917, x-ray method with cats).

Evacuant Suppositories.—A small plug of soap, or a Glycerin Suppository, U.S.P., evacutes the rectum promptly by sensory irritation, without distention.

IRRITANT CATHARTICS

Most of the "active purgatives" are irritants, but they differ greatly in degree and location. The latter depends partly on solubility. If they act high in the small intestines, the peristalsis is likely to be irregular and generally griping, with liquid stools; but calomel (see Index), which begins its action in the duodenum, is usually mild, with soft rather than liquid stools, because its solubility is limited. Bile (see Index) acts on the duodenum, but is mild, because the bile acids are reabsorbed so that the action does not extend far down. Sulfur (see Index) is also rather mild, as it must be converted into the sulfide. The other irritant cathartics may be grouped into the following groups: (1) *Those which act mainly on the colon and rectum* include the drugs containing emodin and other anthraquinone derivatives: Senna, cascara, rhubarb, aloes and perhaps also phenolphthalein. (2) *Those which stimulate peristalsis of the small* *intestine* and inhibit the antiperistalsis of the colon, without producing much irritation or effusion, include castor oil and probably calomel, bile and sulfur. (3) *Those which cause marked intestinal effusion and irritation* comprise colocynth, jalap and presumably the other drastic resinous cathartics, podophyllum, elaterin, gamboge and croton oil.

EMODIN OR ANTHRAQUINONE CATHARTICS

Senna, rhubarb, cascara, aloes and related drugs contain glucosidal compounds which are inactive as such, but are hydrolyzed or oxidized in the alkaline intestine, yielding various oxymethyl-anthraquinones, especially emodin and chrysophanic acid (Buchheim; Tschirch and pupils, 1899). These act chiefly on the large intestines, as laxatives, aperients or ecproctics, with easier defecation of formed stools. They are often more effective when taken in divided doses (three times daily) than as a single dose. With larger doses and with the more active members the action begins in the small intestines, with griping and forced evacuation of liquid stools; but it does not readily progress to inflammation. The effects are fairly easily controlled by grading the dosage, and by repeating the smaller doses, as the action tends to be cumulative. The dosage may be reduced or omitted when the desired degree is attained. These drugs are therefore used especially in chronic constipation, in addition to or alternation with mineral oil. Prolonged use tends to decrease the response of the intestines, so that the effect occurs only with larger doses which are liable to set up chronic inflammation of the mucosa. Cascara is the mildest of these drugs and the most easily controlled. Senna is the most active and generally causes griping and semiliquid stools. Aloe and aloin are intermediate, but can be pushed to drastic action which may result in abortion. Rhubarb catharsis is likely to be followed by constipation, which has been attributed to its tannic acid. *Emodin* (trioxy methylanthroquinone) is probably the most important constituent of this group. It is present in the amount of 0.8 to 1 per cent in senna; 2.6 per cent in frangula; 0.6 per cent in cascara; 0.8 per cent in Cape aloes; and 1.5 per cent in rhubarb (Tschirch and Hiepe). Chrysophanic acid (dioxymethylanthraquinone) is also important. Phenolphthalein acts similarly to cascara and aloes, but the response is variable. Its chemical structure is somewhat different.

The pure emodin substances would be too irritant, but their action is graded by their slow liberation and by the presence of colloid extractives. Numerous isomers are possible (fifteen for emodin alone). The special character of the different drugs is probably due to differences in these isomers, in the stability of their glucosidal combination, and to the presence of other associated substances (tannin in rhubarb).

Fate.—Emodin is partly absorbed and is excreted into the urine and milk (laxative effects on sucklings). The drugs containing emodin *color the urine* yellowish-brown when it is acid, reddish or violet when alkaline. It may be advisable to acquaint the patient with this fact.

Other drugs which change the color of the urine are: *Logwood* (Hematoxylon) does not color acid urine, but produces a reddish or violet color in alkaline urine. *Santonin* gives a yellowish color to acid urine, with a yellow foam; if the urine is made alkaline it gives a pronounced pink. *Picric acid* gives reddish-brown color in both acid and alkaline urine. The various *coal-tar products* give a brownish-black color. *Methylene blue* imparts a green color.

Manner of Action.—The older work (Buchheim; Tappeiner and Brandl, 1889) showed that the action of the emodin group is mainly on the large intestine, which reacts by increased movements also to intravenous injection; and that there is no increase of intestinal secretion. Aloe and podophyllum do not increase the *bile flow* in constipated patients (Ivy, Roth and Gutman, 1945). The x-ray experiments (Magnus, 1909; and Meyer-Betz and Gebhardt, 1912) and the observations through the abdominal window (Lenz, 1923) confirm that ordinary doses of senna do not accelerate the passage through the stomach and small intestine, but solely through the colon. With aloes the lower ileum participates somewhat. The normal peristaltic activity of the colon consists in the occasional formation of limited but firm contraction rings, which persist for some time, either stationary, or traveling slowly up or down the intestine. When these cathartics reach the colon, these contraction rings become much more frequent, tend to travel more rapidly downward, stripping the contents into the rectum.

The localization of this action in the colon is due partly to selective penetration, for anthropurpurin, *f. i.*, stains the mucosa of the colon much more intensely than that of the small intestine. It is possible that sensory reflexes participate. The cathartic effects of senna occur also on *intravenous* or *intramuscular injection*. Overdosage causes convulsions and vomiting (W. Straub and Triendl, 1937).

Susceptibility of Animals.—Rabbits are so refractory to anthraquinone catharsis that they are unsuitable for experimentation. Dogs can be purged, but are not very susceptible. Cats respond well. They require about the same absolute dose as man, 2 Gm. of senna, etc.

Observations of senna actions through an abdominal window were made by Lenz, 1923, by sewing a celluloid pane into the abdomen of cats and controlling the progress of the contents by radioscopy. Senna infusion was administered by stomach tube, with a meal. While the senna sojourns in the stomach, the gastric movements are barely stimulated; but within *eighteen to thirty-five* minutes, before the senna has left the stomach, strong peristaltic waves and a propulsive tonus ring start in the colon, which is normally in almost complete repose. This action—at a distance—lasts half an hour to an hour. There is little further action until the senna itself arrives at the colon, *about one and one-half to two and one-half hours after administration.* This causes immediate stimulation of the propulsive *colon peristalsis*, with inhibition of the normal retention-movements, the stationary or ascending tonus rings and antiperistalsis. Between *two and one-half to five and one-half hours* after administration, as more and more of the senna enters the colon, intensive tubular propulsive movements are set up, and lead to defecation of liquid stools, since there is no time for inspissation. The movements are so violent that defecation may be released from the proximal colon. The defecation is followed by tonic contracture of the colon, more powerful and more persistent than normal. This passes into relaxation of the colon and arrest of all its movements, for one or two hours; then the whole process is repeated, so that there may be four stools in three hours. When the senna has been entirely evacuated, the colon is immobile and remains so for hours. The *movements of the small intestines*, which in the cat are normally of the rosary type exclusively, are also replaced by tubular propulsive peristalsis during the passage of the senna, three and one-half to five and one-half hours after administration. They return to the normal type when the senna has been evacuated. *Emodin* has the same effects of senna; *anthraquinone* causes less stimulation of the propulsive movements and produces stimulation instead of inhibition of retention movements. The senna effects are prevented by anesthetizing the intestines with cocaine or procaine.

Vella fistulas permit observations on unanesthetized dogs. The effects of emodin, cathartics, phenolphthalein and podophyllin on the ileum are similar for intravenous injection and for instillation into the intestinal segment: generally a sudden decrease of tonus followed in two to ten minutes by increase of peristalsis. Atropine first increases, then inhibits the peristaltic stimulation (Gruber, Bryan and Richardson, 1932). With excised small intestines, kept in good condition by *perfusion through their blood vessels*, Carnot and Glenard, 1913, found that the injection of senna infusion, aloin or phenolphthalein into the lumen or vessels causes augmentation of peristalsis, spasm and evacuation. *In segments of excised intestine* suspended in saline solution, cascara increases the rate, but lessens the intensity of the contractions (Flury, 1912).

CASCARA SAGRADA

This is used chiefly in habitual constipation. It softens the stools without noticeable irritation. The susceptibility is not lost with use; on the contrary, the establishment of regular habits usually permits it to be gradually withdrawn. By its bitter taste, it acts also as stomachic. It may be given as the fluidextract, 15 drops three times daily; or in a single dose, a half teaspoonful, in the evening. This causes a single soft stool in the morning. In the Aromatic Fluidextract, which is much more pleasant, some of the bitter and cathartic principles have been destroyed (Wenzell, 1886). It may be given in twice the dose.

It is generally stated that the *fresh bark* is emetic, through the presence of a ferment which gradually disappears as the bark is aged. R. H. True and Klugh, 1909, did not find any emetic effect from the unaged bark. When cascara is administered *hypodermically*, its constituents are rapidly absorbed and excreted by the kidneys, producing renal irritation, but *not* catharsis (Chistoni, 1914).

Preparations.—*Cascara Sagrada*, U.S.P., is the dried bark of the shrub Rhamnus Purshiana, stored at least one year. Cascara sagrada ("Sacred Bark") was used by the early settlers, but was little known to the profession till introduced by Bundy, 1877. Johnson and Hindman, 1914, review its history, composition and bibliography. The active principles are: *Cascarin*, which is a cathartin or emodin principle, isoemodin, bitter resins, etc.; no chrysarobin or chrysophanic acid (Jowett, 1904, who claims that emodin is not the main active constituent). It is used as the ***Extract**, 1 Gm. of the powder representing 3 Gm. of the bark, dose, 0.15 to 0.5 Gm., 2½ to 8 grains. *Tablets of Cascara Sagrada Extract*, U.S.P.; the usual sizes contain 0.12, 0.2, and 0.3 Gm. of Extract. ***Fluidextract**, extracted with hot water, evaporated and mixed with alcohol to about 18 per cent; dose, 1 to 2 cc., 15 to 30 minims. ***Aromatic Fluidextract** (Aromatic Cascara), with the bitter principles partly destroyed by digestion with boiling water, flavored with glycyrrhiza extract, saccharin, anise and coriander oils and methyl salicylate; preserved with 18 per cent of alcohol, flavored with glycyrrhiza, aromatics and saccharin. Dose, 2 to 4 cc., ½ to 1 drachm. *Frangula* (Buckthorn Bark), the dried bark of Rhamnus frangula, is used similarly. *Rumex crispus* (Dock Root) is said to contain chrysophanic acid, about 0.1 per cent of an emodin identical with that of cascara (Beal and Okey, 1919).

SENNA

The effects are more extensive and more irritant than with the other drugs of the group, so that it is better suited for acute than for chronic constipation. There is considerable griping, which may be corrected by carminatives, or by the previous extraction of the resins with alcohol (as in the Fluidextract).

Preparations.—*Senna*, U.S.P., is the dried leaflets of Cassia species. Introduced by the Arabians. Constituents: senna-emodin, senna-isoemodin, senna-chrysophanic acid, and other anthraquinone derivatives (rhein, aloe-emodin), free and in glucosidal combinations; also some salicylic acid (Tutin, 1913, 1914; Tambach, 1913). Dose, 2 Gm., 30 grains. It may be administered as *Fluidextract*, U.S.P.; dose 2 cc.; or as the *Syrup*, U.S.P., 25 per cent flavored with coriander, dose 2 to 8 cc., ½ to 2 drachms. *Compound Senna Powder*, N.F. (Compound Licorice Powder), contains 18 per cent senna and 8 per cent sulfur, flavored with glycyrrhiza and fennel; dose, 4 Gm., 1 drachm. The obsolete *Compound Infusion of Senna* ("Black Draught") contained senna, magnesium sulfate and manna. The seed pods were also used (*Sennae Fructus*, B.P.). *Cassia Pulp*, B.P., is an evaporated watery extract of the ripe fruits of Cassia Fistula. Dose, 4 to 8 Gm., 60 to 120 grains.

RHUBARB

This contains considerable tannic acid as well as cathartic principles. The astringent action predominates with smaller doses (0.05 to 0.3 Gm.), which are used as astringent bitters in gastric catarrh, and in diarrhea. Larger doses (1 to 5 Gm.) are laxative with little colic. They may be employed in chronic constipation, but the astringent action makes it inferior to cascara. It may cause skin eruptions.

The cathartic principles are mainly a *resin*, non-glucosidal, but yielding on hydrolysis various anthraquinone derivatives, which also exist partly free: rhein, emodin, aloe-emodin, chrysophanic acid, etc. The astringent principles are glucosidal compounds of tannin (rheotannic acid), and gallic acid. There is also a large amount of calcium oxalate (Tutin and Clewer, 1911).

Preparations.—*Rhubarb*, U.S.P. (Rheum), the dried rhizome and roots of species of Rheum growing in China and Tibet (species cultivated in this country are devoid of cathartic principles), has been used since antiquity in China, and by the Roman physicians. ***Aromatic Rhubarb Syrup**, U.S.P. (Syr. Rhei Arom.), contains 15 per cent of the Arom. Tr. of Rhubarb, 0.1 per cent of pot. carbonate; dose, 10 cc., 2½ drachms. The *Aromatic Rhubarb Tincture*, U.S.P., contains 20 per cent of rhubarb with aromatics (cinnamon, clove and nutmeg); dose, 4 cc., 1 drachm.

ALOE

The dried juice of the leaves of various species of Aloe from the West Indies, Africa, etc., furnishes the commercial varieties of aloes, which differ somewhat in composition and action. They contain anthraquinone derivatives, especially aloins (10 to 16 per cent). These are glucosides which are probably inactive themselves, but which yield emodin and other active anthraquinone derivatives on cleavage. This cleavage occurs in the intestine; it is favored by alkalis and perhaps also by bile and by iron salts. Aloin may be used as such. Aloe is intensely bitter, so that it is administered in pills. Very small doses may be used as stomachic. Moderate doses are laxative, but somewhat likely to gripe, and are therefore commonly combined with belladonna or carminatives (myrrh, etc.). They do not lose their efficiency on continued use and would be suited to habitual constipation, but have no advantage over cascara. Aloes are supposed to produce considerable congestion of the pelvic organs and are therefore contraindicated in hemorrhoids, menstruation and pregnancy. On the other hand, they may be used as emmenagogues. They are especially prescribed for correcting the constipative action of iron medication. Neither aloe nor podophyllum is cholagogue or choloretic. They do not increase the output of cholic acid, cholesterol or bile pigments (Ivy, Annegers and Atkinson, 1942), nor do they stimulate the contraction or evacuation of the gallbladder (Ivy, Robuck and Stein, 1942); nor the flow of bile in constipated patients (Ivy, Roth and Gutman, 1945).

Aloin is also effective *subcutaneously*, being excreted into the large intestine, but this method is too painful (H. Meyer, 1890).

Aloin Nephritis.—In rabbits, hypodermic injection (2 cc. per kilogram of 5 per cent, repeated on two to three successive days) produces a tubular nephritis. The anatomic lesions have been investigated especially by Mürset (1885); they are practically the same in acute and chronic poisoning, and consist mainly in degeneration of the epithelium of the convoluted tubules. This loses its striations and staining qualities, and the nuclei disappear. The glomerular epithelium is but slightly altered, and the glomerular vessels show no lesions. The urine may be increased or diminished and contains proteins, leukocytes, casts, crystals and blood.

Metabolism.—There is also an increased protein metabolism, resulting in rise of urea in mammals, of uric acid in birds. The latter may develop gout. Dogs show some fever (Berrar, 1913).

Preparations.—***Aloe**, U.S.P., is the dried juice of the leaves of Aloe Perryi (Socotrine) or of A. vera (Curaçao). Brown, opaque glassy masses, aromatic odor, nauseous bitter taste; partly sol. in water, completely sol. in alc. Aloe was used by the Greeks and probably by the Egyptians. Dose, 0.25 Gm., 4 grains, best as pills. *Aloe Pills*, U.S.P., contain, each, 0.13 Gm., 2 grains, of aloes, with soap.

***Aloin**, U.S.P., a mixture of pentosides obtained from aloes (usually from Curaçao, W. Hills, 1908), varies in chemical composition, physical and chemical properties, according to the source. A yellow micro-crystalline powder, practically odorless, intensely bitter taste. Sol in water and alc. Dose, 0.015 Gm., ¼ grain. *Pills of Aloin, Strychnine, Belladonna and Ipecac*, N.F. (formerly "Compound Laxative Pills"), contain, each, aloin 16 mg. (¼ grain), strychnine 1 mg. (1/64 grain), ext. belladonna 8 mg. (⅛ grain), and ipecac 4 mg. (1/16 grain). They have caused many accidental deaths in children. *Nataloin* differs from the other aloins in composition, and is more difficultly hydrolyzed (H. Meyer). *Synthetic anthracene derivatives* with laxative action have been prepared, but have little practical importance (*purgatin*, anthrapurpurin diacetate; *exodin*, methyl esters of diacetyl-hexaoxy-anthraquinone).

PHENOLPHTHALEIN

This is a mild tasteless purgative, acting chiefly on the large intestine, similarly to the emodin cathartics. It is insoluble in water, but forms soluble salts with alkalis. Its action therefore depends on the alkalinity of the intestines and varies with this, so that the response is sometimes slight and sometimes excessive. It is but little absorbed from the alimentary canal, and is ordinarily nontoxic even in large doses; but even the ordinary dose may sometimes cause serious effects. It is used in habitual constipation, and has been exploited under several proprietary names (purgen, laxans, etc.). Phenolphthalein may be taken in the evening, as powder, capsules or lozenges, in doses of 0.1 to 0.2 Gm., 1½ to 3 grains; for bedridden patients, 0.5 Gm., 8 grains; for children, 0.03 Gm., ½ grain. These smaller doses soften and regulate the stools for several days, with little or no colic. Large doses are hydragogue.

Phenoltetrachlorphthalein, 0.4 Gm. dissolved in 20 cc. of neutral olive oil, has been suggested as a subcutaneous purgative (Abel and Rowntree, 1909; Rowntree, 1910).

For the diagnostic phenolphthalein derivatives, see Index.

Absorption, Fate and Excretion.—Phenolphthalein is insoluble in acids, but gives a pink solution with alkalis. It passes the stomach unchanged. It is partially dissolved in the alkaline intestine, but little is absorbed, almost the entire quantity (over 85 per cent) appearing unchanged in the feces (Vamossy). After large doses, traces are found in the urine (Elmer, 1909), which is then colored violet-red by alkalis (Gruebler, 1906). With the usual medicinal doses, it is present in the urine only in conjugation with sulfates; with large doses, a part may be unconjugated. The total urinary excretion is 1.4 to 20 per cent of the amount administered orally (Fantus and Dyniewicz, 1938). *After hypodermic administration*, it is excreted by the urine, feces, saliva, tears, etc. The excretion is rapid, beginning within fifteen minutes and ending in twelve to eighteen hours. The body fluids dissolve it more readily than water (Fleig, 1908). It is excreted into the intestine mainly by the bile and is to some extent reabsorbed in the large intestine (Abel and Rowntree .1909).

The purgative action of this familiar indicator was discovered by v. Vamossy, 1900, when investigating whether the substance would be harmless for denaturing artificial wines; it appears to be connected with the quinone structure. It is but slightly cathartic in rats, cats and dogs, but is effective in rhesus monkeys, although the response is variable. "Yellow phenolphthalein" contains some impurity which renders it about three times as potent as white (E. F. Williams *et al.*, 1934). Ott and Scott, 1908, found evidence that phenolphthalein acts directly on the muscle of the excised intestine. Fleig and others attribute the action to increased intestinal secretion, but the evidence is not satisfactory. It acts also on hypodermic or intravenous administration, reaching the intestine through the bile. *Bile* appears to be necessary for its action, for it is ineffective in obstructive jaundice (T. Steigmann *et al.*, 1938). The blood pressure is scarcely affected, even when large doses are injected into a vein; the kidneys are not irritated, nor are there any other systemic effects. Phenolphthalein itself does not produce local irritation, but its soluble salts are highly irritant. It is not bactericidal (Abel and Rowntree).

Toxic effects in the use of phenolphthalein are exceptional, but may be serious. They consist in enteritis, especially colitis; dermatitis; and hemorrhagic tendencies. One death has been reported (M. Cleeves, 1932). On the other hand, large doses have often been given without bad effects; to man, several grams by mouth, 0.5 Gm. subcutaneously; to dogs, 1.25 Gm. per kilogram. Activated charcoal has been recommended as antidote (Fantus and Dyniewicz, 1938).

Cases of clinical toxicity were reported by Orland, 1913, and others. They presented phenomena of intestinal irritation, ending in recovery. *Dermatitis* was reported by Wise and Abramowitz, 1922, and C. F. McCarthy, 1932. It occurs only in susceptible persons, and consists in erythematous and vesicular rashes of various types, similar to those of antipyrine and arsphenamine. They may be followed by persistent pigmentation. Rosenbloom reported nasal *herpes*. Medicinal doses do not produce *albuminuria* (Fantus and Dyniewicz, 1937).

The sale of phenolphthalein in the United States decreased from 460,000 pounds in 1937 to 245,000 pounds in 1939. The fall may be placed to the credit of the regulations of the Food and Drugs Administration.

***Phenolphthalein**, U.S.P. (Dihydroxyphthalophenone), $(C_6H_4OH)_2CO.C_6H_4CO$, is a white crystalline powder, odorless and tasteless. Almost insol. in water, sol. in alc. (1:13). Dose, 0.03 to 0.12 Gm., ½ to 2 grains. McGuigan *et al.*, 1944, found 0.06 Gm. ineffective in over half the cases; normal individuals required about double, constipated about three times this dose. The same relation held for the official dose (1 Gm.) of cascara sagrada.

CASTOR OIL

This consists mainly of the triglyceride of an unsaturated fatty acid, ricinoleic acid. The neutral fat is not active, but becomes so when it is saponified in the intestine. The cathartic effect is due mainly to motor stimulation of the small intestine. The fluid character of the stools is due to the quicker passage of the feces; the intestinal secretion is not increased.

With the usual dose, ½ to 1 ounce, the response is certain and complete, resulting in a few hours in one or two extensive semifluid stools, with but slight hyperemia or irritation, and little or no colic. The evacuation is so complete that there may be some after-constipation. It is especially suited to the treatment of acute constipation or acute diarrhea from dietetic errors, ptomaine and other poisoning, etc. Continued use may produce gastric disturbance. There is some pelvic congestion, so that it is avoided during menstruation and pregnancy.

Mechanism of action was studied with x-ray by Magnus, 1908, and his observations have been confirmed on man. The pure oil delays slightly the passage through the *stomach* (as do other neutral oils). Rancid oil hastens the gastric expulsion. In the *small intestine*, the segmenting movements and peristalsis are greatly increased, so that the expulsion may be completed in two hours instead of the normal eight hours. In the *colon*, the normal antiperistalsis is allayed, so that the feces escape concentration. The propulsive movements of the colon are not much increased, but the passage of the fecal material is hastened by its thinner consistency. In China it is used as an article of diet. The properties of castor oil were known to Herodotus; but croton seeds were first described in the middle of the sixteenth century. A small amount, 1 to 2 per cent, of castor oil is added to alcoholic *scalp lotions* to leave a slight oil film on the hair. Castor oil is said to be an active *poison for flies* (Boyes and Gurjot, 1919).

Administration.—It is best given an hour before breakfast. The taste may be somewhat disguised by wetting the mouth with hot coffee or milk, and giving the well cooled oil floating in these liquids, so that it will not be so adherent. The aftertaste may be mitigated by peppermint or bread. The *soft gelatin capsules* are tasteless, but since the ordinary size contains only 1 cc., it is difficult to administer an effective dose.

***Castor Oil**, U.S.P. (Oleum Ricini), is a fixed oil expressed from the seed of Ricinus communis. An almost colorless viscid oil, of faint but characteristic odor and extremely disagreeable taste. Sol. in an equal volume of alc. Dose, 4 to 16 cc., 1 to 4 drachms; for infants, a teaspoonful. *Aromatic Castor Oil*, N.F., contains aromatic flavor and saccharin.

RICIN

Occurrence, Clinical Symptoms and Treatment.—This toxic protein is contained in the castor seeds, but does not pass into the oil. Similar phytotoxins occur in croton seeds (*crotin*), and in jequirity seeds (abrin); in the bark of the locust tree, Robinia pseudoacacia (*robin*); and in the seeds of some leguminous plants (*phasin*). The last is but weakly toxic. The ricin is responsible for the toxic effects on eating the castor seeds; five or six of these are fatal to a child, twenty to adults; three or four seeds may cause violent gastro-enteritis, with nausea, headache, persistent vomiting, colic, sometimes bloody diarrhea, thirst, emaciation and great debility. The symptoms usually do not set in until after several days. More severe intoxications cause small frequent pulse, cold sweat, icterus and convulsions. Death occurs in six to eight days, from the convulsions or from exhaustion. The fatality is about 6 per cent. This low fatality is due to the destruction of the poison in the alimentary canal. The *treatment* would be evacuant and symptomatic. Three to ten days are required to complete recovery (critical review and bibliography, Ford, 1913).

Effects on Animals.—The actions can be best studied on rabbits, by hypodermic or intravenous injections. Even with the latter there is an incubation period of at least twelve to eighteen hours before symptoms appear. These correspond to those described for man. They are partly local—gastro-enteritis; and partly central—paralysis of the respiratory and vasomotor centers. Local inflammation also occurs on other mucous membranes to which the poison may be applied, especially the conjunctiva. The phytotoxins have no direct effect on muscle or nerve.

The *autopsy* findings consist in characteristic swelling and reddening of Peyer's patches and mesenteric lymph glands, internal hemorrhages and diffuse nephritis. Flexner, Mueller and others showed that these lesions are not due to thrombosis, but to direct action on the tissues. The site of the injection is boggy. *Temperature* greatly affects the action of ricin. Frogs at 4° C. are not killed by more than a thousand times the dose that is fatal at 37° C. Conversely, hemagglutination requires 100 to 1000 times the concentration at 38° than at 4° C. (Moriyama, 1934).

Action on Blood.—*In vitro*, ricin hemolyzes and agglutinates the corpuscles of nearly all warm-blooded animals (Stillmark, 1888). The agglutination does not seem to occur in the body. Leukocytes, epithelial and other cells (except those with thick membranes, as yeast) are also agglutinated; as likewise the stroma of laked corpuscles (Elfstrand). The presence of serum hinders the effect. The agglutination has been referred to precipitation of the nucleo-albumins (Stassano) or other proteins, such as those of serum (Kraus, 1902). All kinds of colloid precipitates carry down ricin, which is adsorbed by solid proteins and lipoids.

Nature of Ricin.—This appears to be a true protein, for a preparation of ricin has been obtained which is a typical albumin and is so active that 0.0005 mg. is fatal to a kilogram of rabbit (Osborne, 1909). The agglutinating action is also powerful.

Antiricin.—Injections of the phytotoxins produce typical antitoxins, so that an immunized animal can survive 5000 ordinary fatal doses of ricin. Some of the basic work of Ehrlich was done with ricin and abrin. He showed (1891) that the immunity starts in five to six days, and lasts six or seven months. The resistance of the corpuscles is unchanged, the antiricin being contained in the pseudoglobulin fraction of the serum (Jacoby, 1902). It contains antitoxin, antiagglutinin (probably identical) and precipitin. Madsac and Walbum found that this combination obeys the same laws as diphtheria antitoxin. The toxicity of ricin is modified rather complexly by lecithin (Lawrow, 1913).

ABRIN

Abrin, from *jequirity beans* (Abrus precatorius), closely resembles ricin in action, but immunity against one does not protect against the other (Hausmann, 1902). The literature was reviewed by Ford, 1913. Abrin is n-methyltryptophane. Various derivatives have been synthetized and compared by Cahill and Jackson, 1938.

Poisoning.—When the whole beans are swallowed, no toxic effects result, since the shell is so hard that the poison does not dissolve. But if the powder is taken, it produces effects similar to those of ricin. Its toxicity is greatly increased by heating the animals (Lesne and Dreyfus, 1913).

Use in Ophthalmology.—The action on the eye is much stronger than with ricin, producing ophthalmitis. It has been used therapeutically (Weeker, 1882) to clear corneal opacities. This is dangerous unless standardized preparations are used and excessive effects are checked by an antiserum.

CROTON OIL

This contains, besides ordinary fats, about 10 per cent of "croton-resin," the active component (Dunstan and Boole, 1895), producing the local and systemic effects of the oil (Kobert and Hirscheydt, 1890; Boehm, 1915). Croton oil is the most violent of all cathartics, ½ to 1 drop producing burning in the mouth and stomach, often vomiting, and after one-half to three hours, several extensive fluid evacuations, with much colic and tenesmus. It was formerly used in extreme cases of constipation (lead), and in unconscious patients (uremic and apoplectic coma), but it should never be employed. It may produce severe local effects on the mouth, as well as gastro-enteritis. Toxic doses cause collapse. Twenty drops have been fatal, but recovery is said to have followed ½ ounce—presumably because of vomiting. The *treatment* would be evacuant, demulcent, opiates and symptomatic (directed against the enteritis and collapse).

Applied externally, croton oil produces irritation, proceeding to pustulation and even sloughing. When diluted with 2 to 10 parts of olive oil, it may be used as counterirritant, but is dangerous.

Croton Oil (Oleum Tiglii), N.F., is a fixed oil expressed from the seeds of Croton Tiglium. A pale yellow or brownish-yellow, somewhat viscid and slightly fluorescent liquid, having a slight fatty odor. Slightly sol. in alc. Dose, 0.06 cc., 1 minim, on a lump of sugar, slice of bread or lemon.

CATHARTIC RESINS

Jalap, Colocynth, Podophyllum, Elaterin and similar drugs contain active principles which are for the most part resinous (*i. e.*, soluble in alcohol, but slightly soluble in water), often glucosides. On chemic manipulation (probably hydration) these yield resinous acids which are much less active. The resins are highly irritant, producing considerable colic (sometimes vomiting), and several watery stools; in one or two hours with jalap and most of the others, but with podophyllum only after twelve to twenty-four hours. They are used especially in dropsies (Compound Jalap Powder); small doses of podophyllum also as laxative in habitual constipation. The others tend ultimately to produce constipation. Colocynth, and presumably the others, stimulate peristalsis in the small intestine, inhibit antiperistalsis in the colon, and lead to the effusion of fluid from the whole intestinal canal. The resins require the presence of *bile,* which renders them soluble. They are therefore less active in obstructive jaundice. They produce griping and are often prescribed with belladonna and aromatics. If they are not removed by catharsis, they may cause severe enteritis.

The principles are *not as effective when given pure* as when they are mixed with extractive, as in the crude drugs and "resins" (alcoholic extracts precipitated by water), or as preparations of the crude drug. This is due, in some cases, to their being somewhat soluble, and therefore absorbed in the stomach.

Subcutaneous administration produces diarrhea with podophyllin and colocynthin, but is not employed because it also produces nephritis, local irritation and abscesses.

The mechanism of action was studied on colocynth by the x-ray method by Padtberg, 1909. Similar observations have been made with jalap on man: the gastric movements may be slightly increased, but often remain normal. In the *small intestine* the peristalsis is so much quickened that the contents may be completely expelled in half an hour instead of the normal eight hours. This is accomplished by the effusion of considerable fluid into the lumen. In the *large intestine* the propulsion is only slightly increased; but the stools are rendered still more liquid by the inhibition of antiperistalsis and by the secretion of additional mucus. Padtberg, 1911, found that the colocynth peristalsis and effusion are arrested by morphine and opium, although these do not ordinarily act directly on the intestine, but on the stomach.

Unanesthetized dogs with Vella fistulas respond to *intravenous injection* of colocynth or podophyllin as to instillation into the lumen, by strong peristaltic waves while the general tonus of the intestines is decreased (Gruber, Richardson and Bryan, 1932). *Excised segments* of small intestines of rabbits show increased tonus and diminished amplitude. With gamboge, tonus and amplitude are both decreased (N. Hollander, 1927, 1935).

Other Actions.—Excised *uterus* reacts similarly to the intestines. The *frog heart* responds to moderate concentrations by increase of amplitude and of tonus, and finally by systolic arrest. The response to *parasympathetic* stimulation is paralyzed in the intestines, heart and uterus (Hollander, 1935). Convolvulin and jalapin appear related to saponin and agaricin. They are hemolytic in neutral solution. This has been suggested as an index of the intestinal action, but the relation requires confirmation (G. Heinrich, 1918). They are destroyed by alkalis, not by acids.

RESIN OF PODOPHYLLUM

This acts slowly, generally only after twelve to twenty-four hours or longer, producing several soft stools. Larger doses (20 mg., $\frac{1}{3}$ grain or more) act as a hydragogue cathartic; but it is chiefly employed in small doses (5 to 10 mg., $\frac{1}{10}$ to $\frac{1}{6}$ grain) as a laxative in chronic constipation; often combined with aloes or calomel, 0.3 to 0.5 Gm. has been fatal. It is neither chologogue nor choleretic (see Aloe).

Podophyllum Resin, U.S.P. (Podophyllin), is prepared from the dried rhizome and roots of Podophyllum peltatum (May Apple, Mandrake), a plant used by the Indians. An amorphous greenish-yellow powder, of slight peculiar odor and faintly bitter taste. Sol. in alc., insol. in water. Active constituents, resin and a crystalline principle, podophyllotoxin. Dose of the resin, 0.01 to 0.065 Gm., $\frac{1}{6}$ to 1 grain. Very irritating to mucous membranes, esp. of the eyes. Local application of a 25 per cent suspension in liquid petrolatum removes *condyloma acuminatum,* granuloma inguinale and excessive granulations of surgical wounds. The growths blanch within a few hours, become necrotic in one or two days, and drop off on the second or third day, without ulceration or gross scarring. Recurrences are few and can be treated in the same manner. The surrounding normal tissue is usually not affected, nor are true warts nor benign rectal polypi. There are no systemic reactions (Culp and Kaplan, 1944; Tomsky *et al.,* 1942). A single application of podophyllin to *normal* skin, human or rabbit's, produces a transitory alteration in the nuclear pattern of the epidermis, lasting four to six days (J. S. King and Sullivan, 1946).

Other roots and rhizomes related to this group include *Leptandra* (Culver's Root), from Veronica virginica. Contains an amorphous bitter principle, and not a crystalline glucoside, as formerly reported (Power and Rogerson, 1910). "Leptandrin" is a resinoid. Pharmacologically inert, but was supposed to be cholagogic without producing intestinal irritation. Dose, 1 Gm., 15 grains. *Stillingia* (Queen's Root), from Stillingia sylvatica, contains pungent resin and volatile oil. Used mainly in domestic medicine in purgative mixtures, and also as nauseant and emetic. Dose, 2 Gm., 30 grains. *Juglans* (Butternut) is the root bark of Juglans cinerea, collected in autumn. Used as rather mild laxative. Dose of extract, 1 to 2 Gm., 15 to 30 grains. The fldext. of the root, 5 to 20 minims, is said to be a gentle and prolonged laxative similar to rhubarb, and was used in chronic constipation. *Iris* (Blue Flag), from Iris versicolor. Power and Salway, 1911, could not find any active principle, although the drug and the resinoid "iridin" were formerly considered cathartic and diuretic. Dose, 1 Gm., 15 grains. *"Orris Root"* (Iridis Rhizoma), from several cultivated species of iris. Has a violet odor. Is used in sachets and tooth powders, but allergic reactions are rather frequent.

JALAP, SCAMMONIUM, IPOMEA

Jalap is perhaps the mildest member of the group. It produces watery stools within three or four hours, with little intestinal irritation, without gastric disturbance or much prostration. It has little taste and is easily administered. It is used in ascites, cerebral congestion, hypertension; and as adjuvant to anthelmintics. *Scammony* and its equivalent *Ipomea* are closely related to jalap.

Jalap, N.F., is the dried tuberous root of Exogonium Jalapa (Ipomoea purga). Dose, 0.3 to 1.2 Gm., 5 to 20 grains. The constituents have been studied by Power and Rogerson, 1909 and 1912. The *"resin"* is a complex substance, which can be separated by solvents into several glucosidal portions: Jalapin (convolvulin, jalapurgin) and Scammonin (orizabin). *Compound Jalap Powder,* N.F., consists of jalap, 35 per cent, and pot. bitartrate, 65 per cent. Dose, 0.6 to 4 Gm., 10 to 60 grains. *Ipomoea* (Orizaba Jalap, Mexican Scammony) is the dried root of Ipomoea orizabensis. Dose, 0.3 to 1.2 Gm., 5 to 20 grains. *Scammony* is the dried root of Convolvulus Scammonia. It was used by the ancients The dose of *Scammony Resin* is 0.03 to 0.2 Gm., $\frac{1}{2}$ to 3 grains.

COLOCYNTH, ELATERIN AND BRYONIA

A number of plants of the cucumber family yield these drastic drugs. They are of complex composition, each containing several active principles, resinous and alkaloidal. They produce continuous watery stools, with intense irritation and hyperemia. They were formerly employed to reinforce the action of other purgatives, as in the "Compound Cathartic Pills." Colocynth is excreted by the kidneys and milk, and should not be used by nursing women. Elaterin is one of the most powerful cathartics, but is too irritant and causes dangerous prostration.

Bryonia, the root of Bryonia alba and dioica, was used in homeopathy against pneumonia. It was recommended by the "Women Physicians of the Salerno School," about 1100, to redden the face. The introduction of Bryonia into the pleural cavity of animals is said to produce fibrous effusion. According to Jensen, 1915, the fresh root is much more poisonous than the dried. The toxic principles are more abundant in the autumn. At that time the root contains two glucosides: bryonin, soluble in water, inactive; and bryonidin, insoluble in water, paralyzing the nervous system on peritoneal injection. Power, 1912, considers bryonin and bryonidin as impure mixtures and attributes the purgative action to non-glucosidal resins and alkaloids. The dose of Bryonia is from 0.6 to 4.0 Gm., 10 to 60 grains.

Colocynth (Bitter Apple) is the dried pulp of the unripe but full grown fruit of Citrullus Colocynthis. Dose, 0.12 to 0.3 Gm., 2 to 5 grains; 0.6 to 1 Gm. is seriously toxic; 4 Gm. may be fatal. It was one of the constituents of the obsolete "Compound Cathartic Pills" (Comp. Pills of Mercurous Chloride, N.F.). *Gamboge* (Cambogia) is the gum resin from Garcinia Hanburyi. The resin (70 to 80 per cent) contains garanolic acids, which form readily soluble compounds with alkalis, and thus become active in the intestine. The effects resemble those of colocynth; 4 Gm. are fatal. Rarely used in pills. Dose, 0.125 Gm., 2 grains.

Elaterin is a neutral principle obtained from the juice of the fruit of Ecballium Elaterium (used in antiquity). Elaterin consists of two crystalline substances, the levorotatory α-elaterin, which is inert; and 60 to 80 per cent of the active dextrorotatory β-elaterin. Commercial elaterin varies in composition and activity (Power, 1912). Elaterin does not exist as such in the fruit, but is formed during the expression by a diastatic ferment, acting on a glucoside (Berg, 1909). Insol. in water, slightly sol. in alc. (1:325). Dose, 3 to 6 mg., $\frac{1}{20}$ to $\frac{1}{10}$ grain, repeated in five hours if necessary, but not daily; 0.6 Gm. may be fatal. The dose of *elaterium* is 6 to 30 mg., $\frac{1}{10}$ to $\frac{1}{2}$ grain.

◆

CHOLAGOGUES AND CHOLERETICS

The term *cholagogue*, formerly applied to all agents that increase bile flow, is now restricted to those that stimulate evacuation of the gallbladder. Those that increase the actual secretion of bile are termed *choleretics* (Brugsch and Horsters). Significant increase of bile formation is produced by administration of the bile salts and their close derivatives. Salicylate, cinchophen, benzoate and sodium oleate cause some increase; water increases the volume, but not materially the solids. These are practically the only choleretics. The increases reported for other drugs are generally due, not to increased secretion of bile, but to evacuation. The principal cholagogues in this sense are fatty foods; a hormone, "cholecystokinin," produced by them; and (rather weakly) the parasympathetic stimulants (review, A. C. Ivy, 1934). The stools, with moderate *catharsis*, have usually a darker color, suggesting an increased bile content. This is not due to increased secretion of bile, but to the more rapid passage of the intestines, leaving less time for reabsorption and decomposition. The dark color of calomel stools is due chiefly to the oxidation of the bile pigment to a greenish color.

Function of the Gallbladder.—This viscus is not essential, for it is not present in all animals. It is found in most vertebrates, including the mouse, but not in the rat or horse. With the pigeon, it exists in the embryo and disappears later. In man and the animals that have a gallbladder, the bile flows continuously into this reservoir from the liver and is discharged drop by drop into the duodenum during digestion. The slow discharge is advantageous for the emulsification of oil, by securing better contact. The arrival of the bile in the intestines is also a "primer" for increasing the direct secretion of bile, by the absorption of the bile acids. During its sojourn in the gallbladder the bile is concentrated to $\frac{1}{4}$ to $\frac{1}{10}$ of its volume by the absorption of water, together with sufficient inorganic salts to keep it isotonic. This increases the colloids and viscosity to that of a fairly thick mucilage which assists in emulsification. The bile acids, pigments and cholesterol are absorbed slightly.

Evacuation of Gallbladder.—Klee and Klüpfel, 1914, found that this is stimulated by eating, entrance of the chyme into the intestine, injection of Witte's peptone, and especially by the administration of olive oil. No effect was produced by soap and hydrochloric acid. The rhythmic movements are increased during digestion, or by the introduction of acid into the duodenum (Toyoshima and Tsurmaki, 1927). Clinical roentgen observations show that *meals*, especially with fat (cream or egg yolk), evoke gradual contraction and discharge of the gallbladder, beginning when the food passes from the stomach into the duodenum, and generally ending in half an hour, when the gallbladder is about three-fourths emptied (E. A. Boyden, 1927). Similar phenomena have been observed in the flow from the papilla of Vater transplanted into the skin (Winogradow, 1927). The stimulating effect of fats on the gallbladder is not direct, for it is not produced by intravenous injection of emulsified fat or fatty acids or extracts of egg yolk (review, Ivy, 1934).

Cholecystokinin, which exists in acid extracts of the duodenal mucosa, is a potent stimulant of the gallbladder. Intravenous injections of purified fractions raise the gallbladder pressure and secure evacuation, in man as well as in animals. It is probably related to secretin, but they are not identical (review, Ivy, 1934).

Autonomic Drugs on Gallbladder Movements.—The vagus innervation is predominantly motor, the sympathetic inhibitory (Lieb and McWhorter, 1915). Contraction of the gallbladder results in rise of pressure, but not necessarily in evacuation, for the latter requires coordination with the Oddi sphincter.

Parasympathetic Drugs: Pilocarpine, physostigmine, choline and acetylcholine produce marked contraction, but evacuation does not usually result from therapeutic doses in man. Atropine tends to relax the tonus, and therefore permits better filling and tends to delay evacuation. *Sympathetic Stimulants:* Epinephrine and ephedrine have little effect on intravenous injection; they are somewhat depressant to excised preparations. *Muscular Stimulants:* Cholecystokinin contracts and evacuates effectively. With *pituitrin*, hypodermic therapeutic doses in man tend to evacuate, but are less effective than olive oil. The tonus response is variable. *Histamine* increases the intravesical pressure in situ, chiefly by increase in the liver volume. It causes marked contraction in the excised bladder. *Barium* causes contraction. *Guanidine* has little effect. *Muscular Depressants:* Magnesium intravenously, nitrite, ether and alcohol relax the tonus, but have little effect on evacuation. *Miscellaneous: Nicotine* is slightly evacuant in cats; it tends to relax the tonus in situ, and to increase it in the excised. *Ergotamine* produces slight increase of tonus. *Morphine* has little effect, but tends to relax the tonus and increase the amplitude of the rhythmic contraction. *Papaverine*, *sodium salicylate, peptone* and *calomel* have little effect (Lieb and McWhorter, 1915; M. L. Voegtlin and Ivy, 1934, dog in situ; G. M. Higgins *et al.*, 1935, excised; review, Ivy, 1934).

Sphincter of Biliary Papilla.—Reach, 1914, reports that the tonus is increased and the bile flow correspondingly hindered, by morphine, epinephrine, pilocarpine and atropine.

The duodenal-bile reflex to magnesium sulfate is discussed under that drug (see Index).

Choleretic Agents.—The *bile acids* are the most effective substances for increasing the secretion of bile. *Cinchophen* ranks high. It increases the volume up to five times the normal, persisting for four to five hours, with nearly normal concentration of the bile pigments, so that their output is materially increased. The bile salts and cholesterol are decreased. *Salicylates* (5 Gm. per day), benzoates and intravenous injection of phenolphthalein derivatives also cause considerable increase of bile secretion.

The choleretic effect of bile administration was demonstrated by Schiff, 1870. As regards less potent agents, the older experiments on animals with biliary fistulas gave contradictory results because they did not extend over sufficient time to discount the natural variations in bile flow. Reliable experiments on a human patient were made by Pfaff and Balch, 1897. Soto, 1929, working on dogs with aseptic biliary fistulas and fairly constant twenty-four-hour bile secretion, confirmed the choleretic action of salicylate, benzoate and a few others, and the inefficiency of cathartics (calomel, aloes, cascara, phenolphthalein), of sodium sulfate, citrate and acetate, and of methenamine. Chabrol and Maximin, 1929, obtained positive results with bile salts, cinchophen, salicylate and saline cathartics; no increase with acetylsalicylic acid, glycerol, acetyl choline, posterior pituitary and magnesium sulfate. Chabrol, Charonnat *et al.*, 1931, tried some fifty aliphatic substances on biliary fistula dogs, and found only three choleretic (sodium oleate, chloralose and sodium monochloracetate). W. B. Bradley, 1938, studied the response to cinchophen and dehydrocholic acid on biliary fistula dogs.—*Turmeric,* the rhizome of *Curcuma magna,* commonly used in cookery to give a yellow color to relishes, is said to cause marked choleresis by irritation of the hepatic cells; large doses cause fatty degeneration of the liver. It also stimulates the gallbladder. Its action is attributed to a terpene, "curcumene" (Guttenberg, 1927; Kalk and Nissen, 1931).

BILE

The administration of bile or bile salts (sodium glycocholate and taurocholate) stimulates the secretion of bile (Pfaff and Balch, 1897), increases peristalsis (Stadelmann, 1896), and intestinal propulsion (bolus-method, Haney *et al.*, 1939); acts as an indirect antiseptic (Limbourg) by evacuating the intestines; and facilitates the digestion of fat and the solution and absorption of liposoluble substances, such as carotene and K vitamin. They also aid in the absorption of iron. The normal output is fully adequate for these functions, but their administration is indicated whenever the bile fails to reach the intestines after operations on the biliary system. Their use in obstructive jaundice may be limited by the retention symptoms. Added to enemas, bile is used as a laxative against impacted feces and against ascaris, but has little advantage over soap.

The *pharmacologic actions* of bile salts are similar to those of saponins. Like these, they lower surface tension, hemolyze blood, irritate mucous membranes and have a digitalis-like action on the heart. Injection of bile into the intestines does not increase the secretion of pancreatic juice, but weakens the secretory response to injection of peptone, soap and acid (J. E. Thomas and Crider, 1943). Bile is nontoxic by mouth, but when injected into the circulation (Bunting and Brown, 1911) it produces severe nervous and cardiac depression and hemolysis. It is also directly toxic to muscle and nerve. These effects are due to the bile acids. These act as "*hydrotropic*" agents, conferring water solubility on fatty acids, cholesterol, resins, calcium carbonate, phosphate, and the like. The pigments have no marked effect on the circulation or respiration, even on intravenous injection (W. C. Emerson, 1929).

Toxic symptoms of biliary retention (obstruction) consist in dulness, delirium, convulsions, fever, generally fatal in a few days. It is not certain that these effects are due entirely to bile acids or pigments.

The *chemical structure of cholic acid* is related to that of cholesterol, differing chiefly in the side chains. It seems to be formed exclusively in the liver, and bile salts are decreased or abolished by hepatoxic poisons, chloroform or carbon tetrachloride (Bollmann and Mann, 1936). It exists in the bile solely as conjugated compounds with amino acids, glycocholic acid with glycine, and taurocholic acid with taurine, the latter being less toxic. If free cholic acid is administered, it is conjugated so far as glycine, taurine and time are available (Josephson *et al.*, 1938). *Endogenous bile acid production* depends largely on diet. It is high with meats, especially those rich in tryptophane and proline; carbohydrates decrease it; cholesterol has no effect (Foster, Hooper and Whipple, 1941). Numerous derivatives have been prepared synthetically. Cholic acid is also related to bufotalin (toal poison); saponins have a similar structure.

Fate.—Bile salts are *absorbed* promptly and almost completely from the intestines (A. L. Berman *et al.*, 1940), carried to the liver by the portal blood, and again reexcreted into the bile. Only a small part is lost in this cycle (Hoppe-Seyler, 1863), and correspondingly little is synthesized. If bile salts are injected into a vein they are promptly absorbed by the vascular endothelium and then enter the cycle. Very little goes into the urine (review, B. Josephson, 1941). The daily output of cholic acid from biliary fistulas in man ranges from 1 to 2.3 Gm. If the bile is refed, the daily output is about four times this figure (Josephson and Larsson). Treatment with thyroxin interferes with biliary secretion (L. H. Schmidt, 1937).

Choleretic Action.—Intravenous injection of bile salts increases the rate of bile flow to double or more. The action begins in about fifteen minutes and lasts one to two hours. The total output of bile acids, pigment and cholesterol is also increased, although their concentration in the bile may be diminished. This is followed by a compensatory decrease as their level in the serum falls. The total excretion of bile salts falls somewhat below the amount administered (H. A. McGuigan, 1944). The same changes can be produced clinically by oral administration of bile salts or bile. Conjugated bile acids are more effective than cholic acid, and are surpassed by some of the derivatives; for instance, dehydrocholic acid and deoxycholic acid (Hooper and Whipple, 1917; Doubilet, 1937).

Intestinal Absorption.—*Oleic acid,* which is practically unabsorbable from intestinal loops in the absence of bile, is absorbed when bile salts are introduced, practically parallel to their concentration (Verzár and Laszt, 1934; Riegel *et al.*, 1935). In buffer mixtures of *p*H above 6.25, oleic acid is completely dissolved by bile salts, ultramicroscopic observations and diffusion experiments indicating true molecular solution (Verzár and Kuthy, 1929; review, A. C. Frazer, 1940). Bile salts do not exert a hydrotropic action on neutral fats, but promote their emulsification. Lipase is activated partly at least by the emulsification of the fat. Liver esterase is inhibited. The favorable effects on the *absorption of the fat-soluble vitamins A, D and K,* of *carotene* and of *iron* are discussed under these substances (see Index).

The *hemorrhagic tendency* of the biliary deficiency of obstructive jaundice and of biliary fistulas is due to deficiency of prothrombin, which results from the failure to absorb K vitamin in the absence of bile acids. It is promptly corrected by the oral administration of bile acids together with K vitamin, as such or in the diet (Nygaard, 1932; A. J. Quick *et al.*, 1935; Hawkins *et al.*, 1938; E. D. Warner *et al.*, 1938). Hoessler and Stebbins, 1919, claimed that *direct addition of bile to blood* also delays clotting

Detoxifying Action of Bile.—Addition of acids to bile precipitates the bile acids, which then adsorb alkaloids, toxins and other substances (Clementi and Pistorio, 1929).

Bile Salts in Gonorrhea.—Loehlein, 1909, introduced the local injection of bile salts in the acute stage for destroying the gonococci. Hofmann, 1912, found that 1 to 2 per cent had little effect; 5 to 10 per cent gave better but only temporary results.

Toxicity.—Excessive concentrations of bile salts are highly toxic. Small doses stimulate the vagus center; larger doses depress the heart directly, with slow irregular pulse and low blood pressure. They also produce depression of the medullary centers, coma and paralysis; and hemolysis and cell destruction. They have a local vasoconstrictor action (Samelson). Eel serum poison, *ichthyotoxin,* appears to be related to the bile acids (F. Flury, 1929).

Neuromuscular Systems.—The bile salts were reported to act chiefly on the myoneural junction and on the reflex centers of the cord (F. A. Ries and Still, 1930). Bile and bile salts increase *peristalsis* clinically on oral administration or by enema (Glaessner and Singer, 1910). They increase markedly the propulsion of a bolus when introduced into a Vella loop of dog intestine. The other constituents of bile are not concerned in this (Haney *et al.*, 1939). On excised small or large intestines, bile or bile salts produce mainly depression (Ott and Scott, 1909; C. Schwarz and Magerl, 1924), but the large intestines may be stimulated (Schuepbach, 1910). Bile and bile salts, in moderate concentrations, increase the contractions of the pregnant, not of the virgin, uterus. High concentrations inhibit (Cantoni, 1914). Tommaselli, 1930, obtained complete paralysis even with 1:30,000 dilution of sodium cholate. *Excised frog hearts* are strengthened by low concentrations of bile salts. Moderate concentrations cause weakening and irregularity; higher concentrations produce systolic arrest (Shoda and Tominaga, 1927). Bile salts produce reversible contracture of *skeletal muscle. Motor nerve* is first stimulated then depressed by immersion in solution of fresh bile (Perichanjanz, 1921). Purified bile salts are only slightly toxic to muscle and nerve fibers (Ries and Still, 1930).

Cholic acid derivatives have been introduced for therapeutic use, especially for intravenous injection of the sodium salts, as being less toxic than and perhaps twice as potent as ordinary bile salts. For oral administration, however, Doubilet, 1937, found the natural conjugated cholic acid more effective than the desoxycholic, and this more than dehydrocholic acid.

Dehydrocholic acid, N.N.R. (decholin), an oxidation product of cholic acid, is used by mouth or intravenously to increase the volume of bile in the postoperative management of bile tract surgery; in functional insufficiency of the liver and to hasten the shadow of roentgenopaque substances in cholecystography. It does not stimulate gallbladder evacuation. It is contraindicated in complete biliary obstruction, and does not materially hasten the clearance of jaundice after a biliary obstruction is removed. It is claimed to have only a tenth of the *toxicity* of the taurocholate, intravenously (Gillert, 1928). Repeated injections of large doses cause diarrhea. *Renal lesions* with regressive and regenerative changes of the tubular epithelium have been reported in animals. They suggest caution in this therapeutic use (H. L. Stewart and Cantarow, 1935). It is reported to be *diuretic* in hepatic cirrhosis and to potentiate the clinical diuretic response to salyrgan (de Castro, 1934) and to mercupurin (Modell and Gold, 1944). The *choleretic action* amounts to about 40 per cent of the bile volume after intravenous injection of 2 Gm. of the sodium salt into patients (Rusznyak, 1927). In dogs, 5 mg. per Kg. by vein increases the flow to six and one-half times during the first hour (W. B. Bradley, 1938). The *hemolytic* action is only $\frac{1}{120}$ that of the tauro- or glycocholate *in vitro*, and is not attained clinically (E. E. Ziegler, 1931; E. Neubauer, 1921 to 1927). It has the *hydrotropic action* of bile salts and renders estrogens diffusible (Cantarow *et al.*, 1944). The oral dosage is 0.25 to 0.5 Gm. two or three times daily, after meals, for four to six weeks. It has a bitter taste. *Sodium dehydrocholate* is injected slowly by vein as 5 to 10 cc. of the 20 per cent solution, on three successive days. A *circulation-time test* involves perception of the bitter taste after injection of 3 cc.

Deoxycholic acid (*degalol*) was investigated especially by Heinrich Wieland, 1920, and J. Pohl, 1922. The choleretic response on intravenous injection is about double that of cholic acid. Wieland reported that it is twice as toxic; E. U. Still, 1929, claims that it is slightly less toxic. Its advantage appears doubtful (report, Council on Pharmacy and Chemistry, 1941, J.A.M.A., *117*:361).

Ketacholanic acid, a mixture of oxidation products of bile acids, is claimed to have a lower toxicity than the other derivatives, with about equal choleretic potency (C. F. G. Dolkart, 1937).

Bile Pigment.—In man this consists almost entirely of bilirubin; this may be oxidized to biliverdin, which is much more abundant in animals than in man. Bile pigment is formed from hemoglobin and myohemoglobin by the reticulo-endothelial cells generally, especially in the bone marrow, spleen and liver (Whipple and Hooper, 1913), but the role of the liver is chiefly that of excretion (Mann, 1927). Its formation continues after removal of the liver (F. C. Mann, Bollman and Magrath, 1924) and of all abdominal viscera (A. R. Rich, 1925). Its quantity depends on the rate of blood destruction. Bilirubin is chiefly responsible for the yellow color of normal blood serum, although carotenemia may play a part (E. F. Nation and Myers, 1934). The blood plasma normally contains 0.5 to 1.5 mg. of bilirubin per 100 cc.; in severe jaundice this may rise above 40 mg. (review, V. C. Myers and Muntwyler, 1940). The jaundiced color becomes perceptible when the plasma concentration reaches 2 mg. per cent. This generally involves impairment of the hepatic excretion or biliary obstruction; overproduction occurs in hemolytic jaundice; decreased formation in secondary anemia. Addis believed that bilirubin can be resynthesized into hemoglobin. Bile pigments are not absorbed from the intestines (Bollman *et al.*, 1926) Injected bilirubin is not stored. Its injection serves as a liver function test (Harrop and Barron, 1931). *Urobilin* is formed from bile pigment by the liver and bile passages; stercobilin is formed from urobilin by the intestinal bacteria.

Preparations.—*Ox Bile Extract*, U.S.P. (Ext. Fellis Bovis; Purified Oxgall), is an alcoholic extract of bile from the ox (Bos taurus), evaporated and mixed with starch, 1 Gm. representing 8 Gm. of fresh bile. Fresh ox bile contains about 3 per cent each of sodium glycocholate and taurocholate. Very bitter, yellow powder. Dose, 0.3 to 1 Gm., 5 to 15 grains; in pills or formaldehyde-hardened capsules; as enema, 2 per cent. *Ox Bile Extract Tablets*, U.S.P.; usual size 0.3 Gm. Various commercial preparations of *Bile Salts* are used as pills, generally 0.03 to 0.2 Gm.; or as suppositories, in the same dosage. *Sodium Cholate* (not to be confused with sodium cholalate) is a misnomer for "Plattner's Bile," a preparation of impure bile salts. Laxative dose, 0.3 Gm.; or by enema, 0.2 to 0.5 Gm.

◆

ANTHELMINTICS

Anthelmintics (*anti*, against; *helminthos*, worm) are remedies used against intestinal parasites. Active peristalsis tends to remove worms, as well as the other intestinal contents. Active cathartics are therefore *vermifuges*—*i. e.*, drugs which expel parasites. Catharsis alone, however, is usually only partly effective, since the worms fix themselves to the intestinal wall by suckers or hooks; or they may travel against the direction of peristalsis. They must therefore be weakened, narcotized or killed, if the cathartic is to be effective. Most drugs toxic to earthworms produce primary irritation or agitation, resulting in withdrawal of the worm from the neighborhood of the poison. This is probably an important factor in the clinical effect of vermifuges.

The paralyzants or *vermicides* may also become toxic to the host, and should therefore be used only after a positive diagnosis has been made, and then in the smallest adequate doses and under the best conditions. To be available in practice, a vermicide must either be poorly absorbable or it must be specifically toxic to the worms. All vermicides are more or less toxic to all worms, but there is some predilection. In some cases, simultaneous administration of two anthelmintics may be more additive for the worms than for the host. The subject is covered in the book of Chandler and Chopra, "Anthelmintics and their Uses," Baltimore, 1928.

The choice of the special vermicides is based mainly on clinical experience. *Oxyuris* (pinworms), which are mostly in the lower intestines, are treated by enemas of soapsuds, quassia or ferric chloride; but if they are not all reached by these, gentian violet as enteric pills, carbon tetrachloride or chenopodium oil are given by mouth. *Ascaris* (roundworms) are treated with hexylresorcinol pills, formerly with santonin, chenopodium or spigelia; *hookworm* by carbon tetrachloride, chenopodium, betanaphthol, thymol or hexylresorcinol.

Chandler and Chopra recommend carbon tetrachloride for necator (American hookworm), and this combined with chenopodium for ankylostoma (European hookworm). *Tapeworms* are difficult to eradicate because the head is imbedded in the mucosa and is not easily reached from the intestinal lumen. It regenerates the segments which are killed by the vermicide. Liquid diet and other points of technic are important. Tapeworms are treated mainly by aspidium (especially for Bothriocephalus), pelletierine (especially for Taenia), and kosotoxin. Carbon tetrachloride is fairly effective. Gentian violet enteric pills are first choice against *strongyloidiasis* (review, E. C. Faust, 1946). The most difficult parasites are the *whipworms* that reside in the cecum, where the vermicides do not penetrate. It has been suggested that these be treated by intravenous injections, *f. i.*, of neoarsphenamine (Hall and Shillinger, 1924); but this, too, would not reach the cecal contents. Surgical removal may be the only effective treatment.

The effectiveness of anthelmintics may be studied on dogs by comparing the number of worms removed with those remaining, as found by autopsy (Hall and Shillinger, 1924). This needs to be checked by clinical trials, since the conditions of the alimentary tract are different. Preliminary tests may be made by exposing ascarids or other worms to the agents *in vitro*. All clinical anthelmintics are markedly toxic to *earthworms*. These may therefore be used to determine whether a substance has any anthelmintic value, and to compare the relative activity of different samples of a drug, although Lamson and Ward, 1936, claim that the toxicity to earthworms does not correlate closely with pig's ascarids. The "*eelworms*" of vinegar (anguillula aceti) were used as test objects by Rath, 1929, and by Belehradek and Necasova, 1929. In any case, *in vitro* tests need not parallel the comparative clinical value of different anthelmintics; since this often involves factors other than simple vermicidal efficiency, such as toxicity for the patient, irritation of the intestines, etc.

The following are some of the more important results observed on earthworms (Sollmann, 1918): Highly effective are aspidium, betanaphthol, carvacrol, chenopodium oil, chloroform, dibrom and dichlorbenzol, pelletierine and thymol. Santonin is also highly active in the presence of a suitable solvent (mixture of bile salts and sodium bicarbonate). Fresh pumpkin and squash seeds are quite efficient, the active principles being soluble in water and injured by boiling. Fairly efficient are granatum, kamal, kousso. Spigelia is weak.

The routine of the anthelmintic treatment should aim to secure optimal conditions for toxicity to the parasites, and the minimum of toxic effects for the patient. Preliminary fasting and purgation may be employed to clear away protective mucus. These measures also tend to weaken the patient and to increase absorption. *Chenopodium oil and carbon tetrachloride* are quite as effective against ascaris and hookworm and are less toxic to the patient, without elaborate preliminary treatment, merely making the preceding meal light and not too bulky, and with a minimum of fat. The drug may be administered three hours after this meal. For *tapeworm*, however, it is advisable to precede the drug with two days of liquid diet, and to administer a purgative (a tablespoonful of magnesium sulfate in a glass of water) on the preceding night and on the morning of the administration. The anthelmintic is taken fasting, early in the morning, followed two hours later by the second dose of magnesium sulfate. It appears better to take the anthelmintic as a single dose rather than in divided doses, since the former insures the highest concentration, and divided doses increase the absorbing surface. Breakfast may be eaten an hour later. In case of failure, several days should elapse, one or two weeks for tapeworm, before repeating the treatment; this applies even if the failure is due to loss of the anthelmintic by vomiting Pregnancy does not greatly increase the risk of anthelmintics (animal experiments, Savignoni and de Maria, 1933), but they should be avoided if possible.

Catharsis.—Safe doses of the vermicides usually depress but do not kill the parasites, and these would recover if left in the intestines. It is necessary, therefore, to follow the vermicide by an active cathartic. This also prevents further absorption of the drug and so diminishes the toxicity. It should be timed according to the location of the parasites: for hookworm and ascaris it may be administered with the anthelmintic; for tapeworm, one or two hours later; and for oxyuris and trichuris, two or three hours later. Magnesium sulfate (a tablespoonful in a glass of water) is satisfactory as cathartic, and the magnesium may perhaps further depress the worm. There is no harm in giving calomel with the magnesium sulfate. Castor oil produces a satisfactory catharsis, but it has been feared that it may increase the absorbability of most of the anthelmintics, since these are more soluble in oil. This is doubtful, but as it has no advantage over Epsom salt, the latter is generally preferred.

Adjuvant Condiments.—Mustard, pepper or onions are recommended to be used freely in the preparatory supper. These are in fact fairly active vermicides, and while not sufficiently powerful alone, they aid materially the medicinal vermicides (Sollmann, 1918).

CARBON TETRACHLORIDE

This methane derivative, CCl_4, is an effective and inexpensive agent for the treatment of hookworm and tapeworm infection. It is less effective against other worms. Since it is slowly absorbed from the alimentary tract, and is itself somewhat cathartic, the anthelmintic dose lies much below the ordinary toxic dose (probably about as 1:50), and even minor disturbances are generally absent if a saline cathartic is given. Some patients complain of headache, however, and death has occurred, so that its use is not recommended. If the drug is absorbed, it acts similarly to chloroform, being somewhat narcotic, and leading to serious degenerative changes in the liver. With gastric administration this degree of absorption is reached only in the slow intestinal progress of herbivorous animals. Rabbits and sheep, for example, are very susceptible. In man, serious toxic symptoms have occurred from large doses administered against ascaris, and from the inhalation of the vapor when it was used for drying the hair after shampooing; it is a hazard in its use as a cleaning fluid ("*carbona*"), although there is no danger in the use of small quantities for sponging. It is also used extensively as a nonexplosive fat solvent. Industrial poisoning in rubber factories was described by Hamilton, 1915. If ventilation is inadequate, the vapor resulting from the use of carbon tetrachloride may cause serious effects, such as local dermatitis, acute inflammation of the eyes and respiratory tract, and even pneumonia. Chronic intoxication may result in liver degeneration and nephritis. A concentration in the air of 0.1 per cent by volume is considered dangerous; heating the vapor is especially dangerous, since phosgene may be produced by temperatures over 200° F. It is used in fire extinguishers ("*pyrene*"), but this is inadvisable, as fatalities have occurred from the phosgene production in confined space (reference, J.A.M.A., *101:* 1239). *Industrial dermatitis* has been reported from prolonged contact (L. Schwartz, 1939). Good results have been reported from its application to dermatophytoses and burns (G. M. Fasting, 1944).

Use as Anthelmintic.—Carbon tetrachloride is especially effective against necator, less potent against ankylostoma, fairly effective against ascaris, but inferior to chenopodium or santonin. It has little effect against tapeworm.

The anthelmintic action of carbon tetrachloride was demonstrated on dogs by Hall, 1921, and confirmed on man by Nicholls and Hampton, 1922, and especially by S. M. Lambert, 1922. The first dose is usually completely effective in about 95 per cent of the patients. Its effectiveness against *intestinal protozoa* is low, although paramecia are killed instantly by 1:3000 solution.

Administration as Anthelmintic.—Carbon tetrachloride is an active irritant, and is therefore administered in gelatin capsules. Patients should be warned to swallow the capsules promptly, and not to break them in the mouth. The adult dose is 2 to 3 cc. (30 to 45 minims); for children, 0.13 cc. (2 minims) for each year of age up to fifteen years. It should be taken fasting, in the morning. A purgative dose of magnesium sulfate is administered two or three hours after the anthelmintic. It is also advisable to administer a laxative dose of the salt on the preceding day. A test dose of chenopodium oil (3 cc., 45 min.) may be given a week after the carbon tetrachloride to check the success. The administration of the tetrachloride should not be repeated within three weeks. The first dose generally removes 95 per cent of the hookworms, sometimes all. A diet rich in calcium (milk) and carbohydrates should be used for several days in advance, to protect the liver. Fats, including castor oil, and alcohol favor absorption and should not be taken while the drug is in the intestinal tract.

Chandler and Chopra, 1928, suggest the use of carbon tetrachloride and chenopodium oil together, as more effective and less toxic. For ankylostoma or ascaris they recommend 2 cc. of the tetrachloride and 1 cc. of chenopodium, and for necator 3 cc. of the tetrachloride and ½ to 1 cc. of chenopodium, the latter administered in capsules, and the carbon tetrachloride in milk, which diminishes gastric irritation.

Klotz, 1934, reported that adsorption by the tetrachloride on charcoal retains its anthelmintic potency but diminishes its toxicity.

Fate.—The *absorption* is at first rapid, then slow. It is usually stated that alcohol increases the clinical toxicity, presumably by hastening absorption; but in animals this occurs only with 95 per cent alcohol; it is not altered by 50 per cent. Magnesium sulfate also had little effect

(Wells *et al.*, 1925). Large doses are excreted with the fat of the feces. The absorption, distribution and excretion have been studied in dogs by B. H. Robbins, 1929.

Clinical side actions occur especially if the drug is given without the cathartic, or on a full stomach, so that the sojourn is prolonged. Fat appears especially deleterious. The most frequent symptom is headache, which may persist for several days. Many patients become sleepy. Nausea and vomiting are rather exceptional. The immediate toxicity is low because of the limited absorption; even 250 cc. administered to dogs may cause only slight and transient symptoms. The effects on the circulation and central nervous system are similar to those of chloroform. Like this, tetrachroride irritates the skin on local application, and the respiratory mucous membranes if the vapor is inhaled. The serious and fatal effect, hepatic degeneration, occurs later, sometimes with ordinary therapeutic doses, especially in patients addicted to alcohol, in whom the liver may have been impaired. With such patients, it would seem advisable to make a preliminary test of the functional capacity of the liver. Ascaris infections also give a high toxicity, partly by obstructing the evacuation of the drug, and partly by diminishing the resistance of the patients (Tomb and Helmy, 1933).

Toxicity for Animals.—Rabbits succumb to 4 cc. per Kg., while dogs are apparently uninjured by 25 cc. per Kg., by mouth. Administration of 3 to 25 cc. to dogs on alternate days for fifteen weeks caused no loss in weight or other disturbance of health, but autopsy showed early cirrhosis of the liver (P. D. Lamson and Wing, 1926). The difference depends on absorption, for both animals are about equally susceptible to inhalation. Puppies are more susceptible than full grown dogs. Monkeys are uninjured by 1 to 5 cc. by mouth, every two or three days for twelve to sixteen doses. It is much more toxic for cats than for dogs, causing more damage to the liver and kidneys, but the latter are not injured by therapeutic doses. The administration of sugar with the carbon tetrachloride diminishes the damage to the liver in cats, but not in dogs. Sodium citrate diminishes the toxicity by increasing the alkalinity of the intestine, while hydrochloric acid increases the toxicity; magnesium sulfate decreases the toxicity by purgation (A. C. Chandler and Chopra, 1926); fats and alcohol increase the toxicity (Lamson, 1923). Pregnancy does not increase the toxicity as it does with chenopodium.

Bromosulphthalein retention is the most suitable test for hepatic dysfunction in mice (J. Casals and Olitsky, 1946).

Toxic Effects after Oral Administration.—These consist especially in severe damage to the liver, shown by liver-function tests, diminished coagulability of the blood, bilirubinemia, and by the pathological changes at necropsy. There are also nervous symptoms, and death occurs after several days (Lamson, 1923).

Hepatic degeneration, similar to that of chloroform, arsphenamine and phosphorus, is likely to follow especially on continued administration, but three-fourths of the liver may be necrotic in dogs after a single dose of 4 cc. per Kg., and in cats the liver may be practically completely destroyed by 0.25 cc. per Kg. Cats are also more susceptible to renal damage. The liver injury is greatest about forty-eight hours after administration; if this period is survived and the drug is not repeated, rapid repair sets in and after a few days little evidence of the injury remains. Continued administration to dogs, 3 to 15 cc. on alternate days for fifteen weeks, leads to atrophic hepatic cirrhosis (Lamson and Wing, 1926; Chandler and Chopra, 1926). Tracer experiments with deuterium show that the liver fat comes from fat depots. With severe intoxication, acute or chronic, the parenchymatous degeneration extends to other organs; cellular infiltration predominates if the intoxication lasts over eight days in rabbits (Binacalani, 1934). The liver injury prevents the formation of bile salts (Bollman and Mann, 1936). It raises the cholesterol level of the blood (Dervillée *et al.*, 1938). The guanidine level rises in this as in other acute (but not chronic) hepatitis (J. T. Cutler). The degree and permanence of the hepatic lesions on *multiple exposures of rats depend* on the intervals (Cameron and Karuna-Ratne, 1936; Rao, 1936). They range from acute necrosis to hobnail fibrosis, similar to human cirrhosis. The spleen also increases by two to ten times the normal size. Severe progressive macrocytic and hyperchromic anemia develops with bone marrow changes similar to those of pernicious anemia. There is early leukocytosis, later leukopenia (Higgins and Stasney, 1936). Recovery occurs three to six weeks after discontinuing (R. W. Heinle, 1938). Repeated oral administration to mice results in *hepatomas*, resembling those that occur spontaneously or with o-aminoazotoluene (J. E. Edwards and Dalton, 1943).

Toxic effects of inhalation are more acute and chiefly narcotic (Lehmann, 1911; he also investigated other aliphatic fluorine derivatives). Excessive concentrations may be fatal by respiratory or cardiac failure (Lamson). A nearly fatal result occurred from its inhalation when it was used to remove adhesive tape near the face (F. M. Chandler, 1936). Hepatitis has also followed its inhalation in a confined space (Butch, 1932). Three cases of *acute nephrosis* from inhalation, one fatal, are reported by J. R. Forbes, 1944. H. Smetana, 1939, found renal symptoms in nearly a fourth of the toxic cases; more frequently when the exposure was repeated (review, Corcoran *et al.*, 1943). *Toxic concentrations of the vapor* are especially important in industry. Continuous exposure during the whole working day is safe with to 100 parts of vapor per million (by volume); 1000 ppm is safe for peak periods of half an hour, if the total average per day does not exceed 100 ppm; 1600 ppm is safe only for ten or fifteen minutes. Animals exposed continuously to 50 to 400 ppm may at first develop some hepatic and renal degeneration, but they soon recover even with continued exposure, and the regenerated cells have a greater resistance, so that the liability to hepatitis decreases. This may explain the infrequency of cirrhosis in industrial workers. The limiting concentration of 100 ppm has a faint odor to persons coming from fresh air; if the odor is more than faint, the concentration is too high for safety (H. F. Smyth, 1935; Smyth *et al.*, 1936). The recognition and treatment of carbon tetrachloride poisoning are discussed by the Council of Industrial Health, 1946, J.A.M.A., *132:* 786.

Dietary protection against hepatic injury and its consequences is secured to a considerable degree by richness of carbohydrate protein and calcium, and limitation of fats. This holds also for other hepatites.

High glycogen content appears to render the liver cells more resistant to degeneration. High carbohydrate is also important to counteract the tendency to hypoglycemia. It may be advisable to administer insulin with sugar. The renal damage is not decreased (Chandler and Chopra, 1926). Liver injury from chloroform increases with the lipid content of the liver cells (Goldschmidt *et al.*, 1939). The relation to *meat diet* is not so clear. However, Messinger and Hawkins, 1940, showed that feeding with proteins as well as carbohydrates protects against liver injury by arsphenamine. Miller, Ross and Whipple, 1940, found that proteins protect against the hepatotoxic action of chloroform, and showed that this is due chiefly to methionine, and, to a less degree, to cystine. Brunschwig *et al.*, 1945, report protection against carbon tetrachloride liver injury of rats in decreasing degree by sodium thioglycollate, glycollate, glutathione, thiomalate, malate and cysteine; not significantly by aspartic acid, acetate, glutamate, methionine, choline and cystine. Beattie *et al.*, 1944, report successful treatment by *methionine* of a patient with carbon tetrachloride liver enlargement. Daily doses of 3 to 5 Gm. of methionine also protect against trinitrotoluene hepatitis (J. H. Eddy, Jr., 1945); but recovery from infectious hepatitis was not significantly accelerated by such dietary measures (Hoagland and Shank, 1946). In rats inhaling about 300 ppm for six months, methionine and low fat diet protect better against renal injury than against hepatic cirrhosis (P. György, Seifter *et al.*, 1946). Various vitamins, including p-aminobenzoic acid, do not protect (Forbes *et al.*, 1942). Calcium administration was introduced by A. S. Minot and Cutler (J. T. Cutler, 1932) to combat the effects of increased guanidine concentration of the blood which they consider responsible for the toxic phenomena. This is their reason for restricting meat. Cantarow *et al.*, 1938, confirm that the calcium therapy reduced the mortality in cats by half. Chandler and Chopra, 1926, found the toxicity increased by ammonium chloride, decreased by sodium citrate. *Administration of liver preparations* also tends to decrease hepatic necrosis and cirrhosis (H. C. Forbes, 1938).

Carbon Tetrachloride, U.S.P. (Tetrachloromethane, CCl_4), is a clear, colorless fluid. Odor resembles that of chloroform. Not inflammable. Slowly decomposed by light and by various metals in the presence of moisture. Very slightly soluble in water (1:2000). Miscible with alcohol, oils and fat solvents. Dose, 2 to 3 cc., 30 to 45 minims, with caution! *Carbon Tetrachloride Capsules,* U.S.P.; the usual size contains 1 cc.

Other chlorinated hydrocarbons are also potent anthelmintics. Tetrachlorethylene is the most important. *Chloroform* has been used clinically, but is absorbed too readily, as its solubility in water is eight times that of carbon tetrachloride. Other chlorinated aliphatics are used as cleansing agents and lacquer solvents, for instance, *di- and trichlorethylene* and *tetrachloracetylene.* All are liable to produce hepatitis.

Tetrachloroethylene, $CCl_2{:}CCl_2$, is highly *effective* against hookworm, somewhat less against necator than against ankylostoma. It has promise against trichuris and intestinal flukes. It is less efficient against other worms. It is not advised against ascaris, as it causes their migration. It is *safer* than carbon tetrachloride and at least as effective. Therapeutic doses do not damage the liver, but there may be some narcotic effects, giddiness, vomiting and drowsiness; it is therefore well to keep the patient in bed during the treatment. It does not raise the guanidine level of the blood as does the tetrachloride. However, Christensen and Lynch, 1933, claim depression of the heart and respiration and visceral changes. Coma similar to that from chloroform may occur, but is rare (J. H. Sandground, 1941). The drug was introduced by M. C. Hall and Shillinger, 1925, as anthelmintic for dogs. The *clinical dosage* is 1 to 3 cc. in soft capsules of 1 cc. or on a lump of sugar. An ounce or ounce and a half of magnesium sulfate should be administered on the preceding evening, and again two hours after taking the capsules. The patient should fast until the bowels have moved. Fats and alcohol should be avoided. One dose often suffices, and it should not be repeated in less than ten days. It may be given with chenopodium oil. It forms phosgene on exposure to the air, and broken capsules should not be used (Lamson, Robbins and Ward, 1929; Maplestone and Chopra, 1933; Christensen and Lynch, 1933; H. F. Garrison, 1934).

Tetrachloroethylene, U.S.P., is a colorless liquid, boiling at about 121° C. not inflammable; practically insoluble in water, soluble in alcohol and in oils. Average dose, 3 cc. *Tetrachloroethylene Capsules,* U.S.P., usual sizes 0.2, 1 and 2.5 cc.

Carbon tetrachlorethane is also used against hookworm (Maplestone and Mukerjii, 1933).

Trichloroethylene is used especially against oxyuris. It is administered by mouth, fasting, 0.1 cc. per year of age, in 200 cc. of Magnesium Citrate Solution (W. H. Wright *et al.*, 1937). The total should not ordinarily exceed 1.2 cc.

CHENOPODIUM OIL

The volatile oil distilled from American Wormseed is effective, especially against round-worm, hookworm and intestinal amebas. Against hookworms, it is equally or more successful than thymol, and is less unpleasant. It does not require a preliminary fast, and does not usually make the patient sick (Coutant, 1916). It is relatively safe, although the full doses are sometimes toxic. It should not be given to debilitated patients. Children are much more susceptible to poisoning than are adults. The activity, both anthelmintic and toxic, is due chiefly to *ascaridol,* the less volatile fraction, which constitutes 45 to 70 per cent of the oil (Malloy, 1923). The less volatile fraction is less irritant and less emetic (M. C. Hall and Hamilton, 1918).

Historical.—Wormseed was used by the American Indians, probably before Columbus. The oil was employed in medical practice against ascaris, but was not esteemed highly unitl it was introduced against hookworm by Schüffner and Verwoort, 1913.

The anthelmintic efficiency is high against all kinds of nematodes, and low for tapeworms. It is about equal to carbon tetrachloride against necator and more effective than carbon tetrachloride against ankylostoma and ascaris. A single dose of 2 cc. of the oil for adults removes 90 to 95 per cent of the necators, and effects complete removal in 40 per cent of the patients. With ankylostoma it removes 80 to 85 per cent of the worms, with complete removal in 30 per cent (*Hookworms:* Schüffner and Verwoort, 1913; Darling *et al.*, 1918; *Ascaris:* Bruening, 1906, 1912; M. C. Hall and Foster, 1917. *Other parasites:* Darling *et al.*, 1918; Hall and Shillinger, 1924). The effects on the worms are similar to those of santonin, viz., peripheral stimulation, followed with large doses by paralysis (Trendelenburg, 1915).

Amebic Dysentery.—Chenopodium administered as for hookworm promptly relieves the clinical symptoms of subacute and chronic amebic dysenteries and causes the disappearance of the amebas from the stools. Chenopodium may be successful in patients and carriers that have resisted emetine because of the encysted amebas. Relapse may occur, but not oftener than with ipecac (E. L. Walker and Emrich, 1917; Barnes and Coot, 1918).

The administration of chenopodium oil against hookworm does not require preliminary fasting or purging, but the oil is nauseating and must be given in divided doses, 3 capsules of 0.5 cc. (10 minims) at intervals of an hour; 1 cc. with the same spacing is not quite safe. An ounce of saturated solution of magnesium sulfate or a tablespoonful of castor oil is given an hour before the last dose, as the ordinary dosage does not kill but merely paralyzes the worms. Both purgatives decrease rather than increase the toxicity of chenopodium oil (Hall and Shillinger, 1924). If inordinate depression or somnolence or any toxic manifestations set in, the dosage should be discontinued and the saline purge administered at once. The course is repeated every three to five days. until the parasites have disappeared from the feces. The dosage for children is 1 drop per year, on sugar. The treatment may be contraindicated during the fever or acute gastrointestinal inflammations. *Ascaridol* has about twice the potency of the oil and could be used in half the dosage, with less irritation, but it is expensive.

Dosage against Ascaris.—For children, 5 to 10 drops of the oil are given on sugar two or three times a day for two days and followed by a tablespoonful of castor oil (Levy, 1914).

Minor Side Effects of Therapeutic Doses.—Nearly a third of the patients react by some degree of dizziness, nausea, vomiting, tingling in hands and feet, temporary deafness or general depression (D. A. Roth, 1918). Dizziness and nausea are the most frequent. Vomiting, sometimes with streaks of blood, occurs in about 16 per cent of the cases, and increases with the dosage (Darling *et al.*, 1918). *Deafness* occurs in 20 per cent. It varies in intensity from a disagreeable after-effect to complete bilateral loss of hearing, lasting usually for a week to several months, but in rare cases still present after two years (Roth, 1918; Oppikofer, 1919). Oka, 1929, attributes the injury primarily to degeneration of the spiral ganglia, with changes in the Nissl bodies.

Severe human intoxications are exceptional and generally attributable to gross overdosage. However, severe poisoning has been described after two doses of 10 minims, four hours apart (Coutant, 1916), and death has occurred after two treatments with 3 cc. within a week. The symptoms consist in extreme dizziness, prostration, headache, somnolence, stupor. The face is flushed, the respiration is slow; the pupils are sluggish; the hearing is disturbed; the eye muscles may be paralyzed. Albuminuria is frequent. About 70 per cent of the severe cases terminate fatally with rapid stupor and coma, tachycardia, convulsions, rarely hemiplegia. Death occurs usually after two or three days of coma (Levy, 1914; Darling *et al.*, 1918). The *treatment* consists in purgatives and stimulants (Motter, 1914).

Toxic effects on animals have been studied especially by Salant and his co-workers, 1910 to 1916. The toxicity varies greatly, even with intravenous injection. It is increased by starvation, diminished by abundant diet. Cumulative effects have also been observed. Intact animals first show depression of the higher centers, then convulsions. There is a cardiac fall of blood pressure and organ volume, with slowed heart and decreased vagus irritability Somewhat larger doses also decrease the rate and amplitude of the respiration, independently of the circulation. Peristalsis is diminished, by intravenous injection, as well as in the excised intestine. The depression is antagonized by barium, but not by pilocarpine. Renal irritation is also evidenced. Caffeine antagonizes the respiratory depression; epinephrine and digitalis the cardiac depression (Salant and Livingston, 1916). Oral and hypodermic administration may cause *renal disturbance* in rabbits fed on oats, but not in those fed on carrots (Salant and Bengis, 1917). The *mucous membranes* are severely inflamed and remain hypersensitive for five to nine days. Previous administration of fatty oils is protective (Bruening, 1912). Application of ascaridol to the mucous surface of excised small intestines of dogs increases the tonus and pendular movements. This is antagonized by atropine (H. Albert, 1934).

Oil of Chenopodium, U.S.P., is a volatile oil containing not less than 61 per cent of ascaridol, distilled from Chenopodium ambrosioides anthelminticum (American Wormseed). Dose, 1 cc., 15 minims. (Caution!)

THYMOL

This is a phenol contained in the volatile oil of thyme and in a number of other aromatic oils. Its chemical structure is allied to that of creosote constituents. Its actions are also similar to those of phenol. Its bacteriostatic efficiency is higher, restraining the growth of pus organisms in 1:3000. It is not a very active germicide. The local effects and the toxicity are relatively slight, because of its limited solubility and slow absorption. The absorption from the alimentary canal is, however, practically complete (Seidell, 1915). The solution and absorbability are favored by alcohol or oil (Schultz, 1915); these must be avoided in the therapeutic use.

Even after absorption its toxicity is but a fourth that of phenol. About half of the thymol is completely destroyed in the body (Seidell, 1915). The remainder is excreted paired with sulfuric and glycuronic acid (Blum). The symptoms are similar to those from phenol (W. H. Schultz, 1911), except that there are no convulsions, the central nervous system being primarily depressed. It is rapidly absorbed from hypodermic injections of oily solutions (Schultz and Seidell, 1912).

Uses.—Thymol has a pleasant clean taste, and a saturated watery solution makes a rather agreeable and fairly efficient antiseptic and deodorant mouth wash or gargle; lotion for discharging wounds, etc. Internally, it is occasionally employed as antipyretic and intestinal antiseptic. Its main use is an anthelmintic in the treatment of hookworm disease, for which it was introduced by Bozzolo, 1879. It is not very effective, is relatively toxic and has been displaced by other drugs. It is fairly successful in coccidioidal granuloma and has been used against trichinae, with fair results against the intestinal infection (as is also betanaphthol); but no drug is effective against the parasites in the skeletal muscle.

Thymol Test of Hepatic Function.—Administration of 0.5 Gm. of thymol to man usually results in considerable increase of the ethereal sulfate of the urine. This response is sometimes absent in hepatic disease; but it is not distinctive (M. Kahn, 1918).

Antiseptic Efficiency.—Thymol has a high phenol coefficient (25), but it is greatly impaired by the presence of organic matter. For instance, the addition of 3 per cent of dried feces reduces the activity of thymol by two-thirds, that of phenol by only one-tenth.

Yeasts, Moulds and Fungi.—Thymol is active against these in cultures (H. B. Myers) and has been tried against skin infections by these plants, with fair success.

Administration in Uncinariasis.—It is given fasting, in the total dose of 2 Gm. for adults, and the usual modifications for age, divided into three portions, taken an hour apart, best as fine powder in 5-grain capsules. The efficiency is increased by mixing the powdered thymol with equal parts of lactose or, better, sodium bicarbonate (Washburn, 1917). The thymol is preceded and followed by a saline cathartic. The treatment is repeated at weekly intervals until successful. Alcohol should not be taken while the thymol is in the intestines. Although highly effective against hookworm disease, it sometimes fails; produces some disagreeable after-effects in nearly half the patients; in a few, it causes severe poisoning; and its cost is high (Levy, 1914). The smallest wholly effective single dose is 3 Gm.; but even 4 Gm. are completely effective in only 70 per cent of the patients. Incidentally, the 4 Gm. dose removes about 30 per cent of the ascaris worms.

Thymol in Trichinosis.—When the parasites are still in the intestines, thymol may be given by the uncinaria technic. B. A. Booth, Goehring and Kahn, 1916, also report good results in one patient after the parasites had lodged in the muscles, by intramuscular injection of an oily solution (2 to 3 cc. of 6 per cent, daily for seven days; intermit and repeat). No toxic symptoms occurred.

Coccidioidal Granuloma.—In animal experiments, H. S. Sox and Dickson obtained much better therapeutic results with thymol than with other agents tested, including Sb, Cu, Bi, Hg, Pb, SCN and iodide. One human case apparently responded well to thymol administered locally (33 per cent in oil) and orally (6 Gm. daily, as 50 per cent solution in olive oil, in capsules, with meals, for twenty-four days). It was well tolerated.

Toxic Symptoms.—In man, 1 Gm. of thymol generally causes no symptoms except a sensation of warmth in the stomach. Larger doses produce dizziness, severe epigastric pain, excitement, soon followed by nausea, vomiting, marked weakness, drowsiness, quick soft pulse, tinnitus and deafness, salivation, sweating; then collapse with cyanosis, fainting, coma, low temperature, slowed pulse and respiration. Abortion may result. Rashes are not uncommon.

Thymol, U.S.P., occurs as colorless crystals; aromatic thymelike odor; pungent, aromatic taste. Very slightly sol. in water (1:1000); freely sol. in alc. (1:1) or olive oil (1:1.7); sol. in other fixed oils and in vol. oils. Liquefies when triturated with camphor, menthol or chloral. Dose, 2 Gm., 30 grains (caution!) per day divided into three doses, as anthelmintic.

Carvacrol is an isomer of thymol with the hydroxyl in the ortho instead of meta position. It has about the same effect on worms, and the same *toxicity* for rabbits: with oral administration of 1 Gm. per Kg. death generally occurs after several days (Livingston, 1920). It is somewhat more irritant.

Propylguaiacol is effective against ascaris, ineffective against tapeworm, hookworm and flukes. It is easily absorbed from the digestive tract and is quite toxic, depressing the central nervous system and the circulation (Pak and Read, 1936).

Alkyl polyhydroxybenzenes are effective anthelmintics. They cause local irritation similar to that from phenol and resorcinol and are quite toxic. Comparative studies of the series indicate that *hexylresorcinol* has a favorable balance between anthelmintic and toxic effects (Lamson and associates, 1935). It is more effective against ascaris and less dangerous than santonin or chenopodium oil (Cutting).

Hexylresorcinol as anthelmintic.—In man, 0.1 Gm. per year of age to the maximum total of 1 Gm. for adults, administered as crystals by mouth, removes 90 to 100 per cent of the ascarides, 70 to 80 per cent of the necators, 40 to 50 per cent of the trichuris; it is also effective against pinworms. It should be taken before breakfast, followed in three hours by 15 to 30 Gm. of magnesium sulfate. The single dose produces some gastric irritation, but no other symptoms or macroscopic pathologic changes. Repeated doses, however, cause inflammation and necrosis of the small intestines and microscopic injury of the liver and heart. The kidneys appear resistant (Christensen and Lynch, 1933).

Hexylresorcinol, U.S.P.: White or yellowish crystals; irritant to the skin, the alcoholic solution is vesicant. Slightly sol. in water (1:2000); freely sol. in alc., glycerin, vegetable oils. Anthelmintic dose, 1 Gm. *Hexylresorcinol Pills*, U.S.P., are covered with a tough gelatin coating. The usual sizes are 0.1 and 0.2 Gm. **Halogenated Hexylresorcinols** produce similar anthelmintic effects, and proportional local irritation. *Dibromohexyl resorcinol*, however, is not irritant and kills ascaris *in vitro* (H. H. Anderson and Sah, 1942).

Phenothiazine, used on livestock as anthelmintic against a considerable variety of intestinal parasites, has been suggested for human practice against pinworms: —4 to 8 Gm. for adults, about 4 Gm. for children above four years. 1 Gm. below this age, in capsules or in food. It is not reliably effective, however, and a fair proportion of patients have toxic symptoms. It appears to injure the bone marrow (Bercovitz *et al.*, 1943).

ASPIDIUM OR MALE FERN

The oleoresin of aspidium is the preferred drug against tapeworms. The anthelmintic action resides in several closely related substances, complex methane derivatives of phloroglucin and its homologues, with butyric radicals in ketone combination (Boehm, 1897). These are generally insoluble in water and soluble in oil. These substances are so closely related, and change so readily into each other, that our knowledge is confused; even the elementary formulae are in dispute. The most important is probably the *amorphous filicic acid.* It readily forms an inactive lactone, *crystalline filicic acid* or *filicin. Filicinic acid* is an inactive artificial reduction product of filicic acid or aspidin. The purified principles appear too irritant for medicinal use. Analogous compounds occur in several other anthelmintic drugs (rottlerin in kamala; kosotoxin in kousso).

The active constituents of aspidium (Poulsson, 1891; Boehm, 1897) are: amorphous *filicic acid* ($C_{38}H_{40}O_{12}$); aspidinin; albaspidinin; flavaspidic acid (weak); aspidin (probably from other species). The amorphous *filmaron* ($C_{47}H_{54}O_{16}$; Kraft; Jacquet; 1904) is perhaps an impure filicic acid (Schmiedeberg).

Historical.—The use of aspidium against tapeworms and roundworms is mentioned by Pliny and Galen, and its employment as abortifacient by these and by Dioscorides. It was in use during the middle ages, then fell into disuse and was revived by Valmont de Bomare, 1764. Its properties were unknown in India, where it grows abundantly (Chandler and Chopra).

Administration.—The patient should be prepared for twenty-four to thirty-six hours: A soft nonresidue diet should be given: soup, tea, milk and eggs. A saline purgative is administered on the evening before the administration. In the morning, a cup of black coffee is taken, followed by a 2 cc. capsule of the oleoresin of aspidium, repeated at intervals of half an hour to a total of 6 cc.; or less for small or debilitated patients. The last capsule is followed after one or two hours by half an ounce of magnesium sulfate in a glass of water. (Older writers caution against castor oil as dissolving the oleoresin and favoring absorption; but this is contradicted by Hall and Shillinger, 1924.) If the treatment is unsuccessful, several weeks should elapse before another administration. A single treatment with aspidium suffices for about half the cases of taenia, but some resist five or six treatments; it is but slightly effective against nematodes. Filicic acid probably paralyzes the muscles of the parasites without affecting the nerves; at least this is its action in earthworms (W. Straub, 1902). This may be utilized for standardizing filix preparations (Yagi, 1914).

Contraindications.—Aspidium should not be used on weak or emaciated patients, nor on those with gastric or duodenal ulcers; nor in pregnancy; and only with special caution when the liver, kidneys or heart are diseased.

Phenomena of poisoning may occur even with moderate doses (Sidler Huguenin, 1898), and larger doses are dangerous. Four grams of the oleoresin have produced severe poisoning, but 20 Gm. have been given without toxic effects (Drenkhaw, 1911). The symptoms involve chiefly the digestive tract, eyes and central nervous system, one or two of these generally predominationg greatly over the others. Many deaths have occurred when the dosage exceeded two drachms of the oleoresin. The milder symptoms consist in colic, diarrhea, headache, dizziness, dyspnea, yellow vision and sometimes temporary blindness. Severe cases showed delirium, violent muscle cramps, syncope, tonic convulsions and coma; often glycosuria, albuminuria and casts, and icterus; death occurs by respiratory paralysis. *Treatment* would be evacuant, demulcent and symptomatic. Recovery is slow, often with permanent blindness (Stuelp, 1904). This occurs also in animals. It is due to spasm of the retinal vessels, with subsequent optic atrophy (Harnack, 1912). Manic psychosis may develop, followed by catatonia, which may last for weeks (Westphal, 1930). In frogs, aspidium paralyzes the central nervous system, the heart and skeletal muscles; in mammals, it produces local gastro-intestinal irritation, followed by tetanic convulsions with simultaneous central and cardiac paralysis.

PREPARATIONS.—***Aspidium Oleoresin,** U.S P. (Oleoresin of Male Fern; Extractum Filicis), is an evaporated ethereal extract of the green rhizome and stipes of Dryopteris species. It should contain 24 per cent of crude filicin. It is a greenish, thick, oily liquid, often containing a crystalline sediment which is probably inert (Sollmann, 1918), but which should be incorporated before dispensing. Disagreeable taste and odor. The oleoresin preserves its activity indefinitely. Dose, 4 Gm., 1 drachm, in capsules or sweetened emulsion, or by duodenal tube, not to be repeated on the same day.

Kousso (Cusso, Brayera) consists of the pistillate flowers of Brayera anthelmintica. (The male flowers are powerfully emetic and, therefore, useless as vermicides.) Contains *kosotoxin*, related to filicic acid (Leichsenring, 1894; Lobeck, 1901). Dose, 8 to 16 Gm., 2 to 4 drachms, as infusion. It is irritant, and likely to be promptly vomited; said to depress the heart; disagreeable in action; unreliable unless quite fresh. *Kamala* (Rottlera), the glands and hairs from the fruit capsules of Mallotus philippinensis, contain Rottlerin, related to filicic acid (Telle, 1907; Semper, 1910). Dose, 10 Gm., 2½ drachms.

PELLETIERINE

This is a mixture of alkaloids obtained from *Pomegranate bark.* It acts much more powerfully on Taenia than on Ascaris (v. Schroeder, 1884; also affects higher animals). Decoctions of the bark were used as tapeworm remedy by the Romans, but the large amount of tannin (20 or 25 per cent) often causes vomiting, so that the alkaloids are preferred. These are generally given in the form of the tannates to avoid gastric irritation.

Active Constituents.—Tanret, 1878, found two active, volatile alkaloids, punicine and isopunicine. There are, further, two less active alkaloids, methylpunicine and pseudopunicine. More recently, K. Hess and Eichel, 1918, have worked on the separation of the alkaloids and determined their chemical structure.

The *administration* follows the same routine as with aspidium: two days of liquid diet; a strong saline purge on the preceding night; 0.3 to 0.4 Gm. of pelletierine tannate in the morning followed in half an hour with half an ounce of magnesium sulfate in a glassful of water, keeping the patient horizontal to diminish nausea and vomiting.

Toxic Actions.—The ordinary dose often causes mild toxic symptoms: vertigo, dimmed vision, great weakness and cramps in the legs, formication, convulsive trembling, etc. Toxic doses promptly produce mydriasis, partial blindness, violent headache, vertigo, vomiting and diarrhea, profound prostration, sometimes convulsions (Landis, 1889).

PREPARATIONS.—*Pelletierine Tannate,* U.S.P., occurs as light yellow, amorphous powder, of astringent taste, slightly soluble in water. Dose, 0.12 to 0.5 Gm., 2 to 8 grains, suspended in water.

Spigelia (Pink Root), the dried rhizome and roots of Spigelia marilandica. It is said to stupefy round-worms, but the earthworm test shows only feeble activity (Sollmann, 1918) It contains a bitter acrid resin; a poisonous alkaloid, "spigeline," said to resemble nicotine and conine; volatile oil, etc. Little is known of its action. Toxic effects, which are rare, resemble those of pelletierine. Dose, 4 Gm., 60 grains.

Areca, the fruit of Areca catechu, contains a vermicidal volatile alkaloid (arecoline). Used only in veterinary medicine. Arecoline is effective against tapeworms in dogs (Hall and Shillinger, 1924), but it is not reliable clinically It stimulates the parasympathetic mechanism (see under Pilocarpine) and therefore increases peristalsis (Paetz, 1910). *Arecoline hydrobromide* has been used locally, ¼ to 1 per cent, as miotic (smarting).

Pumpkin Seeds (Pepo), fresh or not over a year old, have some popular reputation as adjuvant to tapeworm treatment, an ounce of the seeds being eaten on the day preceding the aspidium. They are not sufficiently active by themselves, but serve to support other measures. They were investigated chemically and pharmacologically by Power and Salway, 1910, but none of the constituents had any action on the host or parasites. Weinblum, 1912, found neither alkaloids nor glucosides, and also considers the action unreliable. The earthworm test, however, shows that fresh seeds are actively vermicidal (Sollmann). This action resides in the lipoids that may be extracted by ether or alcohol (E. Rath, 1929) The seeds are but little toxic to mammals, producing only some diarrhea when 400 Gm. were fed to sheep daily for three consecutive days (Steyn, 1935).

The latex of Ficus species is fatal to ascaris *in vitro,* due to a proteolytic enzyme, "ficin," but this would generally be destroyed by the acid reaction of the stomach (B. H. Robbins, 1930; J. C. Andrews and Cornatzer, 1942). Its pharmacology and toxicology were investigated by Molitor *et al.,* 1941. It is highly effective in preventing the coágulation of blood and of milk, by digesting the prothrombase and caseinogen (Cançado, 1944).

The fresh "milk" of the cocoanut is also said to be anthelmintic. It is doubtful whether it is efficient, for intestinal parasites are abundant in the Philippine Islands, where fresh cocoanuts are consumed freely (De la Paz).

SANTONIN

This is a neutral principle from the Levant wormseed, santonica, a favorite remedy against ascaris since Dioscorides. It is effective only when joined with calomel and a saline purge. It is also used against pinworms if these have ascended beyond the reach of enemas. It is useless against taenia and not very effective against other worms. Santonin is insoluble, nonirritant and almost tasteless, and is therefore easily administered to children, but is no longer recommended, because of occasional severe toxic reactions. Doses but little above the ordinary cause "yellow vision," persisting for some hours, without other bad effects. Overdoses produce serious poisoning.

Fate.—Santonin is the lactone of santonic acid. It is dissolved in the intestine as sodium santoninate, and the greater part is eliminated unchanged in the feces. A small amount is absorbed, oxidized, and the derivatives (especially the crystalline santogenin) (Jaffé, 1890) and a colored compound (oxysantonin) are excreted in the urine (W. Marshall, 1927). This is bright yellow when acid, changing to pink when alkaline. *The color of the urine* may be confused with that of emodin (rhubarb, etc.). The emodin colors can be shaken out with ether, or precipitated by lime or barium water, while the santonin color can not.

Santonin Test of Hepatic Insufficiency.—The conversion to oxysantonin occurs in the liver and has been proposed as a functional test; administering 0.03 Gm. of santonin by mouth and comparing the alkalinized urine with an eosin solution. The color appears normally in an hour, reaches its maximal concentration in three to four hours, and disappears by the seventh or eighth hour (Fernandez, 1935).

Anthelmintic Action.—Santonin is fairly effective against ascaris; but it has a low efficiency in dogs, at best 10 per cent, even when used with purgation (Shillinger, 1927). It was formerly believed that santonin is not directly toxic to worms, but that they attempt to escape from it, and thus flee into the large intestine, from which they are evacuated by the purgative. The apparent harmlessness, however, was due to the failure to imitate the solvent action of the intestine. Solutions of santonin in dilute bile and sodium bicarbonate mixtures are highly toxic to earthworms. The irritant effect on worms plays a part in securing their expulsion, but this effect does not differ from that of other anthelmintics.

The mechanism of its action was studied by Trendelenburg, 1915, on rainworms, leeches and ascaris. It consists in strong stimulation (increased tonus and contractions) of the muscle, persisting after removal of the ganglia. The effect is not produced in anything like the same degree by other substances (although some alkaloids have a weak action), nor does santonin stimulate vertebrate muscle. It is connected with the lactone structure, as is also a depressant effect on the isolated frog heart. The convulsant effect on mammals does not depend on the lactone, but on the naphthaline nucleus.

A number of *simpler lactones* are also anthelmintic and have a similar depressant effect on the neuromuscular apparatus. The dilactone of acetone diacetic acid is effective against ascaris in cats, and practically harmless. Beta angelica lactone is somewhat irritant (von Oettingen and Garcia, 1929).

Administration of Santonin.—The dosage against ascaris is 0.06 to 0.3 Gm. for adults, and 0.01 Gm. per year for children. It may be mixed with sugar. It should not be taken fasting, since this increases absorption. A recommended routine is to eat supper at 5 P.M., administer the drug at 10 P.M., together with 0.2 to 0.7 Gm. of calomel, and follow this at 6 A.M. with a tablespoonful of magnesium sulfate in a glass of water. Fats, including castor oil, should not be taken while the drug is in the intestines. In view of the possibility of toxic effects, it should not be used unless a definite diagnosis has been made. It should not be repeated in less than seven days.

Side Effects.—Giddiness, drowsiness and nausea during the next day are not uncommon. Anomalies of color perception ("yellow vision") and of hearing occur frequently even when there are no other symptoms. The *susceptibility* to these and to more serious effects varies greatly, with many idiosyncrasies, especially with infants.

Xanthopsia.—Doses as small as 0.1 Gm. may cause "yellow vision"—*i. e.*, white light has at first a violet, then a yellowish-green hue, and these colors tint the entire field of vision. The power of seeing in dim light is also lessened. It has been demonstrated that these defects are peripheral (Knies, 1894), and the theory is advanced, based on some experimental data, that santonin impairs the reproduction of the visual purple and violet, which are at first used very rapidly. Another explanation assumes an action on the retinal violet receptors, first stimulant, then depressant (*cf.* W. Marshall, 1928). The media of the eye are not discolored (Filehne, 1900). Colored vision also occurs, but more rarely, with amyl nitrite, picric or chromic acid, and digitalis (de Schweinitz, 1899).

Uric Acid Elimination.—This is increased by santonin, as by other intestinal irritants (Abl, 1913).

Antiglycosuric Action.—Santonin decreases phlorhizin glycosuria in rabbits by raising the renal threshold, for the blood sugar level is not affected (Leulier and Roché, 1931). Santonin has been used clinically in *diabetes* (and also in *epilepsy*), but with little success.

The phenomena of severe intoxication may include vomiting, colic and profuse diarrhea, painful micturition, hematuria, albuminuria, headache and vertigo, extreme weakness, somnolence, hallucinations, finally *convulsions* (which may be unilateral), fall of temperature, coma and death (Binz, 1877; Harnack, 1901). *Treatment* would consist in evacuation, chloroform inhalation against the convulsions and stimulants against collapse.

Fatal Dose.—In children, 0.06 Gm., 1 grain, has produced serious poisoning, and two such doses have been fatal; in other cases, 0.18 Gm., 3 grains, caused only light symptoms, and recovery has occurred after 0.72 Gm., 11 grains. By adults, 0.5 to 1 Gm. and more have been taken without damage (Lewin).

***Santonin, N.F.**, is obtained from Santonica, "Levant Wormseed," the unexpanded flowerheads of Artemisia pauciflora. This also contains cineol, which has no action on ascaris (Bruening, 1912). Colorless crystals (turning yellow on exposure to light); odorless and nearly tasteless when first placed in mouth, but afterward developing a bitter taste. Very slightly sol. in water, sol. in alc. (1:43). Dose, 30 to 60 mg., ½ to 1 grain, in powder, with sugar

LOCAL VERMICIDES FOR THREADWORMS (OXYURIS)

These parasites are usually treated by the rectal injection of various irritants.

The rectum may first be washed with injections of tannic acid or bitters (quassia), to limit the secretion of mucus, and then irrigated with solutions or emulsions of salt (℥ss to pt.), aloes (ʒj to pt.) or turpentine (ʒij to pt.). W. H. Wright *et al.*, 1939, found hexylresorcinol, 1:2000, most effective, injecting a quart for adults, as much as may be retained for children; ten to twelve enemas are generally given in a three weeks' course. Mercury salts are sometimes used as injection or suppository, but are dangerous. Strong sodium chloride solution (half a tablespoonful to 4 ounces of water), injected when itching is felt, relieves this in a minute or two and kills the worms (W. P. MacArthur, 1931).

CONVULSANT POISONS

Convulsions may be caused by direct stimulation of the muscles (veratrine), or of efferent motor nerves (physostigmine, aconitine); by reflexes from strong afferent stimulation; or by stimulation of the motor centers in the cord, medulla or brain, either directly by the drug, or as a result of asphyxia. *Spinal convulsions*, as typified by strychnine and caffeine, are generally symmetrical and, when fully developed, tetanic (*i. e.*, the contractions are maintained). *Medullary and midbrain convulsions* (picrotoxin, camphor, asphyxia) are more irregular, asymmetrical and clonic (rapid intermissions). *Cerebral convulsions* (absinth) are of the epileptic type, irregular, often involving only limited groups of muscles.

STRYCHNINE AND NUX VOMICA

Strychnine, the main alkaloid of Nux Vomica, has considerable toxicologic importance. It increases the reflex excitability of the spinal cord and the medullary centers. Therapeutic doses produce a "bitter" and, therefore, tonic effect on the alimentary canal; and a limited amount of respiratory and vasomotor stimulation. Toxic doses cause characteristic tetanus, violent changes in blood pressure and spasmodic respiration. Death occurs from asphyxia and from the paralysis which succeeds the stimulations. Actions closely resembling those of strychnine are produced by a number of other alkaloids, which have little practical importance.

The **symptoms of strychnine poisoning in man** illustrate the motor phenomena: *With small doses,* there is merely a somewhat greater response to reflex stimulation, and the muscles feel somewhat more taut. As the dose is increased to 5 or 7 mg. (Hartenberg, 1913), this tightening becomes more sensible, especially in the neck and jaws; the movements become rather abrupt; and slight twitchings may appear in the individual muscles, often in the little finger. In paralysis from a high lesion (apoplexy), the paralyzed muscles may be the first to react, since they are removed from the cerebral inhibitory impulses. *With toxic doses,* these symptoms are promptly succeeded by sudden convulsions, usually following some stimulation; or the premonitory symptoms may be absent. The attack may start with a loud cry, which is usually caused mechanically, by the convulsive movement of the air, rather than by pain. The convulsions involve all the voluntary muscles of the body, including the diaphragm. The movements are at first rapidly intermittent, but become promptly tonic, resulting in a typical tetanus. Since all the muscles are contracted, the convulsions are symmetrical, and the body assumes the position corresponding to the stronger muscles, which in most situations are the extensors. Accordingly, the body is arched backward (opisthotonos), so that the patient may touch the ground only with the head and heels. The legs are adducted and extended, the feet curved inward. The arms are either strongly flexed over the chest or rigidly extended, with the fists balled. The jaws are fixed, and foam gathers at the mouth. The rigid diaphragm and the tense thoracic and abdominal muscles arrest respiration, the skin and mucosae become cyanotic and congested; the eyes are protruded, and the pupils dilated. The pulse is small, often imperceptible. The patient remains conscious and suffers severe pain from the violent contractions. The asphyxia may be fatal in the first attack. More commonly there is a remission: The tetanus lasts perhaps a minute; then the muscles relax, and the patient passes into a greatly depressed state, is very anxious and oppressed, with dry throat and thirst, sometimes sweating. This intermission lasts at most ten or fifteen minutes, when there is another attack, usually again following some slight stimulation. If asphyxia is not fatal, it is again followed by remission, and so on. The remissions, however, become progressively shorter, the spasms weaker, and the paralysis is more prominent. *Death* occurs usually in the interval after the second or fifth attack, from exhaustion and general depression. It may be preceded by asphyxial coma. *Recovery* may occur, from sublethal doses or under appropriate treatment, the convulsions and depression disappearing gradually. Animals have been observed to relapse into fatal convulsions several hours after apparently complete recovery (Sollmann), so that patients should be watched.

Reflex Nature of the Tetanus.—The principal symptoms of strychnine poisoning are referable to modified and increased reflex excitability of the spinal cord. The motor reflexes are modified so that smaller stimuli are effective, and the response even to slight stimulation is maximal, tetanic and tends to spread to all the muscles. Ordinary reflexes are increased, but the tetanus depends on the enormous exaggeration of the "startle" reflex from a sudden stimulus or fright (Cushny, 1919). This involves contraction of all muscles and therefore reversal of inhibitory reflexes in reciprocating innervations. Purely inhibitory reflexes (postural, depressor, cerebellar) are not reversed (Bremer).

Dependence of Convulsions on Reflex Stimulation.—In the lighter grades of strychnine poisoning, the convulsions occur only on reflex stimulation. In the severe grades, they may appear spontaneous, but even here they are really reflex, due to slight and accidental sensory stimulations. *Convulsions do not occur spontaneously if all sensory impressions are prevented from reaching the spinal cord;* as by dividing all the posterior roots in frogs (Hermann Meyer, 1846), together with the medulla (Hering, 1893; Verworn, 1900), or by placing the frog in a weak cocaine solution (Poulsson, 1889).

Different Forms of Stimulation.—Practically all kinds of sudden sensory stimulation may provoke the convulsions. The skin is especially sensitive. Sudden light and sound are also dangerous. Gradual stimulation is much less effective, so that a patient may support considerable but deliberate manipulation, such as artificial respiration; when a slight, but abrupt or unexpected, touch would cause an attack.

Stimulation of the exposed intestines does not cause convulsions, since these are poor in sensory fibers. *Chemical stimulation* (the application of dilute acids) not only fails to produce tetanus, but even the normal reflex is greatly diminished (Schlick, 1890). The absence of tetanus is easily explained because the slow penetration of the acid leads to a gradual instead of abrupt stimulation. The various explanations of the diminished reaction are not convincing (Baglioni, 1900 and 1909; Sano, 1908).

The Modification of the Short Reaction of Ordinary Reflexes into the Prolonged Contraction of Strychnine Tetanus.—The tetanus is a true multiple response to a *single* stimulus, for it occurs also if all reflexes but the original single stimulus are excluded; *f. i.*, tetanus occurs in a leg with a single stimulus of its divided sensory nerves, the remainder of the animal being curarized (Veszi, 1913; Buchanan, 1912; Henkel, 1913). *Electromyographic records* from frogs' gastrocnemius show that strychnine tetanus consists of groups of oscillations. The frequency of the groups depends on the temperature of the spinal cord, the frequency of the oscillations on the temperature of the muscle (D. H. Smyth, 1936).

Normal and "Startle" Reflexes.—Cushny, 1919, pointed out that strychnine has two apparently distinct actions on reflexes. A strychninized frog (0.05 mg.) responds to weak and slowly acting stimuli by reflexes of a normal coordinated character, but with lower threshold; whereas stronger and sudden stimuli produce the typical universal tetanus. This differs from normal reflexes not only quantitatively, but in that it causes the contraction of even antagonistic muscles. Cushny considers that this is a distinct reflex, which finds its physiological expression in the "startling," on sudden fright, which is enormously exaggerated by strychnine, so that it tends to displace the ordinary reflexes.

Reversal of Reciprocal Innervation.—Sherrington (1905 to 1909) showed that in a normal animal the contraction of a muscle is accompanied by the automatic relaxation of its antagonistic muscles. The reciprocal reflex is destroyed by such substances as strychnine and chloroform. Even with subconvulsive doses of strychnine, all reflex stimulations result in simultaneous contraction of all the muscles, including the antagonist; with chloroform, they result in simultaneous relaxation. The vasomotor system presents analogous phenomena (Bayliss). Subsequent work, however, showed that purely inhibitory reflexes, such as the vagal inhibition of the heart, are not reversed by strychnine, but only mixed reflexes with a weak augmentory component. The distinction is merely quantitative in that strychnine increases the augmentory component of reflexes more than it does the inhibitory component; in other words, it decreases and equalizes the *chronaxia* of the various groups of spinal reflexes (Bremer; Dusser de Barenne). Direct application of strychnine to *peripheral nerve fibers* also shortens their chronaxia, and this effect is the greater the slower their normal chronaxia (Lapicque, 1929; Bremer and Rijlant); but it is questionable whether this analogy can be transferred to the central action, which is probably not exerted on nerve fibers. Direct application of dilute strychnine solution to frog sciatic nerve slows conduction and blocks the fibers in their trunks (Peugnet and Coppée, 1936). This explains the apparent "*curare action.*"

Cholinesterase is inhibited by strychnine (D. Nachmansohn, 1938). It has been suggested that this raises the excitability so that the discharge from any nerve cell "fires" all the other cells with which it connects.

Central Location of the Tetanizing Action.—The distinction between the possible sites of convulsant action illustrates the general method of experimental pharmacology. Most of these experiments can be carried out more conveniently on frogs, but they can also be demonstrated on mammals (review, Dusser de Barenne, 1933).

The Action Is Localized in the Spinal Cord.—(*a*) *The peripheral motor apparatus* is excluded by section of the nerve trunk, which arrests the convulsions in the corresponding muscles (Johannes Mueller, 1844). Conversely, no convulsions occur if strychnine is injected directly into a muscle—say the leg—provided that the leg is first ligated so that the poison can not reach the general circulation. (*b*) If this experiment is modified so that the nerve is not included in the ligature, the absence of convulsions also proves that strychnine does not affect the *peripheral sensory apparatus* (Magendie, 1819).

(*c*) *The brain and medulla oblongata* are not essential to the convulsions, for these occur in frogs in which these centers have been destroyed. (*d*) *The posterior root ganglia are also not concerned;* for typical tetanus can be obtained by direct stimulation of the cord, when all the posterior roots have been cut in frogs; in dogs even when the afferent fibers from these ganglia have completely degenerated after section (Sherrington, 1898). Nor does the localized application of strychnine to the exposed posterior root ganglia produce any effects (Dusser de Barenne, 1910).

(*e*) *Action on the Spinal Cord.*—By exclusion, the strychnine action is located somewhere in the spinal cord. From much ingenious investigation, it appears that both the motor and sensory portions of the cord must be poisoned to obtain the typical strychnine convulsions.

Methods of Anatomical Isolation.—The basic experiments in this direction were made by Hermann Meyer in 1846: After cutting away the entire posterior columns of the spinal cord, he found that strychnine does not produce tetanus, even if the remaining cord is touched. If the ablation is confined to a part of the cord, the corresponding muscles do not participate in the convulsions. This seems to indicate that the action is located in the posterior and not in the anterior columns. However, as pointed out by Verworn, 1900, the proof is not conclusive, for the operation produces too much shock and, besides, destroys all the physiological relations of the motor cells. Similar objections apply to all anatomical methods, so that these can not furnish conclusive evidence. It was therefore necessary to have recourse to physiological means.

Segmental Application of Strychnine to the Spinal Cord—Houghton and Muirhead, 1895, basing themselves on the earlier and imperfect work of A. J. Spence, 1866, attempted to utilize the fact that impulses go from the sensory cells of the cervical segments of the cord to the motor cells of the caudal segments, and *vice versa*. By destroying the circulation and applying strychnine locally to the exposed cord it is therefore possible to make impulses pass either through a poisoned sensory cell to an unpoisoned motor cell; or through an unpoisoned sensory to a poisoned motor cell. If strychnine is restricted to the cervical half of the cord and the foreleg is stimulated in this frog, the hindleg participates in the convulsions. When the hindleg is stimulated, there is no convulsion. Analogous observations have been made on mammals (Ryan and McGuigan, 1911); on frogs with the sensory paths paralyzed by phenol (Baglioni, 1900); and on the excised nervous system of toads (Baglioni, 1909).

The observations were interpreted as proof that strychnine acts essentially on the sensory mechanism of the cord, and that the motor cells are unessential. However, these results are obtained only when the cervical cord is poisoned. If the strychnine is applied to the lumbar cord, the convulsions do not spread at all to the cervical segments, but remain confined strictly to the poisoned area (McGuigan and Becht, 1914). Furthermore, if the *entire* animal is poisoned by small doses of strychnine, the same phenomena are observed as in the Houghton-Muirhead experiment; namely, minimal stimuli applied to the forelegs produce general convulsions, whereas the same stimuli applied to the hindlegs produce only local contractions. The Houghton-Muirhead phenomenon may therefore be explained by the more easy spreading of impulses in the caudal than in the cephalic direction. (The subject is reviewed by McGuigan, Keeton and Sloan, 1916.)

Localized application to the ventral and dorsal surface of the exposed spinal cord of mammals and frogs has furnished more definite information (Dusser de Barenne, 1910 and subsequently):

1. When the application is restricted to the ventral surface of the cord, no perceptible symptoms are produced.
2. When it is restricted exclusively to the dorsal surface, there is no tetanus; but, instead, a characteristic syndrome, comprising sensory disturbances (paresthesias), increased reflexes, and incoordinate asymmetrical twitchings. These "dorsal symptoms" are sharply localized on the skin according to the level and site of application to the cord; the skin areas being identical with the "dermatomata" defined by anatomic-physiologic isolation methods. They occur even after the division and degeneration of the posterior root fibers.
3. Typical tetanus occurs only if *both* the sensory and motor tracts are poisoned. *F. i.*, if the strychnine is applied dorsally to the arm region, and ventrally to the leg region, then stimulation of the leg causes only normal reflexes (unpoisoned sensory to poisoned motor); stimulation of the arm causes tetanus of the legs (poisoned sensory to poisoned motor) in which the arms do not participate (poisoned sensory to unpoisoned motor). This experiment (which was confirmed by Beritoff, 1913) indicates that both the sensory and motor cells must be poisoned to obtain the typical tetanus.

Cerebral Centers.—No effects are perceptible on ordinary observation. The *action currents* of the brain, as with other convulsant poisons, exhibit peculiar "attacks" of rapid potential changes, not localized, but apparently spread over the entire cortex (M. H. Fischer, 1932). Their significance is not clear, but they are probably mediated through the thalamic nuclei: local application of concentrated strychnine sulfate solution to small areas of the brain surface causes the subjacent cortical cells to send out spikes of unified impulses which "fire" (stimulate) the cells to which these send axons, in a much larger but strictly delimited portion of the cortex. This in turn causes sensory disturbances, hyperesthesia and hyperalgesia, by "firing" cells in the thalamic nuclei serving the sensibility of the parts of the body to which the sensations are referred. This method is employed for sensory localization in the cortex (Dusser de Barenne, 1916 to 1941; review, W. S. McCulloch, 1944). *Local strychninization* of the leg, arm or face areas in the precentral or postcentral *motor cortex* of monkeys produces marked hyperactivity both in the cortex and in the corresponding *thalamic nuclei* (electro-thalamograms; Dusser de Barenne, 1937). The periodic potential discharges occur one or two minutes after the application, and are accompanied by localized or generalized convulsions, which may be inhibited by the local application of 5 per cent phenobarbital (Gozzano, 1936). The excitability of the motor cortex to electric stimulation is increased by the direct application of strychnine (or of picrotoxin). The rhythmic twitching may show the localization of electrical stimulation of the centers. It is not easily abolished by general anesthesia (Bickeles and Zbyszewski, 1913). The action is on the gray matter, for it disappears on ablation, and does not occur on direct application to the white matter (S. S. Maxwell, 1906; Baglioni and Magnini, 1913).

The *sensory cortex of the brain* responds to localized application of strychnine by large and rapid voltage fluctuations at the site of application and in the functionally related areas. This method shows that the cortical sensory area of the chimpanzee is a large region both in front and behind the central fissure (Dusser de Barenne, 1939; P. Bailey *et al.*, 1940). Application of strychnine to the "silent area" of the brain does not produce evident symptoms (Amantea, 1913). The *psychic centers* are evidently not affected by strychnine, since consciousness is not disturbed until the onset of asphyxial coma. However, *direct injection of strychnine into the hypothalamus* causes rage and fear response in cats (Masserman, 1938). Local application of dilute strychnine solutions to the lateral *cerebellar cortex* produces increased extensor tone. Application to the anterior lobe causes alternate dorsal and ventral flexions (F. R. Miller, 1926).

Special Senses.—Strychnine (2 to 3 mg.) increases the sharpness and field of vision for all colors (Dreser, 1894; confirmed by Kayser, 1929, with the liminospectroscope), and also the olfactory sense. The sense of touch is little, if at all, affected. These actions are central. In the eye it also probably acts on the retinal ganglion cells, the effects being obtainable unilaterally by injection into the temples or under the conjunctiva. It has been employed to arrest the progress of optic atrophy amaurosis (Nagel, 1871), sometimes with temporary improvement; ½ to 1 cc. of a ½ per cent solution (2.5 to 5 mg.) being injected into the temple.

Therapeutic Uses of the Spinal Action.—The increased postural tonus of skeletal muscles prompted the use of strychnine and nux vomica as a *tonic* in conditions of fatigue and general weakness; but this would be of no real benefit, and requires doses that verge on the toxic. It was also employed with the idea of taking the place of exercise to preserve muscular nutrition in *functional paralyses*, but ordinary doses would be useless, and larger doses could only be harmful. This probably holds true also for its employment to stimulate the spinal centers in *incontinence of the bladder and sphincters*, and against sexual impotence.

Indirect Results of the Motor Actions.—The increased activity of the muscles brings about several secondary results, such as pain, asphyxia, increased metabolism, disturbance of temperature, tendency to rise of blood pressure and quickening of pulse; early post-mortem rigor. The asphyxia in turn produces its characteristic phenomena.

Effect of Convulsants on Temperature.—All convulsant poisons (santonin, picrotoxin, strychnine) produce changes in heat regulation. Small doses cause increased heat loss and a slightly smaller heat production. Larger doses increase metabolism, through muscular action, and hence increase heat production, which is accompanied by a further increase of heat loss. Paralytic doses diminish the heat production greatly. The temperature is accordingly variable: small doses tend to lower it; moderate convulsive doses would increase it; paralytic doses lower it greatly. The heat loss is particularly conspicuous in small and young animals, while larger animals tend to show a rise of temperature with moderate doses.

The **medullary actions of strychnine** are analogous to its effects on the spinal cord, consisting in a more or less violent and convulsive exaggeration of the reflex excitability, particularly of the respiratory and vasomotor centers, followed by paralysis with toxic doses. These effects are modified by the coexistence of asphyxia. The medullary stimulations are marked and violent with convulsive doses. With therapeutic doses, they are so slight that they can not be demonstrated with certainty, either clinically or experimentally. The therapeutic use of strychnine as a respiratory or circulatory stimulant was doubtless due mainly to the uncritical transfer of the results of convulsive doses to therapeutic doses.

Respiration.—In animals, therapeutic doses of strychnine increase respiration mainly by acceleration (Cushny, 1913). This is due to increased excitability of the center, and indirectly to the increased movements. The increase of respiration is not always conspicuous, on account of the variable excitability of the respiratory center. Clinically, it is practically absent (Newburgh, 1914: Edsall and Means, 1914; Higgins and Means, 1915, 4.5 mg. hypodermically). It is presumably more conspicuous when the excitability is partly depressed, as in anesthesia or morphine poisoning (Hanzlik, 1923); but is practically not very efficient even then (R. Meissner, 1923). Similarly, strychnine causes a distinct and fairly lasting improvement of respiration when this has been depressed by cerebral compression (Loevenhart *et al.*, 1918). With toxic doses, the respiration is spasmodic, arrested during the tetanus, accelerated immediately after, and depressed during the intermissions. The respiratory tetanus is reflex, like the muscular tetanus; it does not occur if the posterior roots have been divided (Pike *et al.*, 1919).

Metabolism.—The increased muscular tone or convulsions result in increased consumption of oxygen and output of carbon dioxide, and increased use of glycogen. The increase of gaseous metabolism is observable even with therapeutic doses (Edsall and Means, 1914). The asphyxia may also cause hyperglycemia and glycosuria. The convulsions lower the *oxygen tension of the blood.* The *carbon dioxide* tension may be raised by the accumulation of *lactic acid,* from the tetanus with inadequate oxygen supply, provided that the glycogen store is adequate (Lusk, 1916). The *urinary acidity* increases (Dietrich and Ebster, 1928). Strychnine does not alter the *oxygen and CO_2 dissociation curves* of blood *in vitro* (W. Ludwig and Ebster, 1927). The *guanidine* level of the blood is not raised by strychnine and other convulsants acting at different levels of the central nervous system, more than would correspond to the renal insufficiency and blood concentration (Ander and Emerson, 1938).

The *epinephrine output* of the adrenal glands is increased by convulsive doses of strychnine. Struggling and asphyxia also increase the output, but G. N. Stewart and Rogoff, 1919 and 1920, found a marked increase, to ten times the normal, by large but subconvulsive doses. Harmon and McFall, 1929, failed to confirm this. *Blanching of the skin* of strychnine-poisoned frogs has been attributed to sympathetic stimulation (A. Hoffman and Wertheimer, 1927).

Therapeutic Doses on the Circulation.—These produce either no effect whatever, or a slight (10 to 20 mm.) rise of blood pressure, fairly well sustained. The rise is rather more marked in the diastolic pressure. Direct observation of the vasomotor center may also, but exceptionally, show a slight and doubtful stimulation; but in asphyxia, the same doses (0.05 mg. per Kg.) cause intense vasomotor stimulation (Pilcher and Sollmann, 1915). These effects (aside from asphyxia) are so inconstant and small that they could be accidental. The cardiac contractions are not changed. Clinical observations on the blood pressure and heart rate, in health and in various diseased conditions (cardiac diseases, fever, etc.), give similarly negative or inconclusive results, even when rather large doses (6 mg. every hour) are used (Newburgh, 1915; Lucas, 1914). Positive results must be viewed with caution. The pulse flow (the change of blood flow during the pulse cycle) is also unaffected in man by 3 to 6 mg. (Hewlett, 1917).

Convulsive Doses.—While small doses of strychnine have but little effect on the circulation, convulsive doses cause a high rise of blood pressure due chiefly to the muscular spasm which mechanically raises the intra-abdominal pressure and increases the peripheral resistance (Abreu and Woodbury, 1943). This is accompanied by direct and reflex stimulation of the sympathetic and parasympathetic centers, including the medullary and spinal vasomotor centers. It is followed by fall of blood pressure through asphyxial depression of the vasomotor center and heart. The partly asphyxiated heart is very susceptible to permanent arrest by vagus stimulation, which is a common cause of death.

This description applies almost equally well to the effects of convulsions produced by any other cause; and particularly to asphyxia. These are both present in strychnine poisoning, and must be contributory factors. However, they are not the only cause of the rise of blood pressure; for this occurs when convulsions are excluded by complete curarization and when asphyxia is prevented by artificial respiration.

The *vein pressure*, which is also unchanged by therapeutic doses, rises during tetanus, indicating cardiac insufficiency (Capps and Matthews, 1913). In man, also, the vein pressure is unaltered by therapeutic doses (G. Rosenow, 1919).

Vascular Areas.—During the strychnine rise of pressure, all the splanchnic vessels contract, while those of the skin (Wertheimer and Belezenne, 1897) and cerebrum (Roy and Sherrington, 1890) dilate. The vessels of the pia mater and retina are constricted (Hirschfelder, 1915).

The vasomotor center is greatly stimulated by convulsive doses, independently of the convulsions or asphyxia. Very large doses (above 1 mg. per Kg.) depress and paralyze the center. Subconvulsive doses may produce slight stimulation in decerebrate cats (Pilcher and Sollmann, 1915; van Esweld, 1930). *The vasomotor reflexes* from the carotid and aortic sinus are sensitized by small doses.

Vasomotor Convulsions.—In curarized animals, the rise in blood pressure occurs spasmodically (S. Mayer, 1872), and can be brought on by reflex stimulation, like the convulsions in ordinary animals. The same dose is required to produce the convulsant and the vasomotor actions. This supports the view that the action of strychnine on the medullary centers is essentially identical with its action on the spinal centers.

Spinal Vasomotor Centers.—Attempts to demonstrate these have usually been vitiated by shock. Langley, 1919, 1924, showed that with spinal curarized cats—provided the blood pressure is good—convulsive doses of strychnine produce a large rise of blood pressure, almost as great as if the spinal cord were intact; this occurs also after the adrenals have been excised. The spinal vasomotor centers therefore play a large part in the vasoconvulsive action of strychnine, at least in cats. The margin between the ineffective and effective dose (about 0.5 mg.) is narrow. Excessive doses decrease the excitability, and tend also to lower the pressure by peripheral mechanisms.

Paralysis of Autonomic Ganglia.—Large doses of strychnine and brucine, like curare, paralyze all autonomic ganglia. This can be antagonized by stimulant doses of nicotine.

Heart.—The opinion that strychnine is a "*cardiac stimulant*" prevailed widely among clinicians, but this term was used loosely and does not necessarily imply that the drug stimulates the heart directly, but merely that it improves the pulse. In fact, strychnine has no effect whatever on the heart in therapeutic doses with *living animals.* Convulsant doses cause some stimulation of the ventricles (Wiggers, 1916). When perfused directly through the *excised* heart, the effects are first stimulant, then depressant (Hedbom, Igersheimer, 1905; Burridge, 1928); but the necessary concentration could not be attained in life. *Perfusion of the cardio-inhibitory center* produces stimulation (cardiac slowing, in turtles; A. D. Bush, 1919).

Therapeutic Use of Medullary Stimulation.—The supposed circulatory and respiratory actions of strychnine led to its use in collapse (fainting, trauma and hemorrhage; fevers; depressant poisons, alcohol, anesthetics, coal-tar derivatives, snake venom, etc.) and in exhaustion of the respiratory center (pneumonia, phthisis); but it is not effective. The clinical studies of Newburgh, 1914, and Lucas, 1914, were entirely negative.

Depressant Effects of Toxic Doses of Strychnine.—The medullary and spinal functions show a curious mixture of stimulant and depressant response to strychnine; the stimulation predominating during the convulsions, the depression during the intermissions. The paralytic effects gradually increase as death approaches, the respiratory center, vasomotor center, vagus center and the cardiac muscle failing in about this order. Exhaustion and asphyxia, as well as the direct depressant action of strychnine, are important factors in this paralysis.

That exhaustion is an important contributory factor is shown by the fact that life may be greatly prolonged by preventing the convulsions through chloral or curare. The prolongation of life by artificial respiration shows the contributory action of asphyxia. However, animals die from large doses of strychnine, when exhaustion and asphyxia are both excluded, in the manner indicated. Indeed, the direct depression seems generally to be the main factor (Heubner and Loewe, 1913). The depressed animals can perform voluntary movements (Busquet and Vischniae, 1938); and depression can occur when strychnine is applied locally to the brain (F. Bremer, 1936). There is reason to believe that in the frog the paralysis of the central nervous system is caused largely by the failure of the circulation through cardiac paralysis; but this is not the sole cause, for the heart is often still beating when the reflexes have disappeared. In mammals death usually occurs before the heart has stopped.

Invertebrates.—Strychnine acts as a weak protoplasmic poison on ameboid cells, yeast, etc. Higher invertebrate animals are relatively insusceptible. Many *insects* appear quite immune, while others are only slightly injured (Juchenack and Griebel, 1910). Strychnine reverses the positive phototropic reaction of certain *aquatic larvae.* It expands the chromatophores in others. It reverses the reciprocal inhibitory innervation of the muscular system of earthworms, planarians and starfish, but not of medusae or sea anemones (A. R. Moore, 1913, 1916). Its antagonism with nicotine on *starfish* is described by Moore, 1920. Romanes, 1884, also reported characteristic effects of strychnine on jellyfish and sea urchin.

In *crawfish,* strychnine does not produce motor stimulation, but central (ganglionic) paralysis (Guillebeau and Luchsinger, 1882). This may be succeeded by temporary recovery, but this is followed by death within twenty-four hours. The paralytic and fatal effects are both antagonized by acetylcholine and mecholyl, not by nicotine. By itself, *acetylcholine* has little effect on crawfish; it quickens the heart and produces some motor stimulation Large doses are depressant. *Nicotine* causes cardiac and motor paralysis (V. Bonnet, 1937).

Phagocytosis is hindered by strychnine *in vitro* (Arkin, 1913); but the doses are very different from the clinical.

Other Peripheral Actions.—Strychnine, when used systemically, has practically no peripheral action on muscle, nerve or glands except the bitter effect.

The *local application of strong solutions* paralyzes most nervous and muscular tissues; for instance, the heart muscle, superior cervical ganglion, striped muscle-endings. The last effect (*curare action,* Lapicque, 1913) also occurs weakly in living frogs. Small doses seem to sensitize the neuromuscular junction, lowering the threshold to indirect stimulation, and delaying fatigue (Hammett, 1916). The curare effects are stronger in brucine; and methyl-strychnine may be counted in the curare group. After death, strychninized frogs cease to respond to sciatic stimulation much earlier than normally (Githens and Meltzer, 1912).

When applied to *isolated nerve,* strychnine (above 1:500,000) diminishes the amplitude of the electric response, blocking conduction before excitation. The refractory period is lengthened, the chronaxia is decreased, the rheobase is lowered by $1:10^6$, and raised by higher concentrations. The nerve is not completely restored by washing (G. Coppée and Coppée-Bolly, 1941).

Bitter Tonic Actions.—Strychnine is very bitter (perceptible in dilution of 1:400,000 to 1:100,000, according to the sensitiveness of the observer). It shares the stomachic effect of other bitters, and is therefore used to improve appetite and digestion in nervous dyspepsias, chronic gastric and intestinal catarrhs, hyperemesis, seasickness, etc., and thus favor nutrition. The increased tone of the muscle creates a feeling of vigor which contributes to the "tonic" effect. Tincture of Nux Vomica (1 cc. diluted, before meals) is often preferred to the alkaloid (1 to 2 mg.). It is often combined with other tonics (Elixir Ferri, Quininae et Strychninae Phosphatum). If the bitter effect alone is desired, the dose of the tincture may be reduced to 1 to 3 drops, which is too small to produce central effects.

It has been employed in *seasickness* as a prophylactic in conjunction with atropine (Skinner, N. Y. Med. Jour., December, 1893; Girard, 1906). The bitter and tonic effects of strychnine make it a useful adjuvant in the treatment of chronic alcoholism and other *drug habits.*

Emetic Center.—Direct application of strychnine or brucine to the floor of the fourth ventricle induces vomiting by increasing the sensitiveness to afferent impulses (Hatcher and Weiss, 1923).

Peristalsis.—Strychnine (or Extract of Nux Vomica) is often added to cathartic pills ("Aloin, Belladonna and Strychnine") with the object of improving their action, especially in atonic constipation. It stimulates the intestines on direct application (Langley and Magnus, 1907), and Yonkman, 1929, observed moderate increase of the motor activity of the small intestines in unanesthetized fistula dogs, after doses that did not increase the somatic reflexes. However, the tonus and peristalsis of the human colon, as observed on fistula patients, were not affected by the hypodermic injection of 2 or 3 mg. of strychnine (Yonkman and Singh, 1934). Toxic doses weaken or arrest peristalsis (Pollak, 1910).

Absorption.—Strychnine is promptly absorbed, mainly from the intestine. In rabbits, none of it is absorbed from the stomach proper.

Gastric Absorption.—Variable results have been obtained by different investigators when strychnine was placed in ligated stomachs. Generally, alcoholic solutions are absorbed readily, aqueous solutions scarcely at all. These results seem to depend partly on the ligation; for from unligated Pavlov's pouch aqueous solutions are well absorbed, better than alcoholic (Ryan, 1912).

Excretion.—Part of the strychnine is excreted unchanged (in man, 20 per cent or less; S. Weiss and Hatcher, 1922), mainly by the urine, practically none in the bile and feces. The excretion by urine starts within five minutes after absorption (Ipsen, 1892), and is practically completed within forty-eight to seventy-two hours (Bukunin and Majone, 1906; Hatcher and Eggleston, 1917), although traces may be found even after five days (Plugge, 1885; Hale, 1909; Kuenzer, 1914). In the remarkable case of a patient who had swallowed 15 grains and survived, Hewlett, 1913, recovered 4½ grains from the first stomach washings, and a total of 1⅖ grains from the urine, mainly between the first and tenth hours. Traces were present on the fourth, none on the fifth day. The urinary excretion of strychnine can be increased to only a limited extent, by very active *diuresis* (sodium sulfate injection); but even when this is maximal, it does not save life after doses only 20 per cent larger than the M.F.D. (Hatcher and Eggleston, 1916; S. Weiss and Hatcher, 1922).

Destruction.—At least a fourth, and often much more, of the administered strychnine can not be recovered from the excreta (Kobert); nor from the tissues of mammals, if these survive the administration three hours. The disintoxication occurs mainly in the liver, chiefly by destruction, but somewhat by storage in a loose combination (S Weiss and Hatcher, 1922). Both processes can be demonstrated by the perfusion of the excised liver. Hashed liver destroys only small amounts. The rapidity of the disintoxication is illustrated by the high tolerance to the repeated administration of sublethal doses. When the administration is spread over twelve days, twenty-five times the ordinary fatal dose does not produce any permanent damage (Hatcher and Eggleston, 1917).

Distribution in Body.—In fatal cases, the strychnine is found mainly in the blood, liver and kidneys, in frogs especially in the spinal cord, but there is no evidence that strychnine is bound by spinal cord emulsions (Dixon and Ransom, 1912).

Sojourn in the Blood Stream.—When strychnine is injected into a vein, 30 per cent leaves the blood stream within two minutes; 50 per cent within five minutes; all but traces in forty minutes. When *added directly to blood,* half or more passes into the corpuscles (S. Weiss and Hatcher, 1922).

Influence of Absorption and Channel of Administration on Effect.—Since the capacity for the excretion and destruction of strychnine is relatively great, the effect of a given dose varies with the rapidity of its absorption. Hypodermic injections are two to eight times more potent than oral administration; intravenous injections are two to three times more active than hypodermic. The effects of rectal administration approach more closely to hypodermic than to oral administration.

The toxicity of strychnine is slightly reduced by administering large quantities of fluid (Kleiner and Meltzer, 1912). Colloids have a marked retarding effect (Hatcher, 1904). Even very large doses may produce no symptoms, if the experiment is arranged so as to make their absorption gradual, as by injecting it into the ligatured limb of a guinea pig. A considerable quantity is gradually absorbed through the ligatured tissue; and if the ligature is released, after several hours, the effects will be correspondingly small.

Influence of Age.—Children are said to be comparatively insusceptible to strychnine. In old people with atheromatous arteries, large doses might lead to apoplexy. With white rats, the toxicity is greater for young than for old animals, and greater for females than for males (Poe, Suchy and Witt, 1936). Chick embryos are highly resistant, tolerating 3 mg.; while three days after hatching 0.25 mg. kill in a few seconds (E. Biocca, 1942).

Increased Susceptibility on Continued Administration.—The continuous use of strychnine does not lead to tolerance; on the contrary, the repetition of its action "educates" the nervous system to respond more readily, so that the effects are apparently slightly increased. After the repeated administration of equal tetanic doses to frogs, the spasms occur earlier and last longer (Mostrom and McGuigan, 1912). In mammals, the experiments of W. Hale, 1909, gave rather inconclusive results, some indicating increased susceptibility, others slight tolerance.

The susceptibility of different animals varies greatly. With subcutaneous administration, man, cats and dogs require about the same dose, 0.75 mg. per kilogram, to produce a fatal effect; rabbits are slightly more susceptible. Guinea pigs and frogs require about six times, and snakes eighteen times, this dose. With the frog, the spasms appear with one-sixth the fatal dose; with the guinea pig they set in only when at least 95 per cent of the fatal dose has been given. The differences for oral administration are greater. Some birds are almost insusceptible to oral poisoning, the fatal dose for chickens by mouth being 30 to 40 mg. per kilogram. *Resistance of fowls to strychnine* is due entirely to the long sojourn and slow absorption from the stomach. If the strychnine is injected hypodermically, or when it is placed in the empty stomach, the toxicity is similar to that in other animals (Heinekamp, 1924).

Temperature on Convulsions in Frogs.—Smaller doses suffice to produce tetanus when the temperature is either below or above the ordinary (55° to 75° F.). In the cold, the tetanus appears later, but lasts longer (Githens, 1913). The rapidity of onset, with large doses, rises with the temperature according to van't Hoff's law (Schlomovitz and Chase, 1916).

Toxicology.—Suicidal strychnine poisoning is not uncommon; accidental poisoning occurs from vermin bait and all too frequently from strychnine-containing cathartic pills, which young children swallow as candy. In the United States about seventy-five young children are thus killed by strychnine annually (Metr. Life Stat. Bul., Feb., 1944).

The symptoms and course of strychnine poisoning have been described under the convulsant effects.

The time of appearance of symptoms and of death depend upon the mode of administration, the condition of the stomach and other factors influencing absorption. With oral administration, the symptoms generally appear in fifteen to thirty minutes; the convulsions sometimes only after an hour or later. Death usually occurs in one to three hours, but the time may be as short as ten minutes, or as late as nine to twenty hours, or even later.

Differential Diagnosis of Strychnine Poisoning.—Strychnine tetanus may be confused with traumatic tetanus, spinal meningitis, epilepsy or hysteria. *Traumatic tetanus* is characterized by previous malaise and slow development. The convulsions begin in the jaw. The muscles remain rigid in the intermission. The course is comparatively slow. Strychnine tetanus may also begin in the jaw, but this is not so conspicuous. In rare cases of strychnine poisoning the muscles also preserve their rigidity during the interval, so that the diagnosis is sometimes difficult. When in doubt, strychnine treatment should be used. The course will clear the diagnosis. In *spinal meningitis* the diagnosis may be made by the fever and history. *Epilepsy* differs by the loss of consciousness; the reflexes are normal. In certain cases of *hysteria* the diagnosis may be impossible. Such cases should also be treated as for strychnine.

The *cause of death* is usually the tetanic arrest of respiration in the course of a major convulsion. This is aggravated by the large demand for oxygen by the violent muscular work, the cardiac strain of the high blood pressure, and the fright of the patient which disposes to ventricular fibrillation. Prevention of asphyxia by artificial respiration raises the fatal dose several times. Death then occurs by the depressant action, whose mechanism is not adequately known, but in which fatigue and acidosis play a part. Sometimes patients may die in the interim between convulsions, by this depression.

Autopsy Findings.—Death by strychnine is characterized by early and often persistent rigor. This, however, is common to all forms of convulsions, and is presumably due to the increased production of acid. The anatomical appearances are those of asphyxia and violent convulsions: venous congestion, often hyperemia of the central nervous system, and small hemorrhages; in a few cases hyperemia of the alimentary tract.

Toxic Dose.—In man, 5 to 10 mg. may exceptionally produce convulsive effects, more pronounced with 20 to 30 mg. These doses may even be fatal. The ordinarily fatal dose, by mouth, would probably be about 100 mg. With efficient treatment, patients may be saved after 250 mg.; and even doses of a gram and over are said to have been treated successfully (Hewlett). The fatal dose of Nux Vomica lies about 0.75 to 3 Gm.

Identification of Strychnine.—Strychnine may be identified in the suspected material, vomitus, or tissues (after isolation and purification) by its taste, convulsant effects on frogs and chemical tests (violet and cherry color with bichromate sulfuric acid). Its *bio-assay* on frogs is described by J. T. Priestley, 1930. Intraspinal injection in mice shows 0.00005 mg. (Spagnol, 1927). Strychnine largely disappears during *putrefaction;* although it may sometimes be found even a year after burial (Sandrich, 1884).

Treatment of Strychnine Poisoning.—Evacuation and chemical antidotes are rarely effective, since the alkaloid is quite rapidly absorbed. Effective methods of sedative treatment have been developed, especially by barbiturates, beginning with intravenous injections, which promptly suppress convulsions and thereby the asphyxia, the pain and even the anxiety. In the meantime, considerable amounts of the absorbed strychnine may be detoxicated in the liver. Such sedatives enable animals easily to survive ten times the ordinarily fatal dosage; with careful management thirty-five fatal doses have been survived. Larger amounts of strychnine require such large doses of the sedatives that death occurs by excessive narcosis, which is only weakly antagonized by the strychnine stimulation. In such desperate cases, it is advisable to run the risk of this less distressing exitus.

Routine Treatment.—Before the arrival of the physician, a chemical antidote may be administered, preferably an ounce of active charcoal in water; less desirably permanganate, iodine or tannic acid. Emetics should not be given (danger of aspiration of vomitus during convulsions). The patient should be kept quiet, isolated in a darkened room, warm, protected against sudden disturbances, reassured and calmed. As soon as possible, a barbiturate should be injected intravenously, slowly, in dosage sufficient to put the patient to sleep or to stop the convulsions; preferably sodium pentobarbital, 3 to 5 grains (0.2 to 0.35 Gm.); second choice, sodium amytal, 5 to 10 grains (0.35 to 0.65 Gm.); the dosage for children being reduced in proportion to the weight. If the convulsive condition ceases, subsequent (and smaller) doses may be administered orally, aiming merely to prevent major convulsions. If barbiturates are not available, the patient may be *lightly* etherized, not to the abolition of reflexes, but merely to relax diaphragmatic spasm (Travell and Gold, 1934). When the patient is narcotized by any of these methods, the stomach may be washed, but this is not necessary and should be attempted only if the technic is sufficiently good so that there will be no aspiration. Charcoal may be left in the stomach after the lavage, or may be administered in water by mouth if the patient is conscious. The patient should be under continuous medical surveillance for several hours. If there is any indication of respiratory spasm, gentle artificial respiration should be instituted. Kempf, McCallum and Zerfas, 1933, report uniform success from this type of treatment in eleven patients, who had taken from ½ to 12 grains of strychnine.

Chemic Antidotes.—Potassium permanganate is probably the most effective, if it is given sufficiently early. One Gm. (¼ teaspoonful) should be dissolved in a quart of warm water, carefully decanted, and administered in tumbler doses at short intervals. Iodine (15 drops of tincture in ½ glass of water) or tannic acid (teaspoon in ½ glass of hot water) merely delays absorption, but this is distinctly useful. Tea or coffee should be avoided, since the caffeine is synergistic. Charcoal or, better, caramel or fuller's earth, delays the absorption of strychnine (Sabbatani, 1914; Fantus, 1915); but their efficiency is limited.

Artificial Respiration and Gentle Movement.—Artificial respiration becomes imperative during spasmodic fixation of the respiratory muscles. It acts not merely by the air exchange, but by the gentle rhythmic movement which diminishes the fright reflex, and thus tends to inhibit the convulsions, so that life is prolonged even when strychninized animals are breathing hydrogen (Meltzer and Gies, 1903). However, in so far as respiration is impeded, breathing of oxygen aids survival (Osterwald, 1900). Practically, it is usually not important. Narcotic concentrations of carbon dioxide also arrest strychnine convulsions (Ryan and Guthrie, 1908). Merely keeping the hands gently on an animal, even without rhythmic movements, allays the convulsions by reducing the liability to fright reflexes (Sollmann).

Aliphatic Narcotics.—The efficiency of choloroform, chloral, ether, paraldehyde, amylene hydrate, etc., against strychnine convulsions has long been known; but their application was limited by the difficulty of administering them during the convulsions, and of maintaining them at a safe level for a sufficient time between the convulsions. Chloroform and chloral (2 Gm. of the latter followed in half an hour by a third gram if necessary) presented the special danger of cardiac depression and delayed hapatitis. *Ether* has again been advanced by Travell and Gold, 1934, who find that it may save dogs from ten times the fatal dose of strychnine, hypodermically; but the etherization must be light, and indeed the lighter, the more severe the strychnine poisoning, since larger doses produce additive depression. It should not be aimed to suppress hyperexcitability, but merely to prevent respiratory fixation. This calming effect of ether persists for half an hour after the discontinuation of the inhalation.

Barbiturates.—Their advantage depends on the ease and relative safety with which sedation can be maintained. It is unsafe to prolong a major barbiturate depression longer than it is needed against the convulsive stage; the barbiturates with briefer action, such as pentobarbital, are therefore preferred, prolonging and adjusting the effect if necessary by repeated fractional doses. By this means, Barlow, 1932, saved rabbits poisoned with thirty-five fatal hypodermic doses of strychnine. Conversely, strychnine saved from not more than two fatal doses of pentobarbital. With the longer-acting phenobarbital, Haggard and Greenberg, 1932, saved rabbits from only five fatal doses of strychnine (dogs from four); conversely strychnine saved rabbits from two fatal doses of phenobarbital.

Apomorphine has been used as depressant (⅕ grain for adults, $\frac{1}{10}$ grain for infants; Marvin); but its efficiency is less than half that of phenobarbital (Haggard and Greenberg, 1932), and the emesis may add to the danger.

Magnesium sulfate, hypodermically or intravenously, diminishes the spasticity, but its margin of safety is too narrow, so that the fatality in animals is not decreased (Haggard and Greenberg, 1932; Trabucchi, 1932).

Bromide, and also iodide, are somewhat antagonistic to strychnine (Campo, 1927), but their action in safe doses is inadequate.

Morphine is theoretically objectionable, since its action on the spinal cord is synergistic with strychnine (Steuder, 1934); there is some evidence to the contrary (E. L. Porter and Lockhart, 1943). It has been employed, however, and its analgesic and euphoristic action would be useful; but it does not take the place of barbiturate. *Dehydration* by intravenous injection of hypertonic dextrose or sucrose was reported by Maloney, 1934, to increase somewhat the resistance to strychnine and picrotoxin. *Epinephrine* counteracts the cardiac depression, on local application (Januschke, 1910), but systemically, it increases the convulsive effects. *Diuresis and catharsis* are probably of little use. Very energetic diuresis (as by 2 per cent sodium sulfate intravenously) is unable to save the animal if the minimum fatal dose is exceeded by 20 per cent (Eggleston and Hatcher, 1917).

Brucine.—The action of brucine is much weaker than that of strychnine, the ratio varying with different animals. The paralytic and curare effects are relatively stronger (resembling methyl-strychnine), so that brucine is less useful therapeutically (*cf.* Dixon and Harvey, 1908).

Brom-strychnines.—The two monobrom-strychnines act similarly to strychnine, but are only ⅛ or ⅑ as effective. Dibrom-strychnine is also convulsant, but in frogs it produces mainly the curare effect (C. R. Marshall, 1912). The toxicity of a number of *strychnine derivatives* is reported by Amann *et al.*, 1943.

Vomicine, a third alkaloid of nux vomica, causes picrotoxin-like convulsions (Ruickoldt, 1930).

PREPARATIONS.—*Nux Vomica* is the dried, ripe seeds of Strychnos Nux Vomica, East Indies; yielding not less than 1.15 per cent of strychnine. It also contains less potent alkaloids (brucine, vomicine), tannic acid and fat. The name "vomica" does not refer to vomiting, but signifies "baneful." The drug was unknown to the ancients and was probably introduced by the Arabs. The first good description occurs in 1540. Strychnine was discovered in 1818. The bark contains the same principles in less amount, but relatively more brucine. It was formerly found in commerce under the name of "false angostura." Several arrow poisons are also derived from the genus Strychnos, especially the Upas Tieuté from Java. Some of the strychnos species do not contain any active principle. "*Upas*" signified "poison tree" in Malay dialect. Another arrow poison of the Indian Archipelago is derived from *Antiaris toxicaria*. These were often confused, and there are many exaggerated and fantastic legends of their toxicity (W. A. Hammond, 1863, "Physiological Memoirs," Lippincott). ***Tincture of Nux Vomica** contains 10 per cent of drug, 0.25 per cent of alkaloids, about 0.12 per cent strychnine, in about 70 per cent alcohol. Miscible with water and alc. Incompatibilities as for Strych. Sulf. Dose, 0.6 to 2 cc., 10 to 30 minims. Maximum dose, 2.5 cc., 40 minims.

The *Extract* is the powdered extract, containing 7.4 per cent of strychnine. Dose, 0.015 Gm., $\frac{1}{4}$ grain.

***Strychnine Sulfate,** U.S.P., is soluble in water (1:35), fairly sol. in alcohol. It occurs as colorless crystals or white powder; intensely bitter, even in dilute solutions. It is *incompatible* with alkalis, iodides and bromides (slow precipitation), tannin, arsenates and arsenites. (The *limits of incompatibility* with alkalis, iodides and bromides were investigated by Finnemore and Williamson, 1914, and I. Simon, 1927.) Dose, 1 to 5 mg., $\frac{1}{60}$ to $\frac{1}{12}$ grain. *Strychnine Sulfate Tablets,* U.S.P., are usually available with 0.6, 1, 1.2, 1.7 and 2 mg. ($\frac{1}{100}$, $\frac{1}{60}$, $\frac{1}{50}$, $\frac{1}{40}$ and $\frac{1}{30}$ grains). The *Elixir of Iron, Quinine and Strychnine,* N.F., contains, in the 4 cc. dose, about 0.7 mg. of strychnine sulfate, 32 mg. of quinine hydrochloride and 23 mg. of iron (as citrochloride).

Other Spinal Convulsants.—Spinal tetanus, similar to that of strychnine, is produced by caffeine, thebaine (an opium alkaloid), gelsemine, calabrine and hydrastine. It is also a late phenomenon in morphinized frogs. *Tetanus toxin* likewise induces spinal tetanus, the minor differences being due mainly to peculiarities of absorption (Froehlich and Meyer, 1915).

The Convulsive Action of Sulfonated Dyes; *Inhibitory Action of Cerebrum.—Acid Fuchsin* (Barbour and Abel, 1910) and other water-soluble, neurophilic sulfonated dyes (Macht, 1912) produce strychnine-like convulsions in frogs. In normal frogs, the tetanus occurs only after a long latent period (up to twenty hours), and requires relatively large doses. If the anterior third of the cerebrum is removed (either before or after the injection), the convulsions occur much more promptly (within thirteen minutes), and even much smaller doses ($\frac{1}{10}$ to $\frac{1}{20}$) suffice. This was originally attributed to the removal of inhibitory central impulses; but Thomas, 1920, and Syz, 1923, find that identical results are produced by injury to any part of the nervous axis, and incline to attribute the greater effect mainly to more rapid penetration of the injured tissue.

Cardiectomized Frogs.—Joseph and Meltzer, 1911, found that the late convulsant action of acid fuchsin and of morphine could be greatly hastened, and that a much smaller dose would suffice, in frogs in which the heart had been tied, the circulation of the blood being thus arrested. According to Abel, 1912, this interesting observation is explained by the peculiar distribution of the poison. The ligation of the heart prevents the dissipation of the poison in the body, and the anterior lymph hearts drive the solution directly into the communicating vessels of the central nervous system. This is therefore exposed to a much more concentrated solution. At the same time the interruption of the normal circulation, and the partial asphyxia, increase the sensitiveness of the nervous system to convulsants, for the outbreak of these is hastened even if the heart is excised *after* the drug has been injected. Meltzer, however, did not accept this explanation.

Carbon Dioxide.—This also greatly hastens the convulsions, when its tension in the air exceeds 20 per cent (Joseph, 1915). The gas also lowers the threshold for strychnine convulsions (Pilcher and Sollmann, 1915).

Tetanus Toxin.—The position of the patient in fully developed traumatic tetanus resembles that of strychnine, but the spasm is at first confined to the traumatized region, and corresponds to an exaggerated postural tonus. The site and mechanism of the action have been extensively investigated. Intramuscular injection of a small amount of tetanus toxin (a crystallizable protein; Pillemer *et al.,* 1946) into the hind leg of a cat produces tetanus confined to these muscles. The original action is central, for it does not develop if the leg is denervated before the toxin injection. The sharp localization indicates that the action is confined to the corresponding part of the spinal cord; and this implies (contrary to the view of Abel, 1934) that the toxin does not reach the central nervous system by absorption into the circulation, for in that case the whole length of the cord would be affected, as with strychnine. Indeed, intramuscularly injected tetanus toxin reaches the cord when any transport through the circulation is excluded by a large excess of circulating antitoxin. It appears that the toxin ascends in the motor nerve and is fixed in the corresponding segment and side of the cord (Acheson and Ratnoff, 1942; review, U. Friedman, 1942). No definite change in the functions of the end plates has been established (A. Perdrup, 1946).

After five days, the local contracture persists when the nerve is cut. This later phenomenon is a purely muscular contracture, without action current, located in the region of the neuromuscular junction (A. M. Harvey, 1939). It may be conceived as an increased acetylcholine effect, possibly by interference with choline esterase (Göpfert and Schaeffer, 1940).

The spasm may be combated by central narcotics (scopolamine, magnesium), or by weak curarization which blocks the excessive postural impulses but leaves the spontaneous movements, or by local anesthetics which block the afferent impulses. R. Spaeth advises barbiturates or avertin in amounts no greater than to prevent painful spasticity, continued until no longer needed for this purpose. These measures are only symptomatic and temporary. The effective treatment is by specific antitoxic serum, especially as prophylaxis. Intrathecal application of the tetanus antitoxin has proved rather disappointing.

PICROTOXIN

This non-nitrogenous neutral principle stimulates convulsive centers, especially in the medulla, perhaps also in the midbrain, and, with large doses, in the spinal cord. The respiratory and vasomotor centers and the autonomic centers are also stimulated. Picro-

toxin is perhaps the most effective antidote to serious acute poisoning by the barbiturates, and probably also other narcotics; but its actions pass readily out of control and become dangerous. They set in later and persist longer than those of metrazol, which is used more safely for the same purposes. Picrotoxin has been suggested for the convulsion treatment of schizophrenia, but the same objection holds.

Origin.—Picrotoxin occurs (5 per cent) in Cocculus indicus, the seeds of Anamirta paniculata. These have been used for poisoning fish (hence "fish berries"); to adulterate beer, in place of hops; in "knockout drops"; and as pediculocide (tincture or 2 per cent ointment). All these uses are dangerous. Picrotoxin consists of a mixture (or perhaps a feeble combination; Sielisch, 1912) of nearly equal parts of picrotoxinin and picrotin (Cervello, 1911; structural formula, Angelico, 1912). These are closely allied chemically and have identical actions, but picrotoxinin acts far stronger.

The symptoms of picrotoxin poisoning in man, with oral administration, consist in a burning sensation, nausea, salivation, cold sweat, pallor, colic, vomiting, diarrhea, slowed or quickened pulse; palpitation; shallow respiration. These are rapidly followed by confusion, stupor and unconsciousness, then, after one-half to three hours, trembling, clonic and tonic convulsions. The convulsions may be delayed for five to thirty minutes even with intravenous injections of 5 to 12 mg. They may consist of uncontrollable twitching with persistent consciousness, or full-fledged convulsions with the patient unconscious. Recovery is fairly rapid, with some depression. In fatal cases the convulsions generally pass into paralysis and death by asphyxia, after several hours.

The postmortem findings are those of asphyxia. The poison disappears rapidly during putrefaction (within one or two weeks), so that the *toxicologic analysis* must be made promptly. The characteristic effect of the isolated poison on the frog constitutes the best test. The intensely bitter taste is discernible in dilutions of 1:80,000.

Treatment.—The chemic alkaloidal precipitants would not be efficient. The best treatment would be emetics (if vomiting has not occurred), barbiturates, chloral or chloroform.

Symptoms of picrotoxin poisoning in mammals were described by J. Crichton Brown, 1875, as salivation and vomiting (central; Eggleston and Hatcher, 1915); then quiet and apathetic; then restless and apprehensive; then trembling of legs; lies on side, with efforts to stand; progressively stronger twitching of face and neck muscles; head drawn back. Then, suddenly, generalized clonic convulsions; clonic champing of jaws; closing of eyelids; marked frothing at mouth; involuntary urination; pupils dilated during the convulsions. The clonic spasms change imperceptibly to running movements, become slower, and finally cease. The animal remains quietly on its side, and then, after some efforts, regains the erect position. After a time, varying with the dose, the convulsions may recur.

The location of the picrotoxin convulsions is chiefly in the medulla oblongata, in mammals as well as in frogs. They persist after removal of the cerebral hemispheres (Gruenwald, 1909), and even on transection below the optic thalami (Pollock and Holmes, 1915), but disappear or become of the spinal tetanus type after section behind the medulla, or if the application is confined to the spinal cord. This is ordinarily eclipsed by the more potent medullary stimulation (Luchsinger, 1878). Direct application to the cerebral cortex also produces some stimulation (Maxwell, 1906 and 1907). Somewhat larger doses are required to induce convulsions in frogs after removal of the cerebral lobes, and considerably larger after removal of the midbrain. From this and reflex irritability computations it has been argued that the convulsions originate in the midbrain with minimal doses, that larger doses involve also the medulla, and very large doses extend to the spinal cord. Direct injection into the hypothalamus causes autonomic and emotional stimulation similar to that of metrazol (Wasserman, 1938). Although the convulsions appear to occur spontaneously in cycles, they are prevented by removal of the skin in frogs, so that they involve the intactness of sensory impressions (H. Schriever and Perschmann, 1935).

After-Depression.—Quantitative studies show that picrotoxin and metrazol convulsions are followed by a period of depression lasting about an hour, not accompanied by prostration or anesthesia. Loss of placement reactions indicates that it is cortical. This post-convulsive depression is not found with coramine, caffeine, cocaine or amphetamine (Dille and Hazleton, 1939).

Picrotoxin in 4:1000 solution (decidedly above the concentrations attained in life) inhibits *oxygen uptake by cat brain in vitro,* and the oxidation of pyruvate, glutamate, fumarate and succinate (J. R. Klein, 1943).

Toxic Dose.—According to Lewin, 0.03 to 0.24 Gm. of cocculus by mouth is toxic, 2.4 Gm. are fatal. Of picrotoxin, 20 mg. are toxic; the fatal dose is not known. The intravenous minimal convulsive and fatal dose varies with the speed of injection. In a schizophrenic patient, 4.5 mg. = 0.07 mg. per Kg. produced generalized clonic twitching at intervals of ten to twenty seconds, for an hour; in the same patient, 7 mg. = 0.11 mg. per Kg. resulted in a grand mal convulsion; but with another patient, 12 mg. = 0.17 mg. per Kg. had no effect whatever (G. H. Williams, Jr., 1938). Rabbits, under usual conditions of intravenous injection, are convulsed by 0.75 to 0.8 mg. per Kg., and 50 per cent are killed by about 1.2 mg. per Kg. (H. W. Werner, 1938; R. Kohn, 1938). They therefore appear to be much more resistant to the convulsions than are humans. Dogs are intermediate, and require 0.3 mg. per Kg. intravenously for convulsions, and 1.5 mg. per Kg. hypodermically for death. *Dehydration* of rabbits by intravenous injection of hypertonic dextrose or sucrose solution renders them more resistant to picrotoxin and strychnine convulsions (Maloney, 1934). *Lowering the Body Temperature* of cats to 20° to 23° C. raises the convulsive dose of picrotoxin to nearly double; the convulsions are less severe but more prolonged; the survival time is about eighteen times as long. The dose of metrazol is not materially affected; strychnine is rendered more toxic by cooling (R. T. Stormont and Hook, 1941).

Fate.—Picrotoxin, injected intravenously, disappears rapidly from the blood and cannot be demonstrated there or in the liver or muscle after two hours (Duff and Dille, 1939). It has been calculated that rabbits destroy the convulsive dose (0.8 mg. per Kg.) in about an hour. Less than 10 per cent of this is excreted by the urine

(J. M. Dille, 1938). Chistoni, 1912, claimed that the picrotoxin is excreted partly unchanged and that the *picrotoxinin* is decomposed. Picrotoxinin is somewhat more potent, 1 mg. per Kg. intravenously being fatal to 50 per cent of rabbits (R. Kohn, 1938).

Other Central Actions of Picrotoxin.—The *respiration* is stimulated before the convulsions. In cats with 0.25 mg. per Kg. intravenously, there is a latency of a quarter to half an hour, then abrupt and prolonged increase of inspiratory response to standard electric astimulation (J. A. Wells *et al.*, 1944). With convulsive doses the respiration becomes irregular during the initial twitching and arrested during the clonic spasm (Pollock and Holmes, 1915). These authors point out the similarity of the respiratory, convulsive and circulatory changes with those of epileptic attacks (Pollock and Treadway, 1913). The threshold of the respiratory center to CO_2 is lowered by coriamyrtin (Wieland, 1915). *Spasms of the laryngeal muscles* lead, in the frog, to distention of the body with air and to a characteristic cry similar to that sometimes heard with strychnine. In the early stages, the *blood pressure* may rise from stimulation of the vasomotor center. About three to eight seconds before the convulsions, the blood pressure falls, remaining low until asphyxia sets in (Pollock and Holmes, 1915). The *heart* is greatly slowed, and may even cease for a time. After division of the vagi, the heart returns almost to normal. However, some depression of the cardiac muscle is involved in this slowing. Later there may be a quickening, due partly to stimulation of the accelerator center and partly to paralysis of the vagus center and to fatigue of its endings. The *vomiting, salivary* and *sweating centers* are also excited. The sweat may be suppressed by vasomotor constriction. Direct application of picrotoxin to the floor of the fourth ventricle produces vomiting (Hatcher and Weiss, 1923). Injection into the infundibular region of rabbits results in marked fall of temperature, suppressed by narcotics, attributed to stimulation of a cooling center (F. E. Rosenthal, 1941).

Autonomic Centers.—Gruenwald, 1909, pointed out that picrotoxin produces the symptoms of parasympathetic stimulation: contraction of pupils, salivation, vomiting, slowed pulse, contraction of urinary bladder, erection, etc. These effects are central, for they do not occur after section of the nerves. They are not hindered by decerebration. In turtles, the injection of picrotoxin produces powerful tetanic contraction of the stomach. This does not occur if the vagi have been divided (F. T. Rogers, 1918). *Uterine spasms* have been observed; they are central, for they cease on destruction of the spinal cord. Picrotoxin and metrazol induce *ovulation* in rabbits, probably by stimulation of the hypophysis (C. M. Brooks *et al.*, 1940).

The lactic acid content of the brain is increased by picrotoxin and sometimes by metrazol, but much less than by cyanide (W. E. Stone, 1938). Picrotoxin produces *hyperglycemia* in well fed rabbits (D. Campbell and Morgan, 1933). It may be suppressed by many aliphatic narcotics (F. E. Rosenthal, 1941).

Fish.—The effects of picrotoxin on these, studied by E. Bachrach and Binet, 1928, differ apparently from those in mammals and frogs.

Peripheral Actions of Picrotoxin.—The *excised heart of frogs* is weakened by concentrated solutions. *Perfused vessels* of the frog are dilated, while those of the rabbits' ear are not affected. *Excised intestine* of rabbits is stimulated by small doses, paralyzed by large; *excised uterus*, gravid or nongravid, is stimulated. *Skeletal muscle* and *motor nerves* are somewhat depressed (M. Ogawa, 1928). *Hemolysis*, similar to that of saponin, is said to be produced by picrotoxin, circutoxin and phytolacca decandra.

Picrotoxin against barbiturate poisoning should be used only in cases with deep coma. The clinical data are reviewed in a Report of the Council on Pharmacy and Chemistry, 1939, J.A.M.A., *112:* 431. To this time twenty-seven cases had been treated. The results appear rather favorable. The dosage must be individualized, but generally 1 to 10 mg. should be injected by vein at intervals of one to thirty minutes until there is definite improvement, or until spastic symptoms indicate approach to dangerous overdosage.

A Picrotoxin Injection, containing 3 mg. per cubic centimeter, is administered by vein, beginning with a test dose of 2 cc., followed by 4 to 5 cc. every fifteen minutes until the patient is somewhat awakened. The dosage may then be decreased and the intervals lengthened, stopping short of muscular twitching. Severe cases may require occasional injections for two or three days. If the proper dosage is exceeded, convulsions may need to be controlled by Pentothal Sodium, 0.1 to 0.2 Gm. by vein. No picrotoxin fatalities have been reported from this treatment of clinical barbiturate poisoning, even when the dosage of picrotoxin was 200 or 300 times that which is toxic to normal individuals.

This use of picrotoxin was introduced by A. H. Maloney, Fitch and Tatum, 1931, on the basis of animal experiments. In animals, recovery begins with simple reflexes; for instance, blinking and spasmodic movements of the legs. Large doses are required, so that the animal not infrequently goes into convulsions. These are then controlled with ether. Experimental comparisons of the antidotal value of picrotoxin, metrazol, coramine, coriamyrtin and strychnine have given somewhat contradictory results (Barlow, 1938; Werner, 1938; Chakravarti, 1939; Blackwenn *et al.*, 1940). On the whole, it seems that picrotoxin is the most effective. Picrotoxin is also mutually antagonistic to chloral, paraldehyde, alcohol and bromide (Barlow, 1938; Schriever and Perschmann, 1935).

In schizophrenia, picrotoxin convulsions, induced by intravenous injection, are about as effective as metrazol treatment. They do not produce the terror characteristic of metrazol (Guy H. Williams, Jr., 1938; A. A. Low *et al.*, 1939), but the delayed action adds to the discomfort of the patient and makes control of the dosage more difficult, and it is therefore more dangerous.

Picrotoxin, U.S.P. (Cocculin), is soluble in about 350 parts of water. Average dose, 2 mg. *Picrotoxin Injection*, U.S.P.; the usual size contains 3 mg. in 1 cc. of isotonic sodium chloride solution.

Related Poisons.—Effects similar to those of picrotoxin are produced by neutral principles from a variety of other plants. *Cicutoxin* occurs in the rhizome of *Cicuta virosa*, "*Walter Hemlock*," an umbelliferous plant eaten by mistake for parsley, etc. The American species, Cicuta maculata and bulbifera, are also toxic. Poisoning may be treated by intravenous injection of a barbiturate (M. M. Miller, 1933). Cicutoxin is a complex pyrone derivative (C. A. Jacobson, 1915). Some of the *decomposition products of digitalis* (digitaliresin, toxiresin) are also counted in this group. Less important are: *Coriamyrtin* (from Coriaria myrtifolia), and *Tutin* (from Coriaria species of New Zealand, C. R. Marshall, 1910; Blackwenn *et al.*, 1940). Coriamyrtin seems to vary. That first isolated by Riban was very soluble, while Merck's is almost insoluble, but probably more active (Marshall, 1912). W. W. Ford, 1910, found that tutin combines with nervous structures, thereby losing its toxicity, but no tolerance is acquired. *Star anise,* the seeds of Illicium anisatum, of the magnolia family, produces medullary convulsions analogous to picrotoxin. They may be treated by chloral, barbiturates, chloroform and calcium lactate (B. E. Read and Kiang, 1927). *Antiaris toxicaria,* a "*Upas tree,*" has perhaps somewhat similar effects. H. N. Ridley, 1930, found that injection of the latex into toads is toxic, with slight convulsions and some peripheral actions. It had no effect on dogs, probably because it is not readily absorbed. The skin glands of *salamanders* secrete alkaloids (saladarine and others) which produce violent convulsions of the picrotoxin type. They are also local anesthetics and have various effects on smooth muscle (review, O. Gessner, 1938).

SYNTHETIC MEDULLARY STIMULANTS AND CONVULSANTS

Metrazol (*Cardiazol*), **Nikethamide** (*Coramine*) and **Hexeton** are synthetic drugs of rather unrelated composition, which produce closely similar effects, stimulating the midbrain, the medullary centers and perhaps the spinal cord. The convulsions are irregular and cyclic, and resemble those of epilepsy, picrotoxin, camphor and cocaine. Metrazol convulsions resemble those of picrotoxin more than of camphor in site of action and in absence of depressant phase. They are used in the treatment of schizophrenia. These drugs are also useful in narcotic poisoning, especially by the barbiturates, being more effective than caffeine and safer than picrotoxin. They were introduced as substitutes for camphor, to produce respiratory and circulatory stimulation in collapse, but they have little effect unless their dosage approaches the convulsive. The therapeutic claims tend to go beyond this rather limited field.

Metrazol, N.N.R. (*Cardiazol*), pentamethylenetetrazol, occurs as white crystals, freely soluble in water and in most organic solvents, with neutral reaction. Stable and resistant to most reagents. Marketed in bulk, as tablets of 0.1 Gm., and as 10 per cent sterile solution. Dose, 0.1 to 0.3 Gm., by mouth, intravenously or by vein, repeated as needed. *Nikethamide* (*Coramine*) is used orally or hypodermically as 1 to 2 cc. of a 25 per cent solution. *Icarol* is a mixture of coramine and an ephedrine derivative, intended against shock and anesthesia accidents. *Hexeton,* $CH_3.C_3H_7.C_6H_6O$, is chemically related to camphor. Its dosage is 1 cc. of 10 per cent intramuscularly, or 1 cc. of 1 per cent intravenously. Metrazol (Cardiazol) and Coramine were reviewed by F. Hildebrandt, 1937.

Convulsion Treatment of Schizophrenia.—Von Meduna, 1934, conceived the idea of treating this disease by epileptoid convulsants, on the assumption that clinically the two conditions appear to be mutually exclusive. Camphor was used at first, but was displaced by metrazol because this is more easily controlled. It is also safer than insulin hypoglycemia, which is similarly convulsive, and the therapeutic results are at least as good. Either may succeed when the other fails. Nitrous oxide, carbon dioxide and electrically induced convulsions are also effective. Severe oxygen lack as such has no beneficial effects (Horvath *et al.*, 1943).

The therapeutic results are reviewed by von Meduna and Friedman, 1939; Finkelman *et al.*, 1938, and H. H. Reese, 1939. The improvement consists in progressive restoration of contact with the surroundings, following a number of injections, and is apparently more or less permanent. The benefits are greatest in cases that have lasted less than one and a half years, and are slight after four years. (Complete remission occurs in 61 per cent of the acute cases, 37 per cent of the subacute, and 8.4 per cent of the chronic; von Meduna and Friedman.) The catatonic type responds best, then the paranoid.

Serious *accidents* are rare, the mortality being 0.3 per cent or less, perhaps because the metrazol convulsions are so brief. *Minor complications* are frequent. The most common are temporary subluxations and other dislocations and fractures. Compression fractures of vertebrae, generally multiple but not disabling, have been reported in nearly half of the patients (Polatin, Friedman *et al.*, 1939; B. T. Bennett and Fitzpatrik, 1939). Traumatic injuries may be prevented by intravenous injection of curare (A. E. Bennett, 1940) or by spinal anesthesia (Hamsa and Bennett, 1939). A death from *intracranial hemorrhage* has been reported (Roback and Miller, 1940). Monkeys show vascular damage, subarachnoid hemorrhages, and moderate *changes in cells of the cerebral cortex and basal ganglia,* but these are not always present and are not proportional to the convulsions (S. Arieti, 1941; Strecker *et al.*, 1939). Similar changes occur in insulin convulsions (K. H. Finley and Brenner, 1941). The *blood pressure* rises during the convulsions by an average of 100 mg. Hg., mainly as a consequence of contraction of skeletal muscles (it is prevented by curare) and the resulting increase of intra-abdominal and intrathoracic pressure; vasomotor stimulation plays a minor part. The pressure is also transmitted to the cerebrospinal fluid so that there is generally little increase of stress on the cerebrospinal vessels (Woodbury, Hamilton *et al.*, 1941), but the vessels of the cerebral cortex are congested even if the blood pressure is not raised (M. H. Fischer and Lowenbach, 1934). The heart rate is moderately quickened. Temporary cardiac disturbances occur exceptionally and are not serious (McAdam, 1938; Messinger and Moros, 1940); but sometimes they persist for months, indicating permanent lesions of the myocardium (Regner and Ewert, 1939). Memory defects have been reported (Zinskind, 1941). *Contraindications* to metrazol convulsions are relative. They include weakness of the bony system, for instance by prolonged bed confinement during the preceding year; acute infections; cardiovascular disease; severe intracranial injuries; exophthalmic goiter; latent tuberculosis; seropositive syphilis.

Administration.—The metrazol is given by rapid intravenous injection of a 10 per cent solution, before breakfast, in the smallest dosage that produces the typical epileptiform seizure, at least twice a week, until there is definite improvement, to be resumed if the improvement does not hold. Generally, 25 to 30 injections of "grand mal" are needed to obtain the full benefit or to decide that the treatment is useless. Rapid injection is necessary to produce the major convulsions. Subconvulsive doses cause relapse, and by their anxiety reactions create aversion and opposition. Excessive convulsions (more than three or four) may be arrested by barbiturate, avertin or ether. The pattern of motor response is set in the first injection, permitting precautions against mechanical injury. With resistant cases, Georgi and Strauss, 1937, first induce insulin shock, and administer metrazol after two hours of hypoglycemia.

The *dosage* is started with 3 to 5 cc. of the 10 per cent solution (1 cc. per 30 pounds of body weight). If this dose proves convulsive, it is maintained in subsequent injections; if not, it is increased progressively by 1 cc. at each subsequent injection, until the convulsive effect is secured. Meduna advised to keep the patients on alkali.

The *clinical convulsive response* usually sets in within a few seconds and ceases in a few minutes. *Subconvulsive doses* produce pallor, cough, anxiety, mental confusion and a few myoclonic movements. The *typical reaction* runs the following course (chiefly from Finkelman *et al.*, 1938, and H. Strauss and Landis, 1938): In two to five seconds after the rapid intravenous injection, the patient coughs; five seconds later, marked pallor of the face; then intense blepharospasm, a facial expression of fear and bewilderment, the mouth is widely opened (*a rubber wedge should now be inserted between the teeth to prevent biting the tongue*); then *myoclonic movements* of the face, shoulder, arm, sometimes on one side, then well marked rhythmic clonus; and then, some thirty seconds after the injection, the *tonic phase*, with the head retracted, the back arched, the arms and legs extended, the wrist and fingers flexed, the legs sometimes scissored, goose flesh, apnea with marked cyanosis, rise of blood pressure by 20 to 60 mm., erection and ejaculation of semen. The convulsions involve simultaneous and persistent contraction of all muscles and resemble decerebrate rigidity. After five to thirty seconds the tonus lightens to a *second clonic phase*, first at the fingers, finally at the legs, which lasts about twenty-five seconds, with decreasing intensity. The patient then relaxes, deep respiration resumes, urine is passed. The patient, who has been unconscious throughout the tonic phase, is now confused, drowsy, probably asleep. After a few minutes of rest there may be some further relatively mild convulsive movements. In about five minutes after the injection the patient may be roused, but remains confused for several hours, with complete amnesia of all the events since the injection. Exceptionally, the onset of the convulsions is deferred for fifteen to twenty minutes, with little effect in the interim (H. W. McAdoo, 1938). The *preconvulsive anxiety* is described as a feeling of impending death and annihilation, but a normal individual who underwent the experience describes the sensations as "mildly unpleasant but not alarming" (Gillespie, 1939). The patients, however, find the reaction distressing, especially with subconvulsive doses or petit mal. It is largely wiped out of memory by the amnesia of the major convulsive seizures. It may be eliminated by preliminary nitrous oxide administration, but it is not known whether this is equally effective. Metrazol convulsions are accompanied by central excitation of both divisions of the *autonomic system*, especially the sympathetic, and this occurs also if the convulsions are prevented by curare (Gellhorn and Darrow, 1939). The *blood chemistry changes* of metrazol convulsions have been studied by S. Maurer *et al.*, 1938. Therapeutic convulsive doses lower the oxygen saturation of the blood to 42 per cent (Himwich, Bowman *et al.*, 1938). The brain metabolism is diminished by the anoxia (Himwich *et al.*, 1939); its lactic acid may be increased (W. E. Stone, 1938).

Convulsions in Animals.—The description of the clinical convulsions applies also to animals, except that the spasms are more prolonged with increase of dosage, and lead to asphyxial death. In rabbits, they result in acidosis (lowered CO_2 combining power of the blood, increase of its *p*H by 0.2 to 0.4, increased acidity of the urine; S. Dietrich and Ebster, 1928). The blood sugar rises (Kastein, 1937). The convulsive response is decreased by repeated injections, by starvation, dehydration (merbaphen), and by calcium; it is increased by water retention (Kastein, 1937). The convulsions are succeeded by *depression*, probably cortical, lasting about an hour (see under Picrotoxin, Dille and Hazleton, 1939). Like picrotoxin, metrazol induces spontaneous *ovulation* in rabbits (C. M. Brooks *et al.*, 1940). *Repeated injections* on alternate days diminish the convulsant response in rats; when spaced at weekly intervals, the susceptibility is increased (Sacks and Glaser, 1941).

Subconvulsive doses of metrazol increase the susceptibility of rats to sound-induced convulsions ("*audio-epileptic seizures*"). This applies also to other drugs that increase motor excitability, such as caffeine and strychnine (K. U. Smith, 1941; Snee *et al.*, 1942).

Location of the Convulsant Action.—The character of the convulsions indicates their origin in the midbrain. They occur quite typically in cats and rabbits whose hemispheres have been removed, an operation which prevents the clonic spasms of camphor and cocaine, and modifies those of picrotoxin (H. Bertha, 1927). Direct injection into the hypothalamus causes autonomic stimulation, cyclodilatation, piloerection, urination, defecation, marked emotional excitement and increased response to faradic stimulation of the region (Masserman, 1938). The *action currents* of the cerebral cortex react alike to metrazol, cocaine, caffeine and strychnine, by "attacks" of rapid potential changes, followed by temporary inexcitability, (M. H. Fischer, 1932); the striate and precentral areas respond with four types of potential waves (J. E. Goodwin *et al.*, 1938). Metrazol, nickethamide, caffeine and strychnine in sufficient doses all cause contraction of extensors and flexors on stimulation of homolateral sensory nerve (Knoefel and Murrell, 1935). Typical convulsions occur after removal of the thalami (R. Schoen, 1926); but there is probably some action on these and on the cortex and spinal cord. Unlike strychnine, metrazol does not upset reciprocal innervation (review, Hildebrandt, 1937).

Nonconvulsive doses (0.2 Gm.) do not materially affect physical *work performance;* but fine coordination (marksmanship) is lowered (O. Graf and Muller, 1938).

Antagonistic Drugs.—Pyridine, nicotinamide, cinchophen and aminoacetic acid hinder convulsions by metrazol, but not by picrotoxin or electric stimulation. The reason is not clear (L. J. Pollock *et al.*, 1941).

Use in Narcotic Poisoning.—Metrazol with ephedrine is probably the safest effective treatment of severe but recent coma from barbiturates and other narcotics, according to animal experiments; but it is necessary to approach the convulsant dose, and the effective margin is not large (O. W. Barlow, 1938). The same limitation applies for morphine (metrazol, R. G. Smith, 1928; hexeton, Helairs, 1927). Picrotoxin is more effective but more dangerous. Coramine is much less effective (Warner and Tatum, 1939; O. Gros, 1936). They are not very useful against fatalities from volatile anesthetics (Guns, 1926). *Metrazol and strychnine together* have a more than additive effect against narcosis, indicating a different site of action (W. Koll, 1937). Metrazol may be used to test the *potency of anticonvulsant drugs* (G. M. Everett, 1946), but does not differentiate between grand and petit mal

Effects on Respiration and Circulation; Use in Collapse.—Full doses of these drugs raise the blood pressure (after a preliminary fall) and stimulate the respiration, but this occurs only when the convulsant effects are reached or approached (metrazol, Cramp, 1927; nikethamide, Massart, 1930), and their therapeutic usefulness is therefore questionable; but they are often given in severe collapse of all kinds, more with the idea of doing something than of accomplishing anything tangible.

The *respiratory stimulation* is directly central with metrazol; partly central and partly carotid sinus reflex with nikethamide (Zunz and Tremonti, 1931). Morphine depression of the respiration in man is counteracted more effectively and more promptly by metrazol, hypodermically, than by coramine (C. S. Hicks, 1935).

The blood pressure falls with moderate doses (to 10 mg. per Kg. by vein) through dilatation of the splanchnic vessels. With larger doses the fall is followed by a rise. Convulsive doses also show an initial drop of pressure followed by a rise (Haury and Gruber, 1939; Gellhorn and Darrow, 1939). *The rise of blood pressure* (which is least with hexeton, Stross, 1928) is chiefly convulsive, but some stimulation of the vasomotor center occurs with subconvulsive doses (van Esweld, 1931; Woodbury *et al.*, 1941). The coronary vessels are mildly dilated (Linder and Katz, 1941). The heart is not stimulated directly (Leyko, 1930; nor by nikethamide or camphor, S. Krop, 1944), but may be depressed, especially by intravenous injection. These drugs are ineffective against the cardiac depression of quinidine (M. H. Barker and Levine, 1928). Leuth, 1938, reported that metrazol greatly benefits some patients with complete heart block of the Adams-Stokes syndrome. Metrazol has little if any effect on *smooth muscle,* even in 1:2000 concentration (Hildebrandt, 1937).

Fate.—Metrazol is rapidly absorbed from the gastrointestinal tract and even more rapidly from the oral mucosa (H. Kuschel, 1939). It leaves the blood rapidly after intravenous injection (Werner and Tatum, 1939), so as to establish practically equal concentrations in the muscle, brain, liver and blood (H. J. Tatum and Kozelka, 1939). Its fate is not well known. It is detoxicated fairly rapidly, presumably by conjugation, in which the liver plays a part (H. J. Tatum, 1941); but this is not essential to the detoxication (O. Ridder, 1927; Fournier and Selye, 1942). Very little is excreted by the urine and bile.

Nikethamide, *Coramine,* is the diethylamide of nicotinic acid, and has some of the antipellagric action of nicotinic acid amide. The latter and nicotinic acid are somewhat narcotic. The monoethyl amide is strongly narcotic and somewhat stimulant; the diethylamide produces chiefly *convulsions* resembling those of camphor, but involving the whole central nervous system. It is imperfectly antagonistic to narcotics, and large doses cause additive depression. Subconvulsive doses produce rather lasting increase of the rate and depth of *respiration,* especially if this has been depressed by narcotics. The carotid sinus is involved in the respiratory stimulation (Zunz and Tremonti, 1931). The *blood pressure* rises, sometimes after a sudden and temporary fall. The rise is due to vasoconstriction and muscular spasm. It is slight with subconvulsive doses. Nikethamide has no direct effect on the *cardiac muscle* (S. Krop, 1944) and probably little if any on the coronary circulation. It produces feeble stimulation of *excised intestine* (F. Uhlmann, 1924). These actions would furnish little if any indication for its use in circulatory collapse. It may benefit abnormal *respiration* associated with cardiac disease (Stroud and Twaddle, 1940), and the respiratory depression of narcotic poisoning, similarly to metrazol and picrotoxin. In emergencies, a 25 per cent solution would be injected by vein, the dose (about 3 cc.) depending on the rate of injection, since it is rapidly detoxicated (review, Hildebrandt, 1937; Council on Pharmacy and Chemistry, 1942, J.A.M.A., *118*:1052).

Methylglyoxal produces severe and bizarre psychomotor activity, tonic distortions, salivation and incontinence (Fischler and Hirsch, 1927).

CAMPHOR

Camphor, $C_{10}H_{16}O$, is a derivative of terpene, $C_{10}H_{16}$, and is therefore allied to the volatile oils. Like these, it is a mild irritant and antiseptic and is often employed as counterirritant in the form of Spirit or Liniment. Larger doses produce convulsions, similar to those of metrazol, but much more persistent. They are important in poisoning, and have been employed in schizophrenia, but here it has been displaced by metrazol. Smaller doses were used to stimulate the circulation in collapse, but appear to be ineffective.

Camphor Isomers.—The structure of camphor is nearly related to p-cymol and to carvacrol (Bredt, 1893). It is asymmetric, the natural camphor being dextrorotatory, the synthetic racemic, and "matricaria-camphor" levorotatory. The actions of the three isomers appear to be qualitatively identical, and of the same order of magnitude, as to general toxicity and the response of the frog heart (Joachimoglu, 1916) and of the mammalian heart (Froehlich and Pollack, 1920, etc.). Natural and synthetic camphor are both official and may be used indifferently.

Historical.—The therapeutic employment of camphor in the Orient antedates history, but it does not appear to have been known to the Greeks, and came into use in Europe in the medieval period.

Related Drugs.—Fenchon, the characteristic constituent of fennel oil, is isomeric with camphor; it is also used as counterirritant. It is a fluid, and may be applied as such, or diluted to 10 per cent with alcohol or oil (I. Schlesinger, 1914).

Borneol (Borneo-Camphor, $C_{10}H_{18}O$) is used in the Orient. It acts similarly to camphor.

Camphoric acid, $C_8H_{14}(CO_2H)_2$, was introduced by Fuerbinger, 1888, against the night sweats of phthisis. It aroused some enthusiasm at first (literature, Fujitani, 1906), but experimental investigations gave negative results (Roth, 1911), and the clinical effects were also disappointing. Tyrode, 1908, could discover no effects of any kind. Fujitani and Roth described central and peripheral stimulant and depressant effects, somewhat different from camphor. It produces rather marked stimulation of the respiratory center in mammals. The average dose is 0.2 to 2 Gm., as powder.

Monobromated camphor, $C_9H_{15}BrCO$, acts similarly to camphor, but has no advantage, and has not been as well studied. Its average dose is 0.125 Gm., in powder or capsules. Wortix, Coombs and Pike, 1931, have used it as a standardized convulsant for cats. The convulsant dose averages 4.8 mg. per Kg. of body weight; the minimal fatal dose, 14.8 mg. per Kg. Subconvulsant doses may produce a single myoclonic twitch; small doses cause a single attack, resembling human epilepsy; large doses produce a status epilepticus, with recovery in twenty-four to forty-eight hours, or death by respiratory failure.

Allo-p-oxycamphor (*"vitacamphor"*) is claimed to be formed from camphor in the body. When injected hypodermically it is easily and quickly absorbed with little local irritation. K. Tamura *et al.*, 1932, claim that it stimulates the heart, *in situ* and excised; that larger doses stimulate the respiratory center, still larger doses the vasomotor center. Convulsions require even higher doses.

Diethylene camphor sulfonate (*"Solucamphor"*) is also claimed to stimulate the heart and respiration in chloroformed dogs (Henrijean and Waucomont, 1930).

Absorption, Fate and Excretion.—Camphor is readily absorbed from the mucous membranes and subcutaneous tissue. Hatcher and Eggleston, 1914, found the absorption more rapid from oral than from intramuscular administration. It is rapidly oxidized to *campherol*, $C_{10}H_{15}O.OH$; and this excreted in combination with glycuronic acid, $C_{10}H_{15}O.O.C_6H_9O_6$ (Schmiedeberg and Meyer, 1879). This destroys the activity of the camphor; and accordingly, Happich, 1912, claims that the toxicity is higher when glycosuric acid formation is disturbed through starvation or deprivation of oxygen. Similarly, he states that intra-arterial injections are more than twice as toxic as intravenous. *Borneol* is similarly conjugated, and has been proposed as a test of liver function. With one gram orally, normal subjects excrete 60 to 100 per cent as glycuronide within twenty-four hours (Ottenberg *et al.*, 1943).

Camphor poisoning occurs commonly from the consumption of spirit of camphor as intoxicant, or by giving "camphorated oil" to children by mistake for castor oil. The symptoms are nausea, vomiting, colic, vertigo, disturbed vision, tipsiness, excitement, panic anxiety with assault or suidical mania, confused delirium, loss of consciousness, face flushed then pale, impulsive movements, then epileptiform convulsions, which may last for many hours. They occur in man after 1.5 Gm. (Austragesillo, 1915), equivalent to 2 teaspoons of the camphorated oil, or a tablespoon of the spirit. Anuria is common. *Death* is rare in man, occurring by asphyxia and collapse. *Convalescence* may last several days or weeks; the gastric disturbance is especially persistent (illustrative reports, Stanley White, 1903; F. Baker, 1910; Koppang, 1912). The *treatment* consists in evacuation by apomorphine. If the spirit was taken, olive oil would first be given, to dissolve the camphor, so that it may be evacuated, but the oil should not be left in the stomach, or it may hasten absorption, as does alcohol. The convulsions may be controlled with barbiturates, if necessary.

The *toxic dose* varies greatly: 0.7 to 1 Gm. has been fatal to children and toxic to adults; 2 Gm. generally produced dangerous effects; but 15 Gm. have been survived (Koppang); and in an infant of eighteen months, 1 Gm. produced little if any symptoms (Miller, 1914). Benz, 1919, reported the poisoning of twenty children by the oral administration of 1 to 1½ tablespoons of camphorated oil. All were more or less convulsed, with blue-black lips, but otherwise fair color. The severe cases had lockjaw. Emesis was induced by mustard water, and all recovered promptly (twenty minutes to four hours). The *minimal fatal dose* for cats, on intraperitoneal injection, is 0.4 Gm. per Kg. (Joachimoglu).

Solvent and Place of Administration on Toxicity.—Cairis, 1914, and Carnot and Cairis, 1914, studied these on guinea pigs. With oral administration the toxicity of camphor is greatly decreased by oil. Hypodermically, oil solutions are also less toxic than alcoholic, ethereal or even watery solutions. Intraperitoneal are more toxic than hypodermic injections. Oral administration is more effective than intramuscular (Hatcher and Eggleston, 1914).

Location of the Convulsant Action.—In mammals, this is chiefly above the optic thalami, for section below these abolishes or greatly diminishes the convulsions (Albertoni, 1882; Morita, 1915). The motor cortex participates, for the direct application of powdered camphor to this region results in jacksonian and generalized epileptic spasms (Trabuschi, 1928). The spinal cord also shows some stimulation, and finally paralysis, but this does not come on until late, and is not important in mammals.

In *frogs*, the action on the spinal cord is *pronounced* and consists in a *paralysis*. This entirely obscures other actions which the drug may have higher up in the nervous system in these animals. It appears that the path for reflex impulses is blocked before that for impulses coming from the higher brain (Wiedemann, 1877; Binz, 1878). The symptoms are described by Grove, 1910.

Clinical Use of Camphor to Improve the Circulation.—The injection of camphor as a temporary "whip" to the heart, especially in collapse, is not well supported by decisive critical evidence, either clinical or experimental, and is disapproved by leading clinicians (report, Council on Pharmacy and Chemistry, 1943, J.A.M.A., *121:* 431).

Camphor was employed intramuscularly, dissolved in sterile olive oil, 1 to 2 cc. of the 10 per cent solution being repeated in ten- to fifteen-minute intervals as needed. For babies of one year, A. Jacobi advised $\frac{1}{10}$ to $\frac{1}{4}$ grain every two hours. Intravenous injection (250 to 350 cc. of 0.1 per cent in saline) is safe, but ineffective (Weintraud, 1913).

In normal individuals and in cardiovascular disease, camphor (even up to 3 Gm. hypodermically—Heard and Brooks, 1913) does not alter the blood pressure or the rate or quality of the pulse. Hewlett, 1917, failed to find any change in the blood flow of the human arm after hypodermic injection of 0.3 to 0.7 Gm. of camphor in oil.

Experimental effects of camphor on the circulation are inconstant, different investigators reporting divergent results and conclusions. Generally there is no definite response if the circulation is normal. When the heart muscle is depressed in various ways, camphor may, under favorable experimental conditions, improve the cardiac contractions and remove arrhythmias. The response is uncertain and gives only doubtful support to the claimed therapeutic action.

Blood Pressure.—The earlier investigators generally described rise of blood pressure from vasomotor stimulation. Widermann, 1877, and Stockmann, 1888, observed rhythmic rises of blood pressure, attributed to heightened reflex irritability. Stimulation of the vasomotor center, however, does not occur with therapeutic doses, but only as the convulsant effects are approached, and especially during the convulsions proper (Pilcher and Sollmann, 1915). Heathcote, 1923, found no rise of blood pressure in anesthetized animals, unless convulsions occurred. When these were prevented by removal of the cerebral hemispheres, doses up to 1 Gm. per Kg. did not raise the blood pressure. Liebmann, 1912, describes persistent fall of blood pressure, attributed to peripheral action on the blood vessels.

Excised Vessels.—Likhtacheva, 1916, reported that camphor, borneol and menthol, in 1:2500 to 1500 dilution, produce a dilatation of coronary and other vessels, strongest with borneol and weakest with camphor. More dilute solutions (1:10,000 to 50,000) have no effect on the coronary artery. Other arteries are temporarily constricted. Perfusion experiments have also been made by S. Oda, 1927.

Actions on the Heart.—Improvement has been recorded, especially of depressed hearts; but the results are uncertain.

Perfused rat heart has been found an especially suitable object for demonstrating the improvement. After being injured by cooling, electric stimulation, phosphorus, digitalis, yohimbine, or chloroform, the addition of camphor (natural or synthetic) usually increased the rate and removed arrhythmias; the tonus was generally improved; so also the coronary flow. These favorable results did not always follow; indeed, the heart sometimes became worse (Froehlich and Pick, 1920).

The hearts of most other mammals are not improved, in situ or excised, normal or depressed by various means, according to most observers (Plant, 1914; Richards, 1914; Heard, 1915); except that there is some dilatation of the *coronary vessels* (Bodo, 1928). *Excised papillary muscle* of cats is not stimulated (S. Krop, 1944).

Frog's Heart.—The effects are slight and inconstant with normal hearts, but camphor restores the beat of frog hearts arrested by muscarine (Harnack and Witkowski, 1876) or by chloral (Boehm, 1905), or fibrillated by electric stimulation or aconitine, or arrested systolically by strophanthin (Froehlich and Grossmann, 1921; Sasaki, 1921). The restoration is only transient (Plant, 1914). Joachimoglu, 1917, found a similar response to all kinds of local irritants, so that it does not appear to be characteristic for camphor. *Direct effects on the ventricular muscle* (Straub's method) were studied by Joachimoglu, 1917. Very weak solutions (1:4000) increased the amplitude slightly; depression occurred with concentrations above 1:2500 and arrest above 1:1250; the hearts may recover spontaneously. The three isomers act quantitatively alike; except that with the racemic the arrest lasts only fifteen minutes, whereas the others recover only after one and one-half to three hours. Menthols also stopped the heart, but weak concentrations did not accelerate. Junkman, 1925, found some prolongation of the refractory phase. With *ventricular strips* of turtle hearts, Plant observed slight quickening, not modified by chloral. The ultimate effects of strong solutions of camphor are depressant, weakening and slowing the beats. Camphor produces *parasympathetic paralysis in turtle auricle*, blocking the response to vagus nerve and postganglionic stimulation, and antagonizing acetylcholine, similarly to atropine (A. Collard, 1941).

Other Uses.—Camphor Spirit is a household remedy in colds and bronchitis. It was thought to be somewhat expectorant, diaphoretic and antipyretic (Binz, 1875 and 1877), but neither small nor convulsive doses are antipyretic in animals (Seymour and Boyd, 1946). The skin vessels are dilated. It was also advised in *tuberculosis*. It has been used as a nervous depressant in hysteria, epilepsy, chorea and convulsions, and as an anaphrodisiac. This rests on no rational basis.

Respiration.—The effects of nonconvulsant doses are slight and inconstant. Higgins and Means, 1915, studied the effects on man, using 0.4 to 0.5 Gm., hypodermically.

They found the center sometimes slightly stimulated with bronchodilatation and slight increase of carbon metabolism. The rate was often slowed, the volume, single or minute, was unchanged. In animals, Wieland, 1915, claims lowering of the threshold for CO_2. Isaak found it especially effective after morphine. Voegtlin and Wiggers, 1918, obtained uncertain stimulation after morphine and other depressants. Hanzlik, 1923, observed a fair increase of respiration after hypodermic injection of camphorated oil (20 per cent) in anesthetized rabbits.

Lactation.—Camphor has been used to prevent postpartum engorgement of the breast, and to induce rapid involution. There is no satisfactory evidence of this clinically. Controlled experiments in animals show no effect, even with large doses (R. R. Greene and Ivy, 1938).

Excised ureter is stimulated by the l isomer; the d is indifferent (Macht, 1918).

Skeletal Muscle.—Direct application produces a curare effect in frogs, not in mammals. Other camphors derived from various volatile oils also produce this effect (Hildebrandt, 1902).

Invertebrates.—Newly hatched squid, placed in $\frac{1}{10}$ saturated solution of camphor in seawater, responds by spasm of the mantle and contraction of the chromatophores. The stimulation appears to be in the ganglia. It is followed by paralysis, which may be overcome by nicotine (Moore, 1919).

Leech Muscle.—Joachimoglu, 1920, found that the three isomers produced quantitatively identical effects; *i. e.*, strong increase of tonus and rhythmic contractions, with concentrations of 1:1000 to 5000. Thymol acts similarly.

Local Actions.—Externally, camphor acts similarly to the volatile oils, producing mild analgesia and rubefaction, with little sensory irritation. It is applied in neuralgia, inflammations, etc., as the Spirit (10 per cent) or as Camphor Liniment (20 per cent), often reinforced with 5 to 10 per cent of chloroform or oil of turpentine. It is used (5 per cent) in oily nose sprays or nose drops.

The **irritant action** of small doses of camphor *on the digestive canal* is used *against dyspepsia*. Large doses produce *vomiting*.

Antiseptic Action.—Camphor is feebly antiseptic, the isomers being about equivalent (Joachimoglu, 1917). A saturated solution is used as stimulant *mouth wash* and *gargle*. A bit of camphor is a good preservative for hypodermic solutions, proteins, etc. (Romanelli, 1917).

Pneumonia.—Seibert, 1912, claimed that camphor reduces the toxemia and prevents the crisis, but the benefits are doubtful and the treatment has not obtained wide acceptance. Leo, 1913, preferred *intravenous injection* of the saturated watery solution. E. Stein, 1915, tried camphor against experimental pneumococcus pneumonia. He found that the different races of organisms differ in susceptibility.

PREPARATIONS:—*Camphor*, U.S.P. (Camphora), is a ketone, $C_8H_{16}CO$, obtained from the camphor tree, Cinnamomum camphora (Natural Camphor); or produced synthetically (Synthetic Camphor). White translucent masses of crystalline structure; a characteristic odor and warm, aromatic taste. It is slightly sol. in water, freely in alc., fixed and volatile oils and fat solvents. Dry camphor volatilizes readily, but its solutions are practically stable, even in open bottles (La Wall, 1909). Dose, 0.2 Gm., 3 grains, by mouth; or as 10 per cent solution in olive oil hypodermically. The solubility of camphor at ordinary temperature is 1:598 of water; 1:577 of Ringer's solution (Leo and Rimbach, 1919). The U.S.P. lists the *Spirit* (10 per cent), dose, 0.3 to 2 cc., 5 to 30 minims; *Liniment* (20 per cent in cottonseed oil; and *Water* (saturated aqueous solution, U.S.P., dose, 15 to 30 cc., ½ to 1 ounce). *Camphor and Soap Liniment*, U.S.P. ("*Soap Liniment*"), contains 4.5 per cent of camphor, 6 of hard soap, 1 of rosemary oil, in 70 per cent alcoho-

Absinth Convulsions.—The herb Artemisia Absinthium contains a volatile oil, whose chief constituent is *thujone*. This produces effects similar to those of camphor (Hildebrandt, 1901 and 1902; Matzel, 1905). Intravenous injection of 0.03 to 0.06 cc. of absinth oil, as 5 per cent alcoholic solution, into a cat or rabbit produces effects similar to those of camphor: marked excitation of the autonomic system, followed promptly by unconsciousness and general epileptiform convulsions, clonic then tonic. The convulsions wear off rapidly, and the margin between the convulsant and fatal dose is much wider than with camphor or picrotoxin. The convulsions are antagonized by phenobarbital, bromide or chloretone (Hrubetz and Pike, 1936; W. L. Sampson and Fernandez, 1939). The convulsant threshold is lowered by epinephrine, pitressin, nicotine and histamine; it is raised by parasympathetic stimulants and by large doses of nicotine and ergotamine. The parasympathetic antagonism is abolished by atropine, which has little effect by itself (H. W. Keith and Stavraky, 1935).

Absinthe and vermouth liqueurs were formerly prepared from species of Artemisia, with other aromatic oils. Continued overindulgence in "Absinthe" was believed to cause mania and other symptoms (review, I. L. Meyers, 1916). The present "absinthe" contains 0.1 to 0.2 per cent of aromatic oils, chiefly anise (anethol) and *no* thujone or acetone substances, in 40 to 45 per cent alcohol (references, J.A.M.A., 1939, *113*:1822).

MENTHOL

This is prepared from the volatile oils of various mints. It acts similarly to camphor, and is used especially locally against headache, neuralgia, itching, etc. Applied to the skin, it produces at first a cool sensation, followed by slight prickling and burning. The cooling effect is not physical, the temperature of the skin being normal or even increased. It is explained by specific stimulation of the nerve endings, for cold (Goldscheider). Alcoholic solutions are antiseptic.

Menthol has also been produced synthetically. This racemic form is about half as toxic as the natural, but its effects are similar, and its odor and taste are indistinguishable (H. Seel, 1927).

Menthol has a purely depressant effect on the frog heart (Joachimoglu, 1917).

***Menthol**, U.S.P., $C_{10}H_{19}OH$, is a secondary aromatic alcohol obtained from mint oils or prepared synthetically. It may be levorotatory or racemic. Colorless crystals of peculiar odor and warm aromatic taste. Only slightly sol. in water, freely in alc. Dose, ½ to 2 grains, B.P.; as carminative, etc. Externally, in alcohol, oils or ointments, 1 to 5 per cent, on mucous membranes and in herpes, 10 to 25 per cent on intact skin.

BULBOCAPNINE

This alkaloid induces plastic (catatonic) rigidity of the skeletal muscles by peculiar narcotic and stimulant actions, a "perturbation of the cortico-diencephalic automatism" (Bremer). It has been suggested against the tremors of the postencephalitic Parkinson syndrome.

Origin.—Bulbocapnine is an alkaloid, chemically related to apomorphine, isolated along with several other alkaloids from the tubers of Corydalis cava, a plant of the family of the "Dutchman's breeches." The actions of isocorydine, an alkaloid of the related Dicentra canadensis, resemble closely those of bulbocapnine (Waud, 1934). *Capaurine*, an alkaloid of Corydalis aurea, causes central paralysis in frogs, convulsions in mice and rabbits, and depression of cardiac and skeletal muscle (A. K. Reynolds and Waud, 1944). Of fifteen alkaloids from this family of plants, including protopine and chelidonine, only two produce catalepsy. All stimulate the uterus of guinea pigs and rabbits, and have various effects on other smooth muscle (R. C. Anderson and Chen, 1946).

Phenomena of Bulbocapnine Catatonia.—F. Peters, 1904, found that a peculiar narcotic and cataleptic condition is induced (in cats and dogs by 25 to 100 mg. per Kg.; in frogs by 20 mg.). It occurs also in monkeys (de Jong, 1934), in mice and in birds (Henry and de Jong, 1930). There is a striking plastic rigidity similar to, but not identical with, catalepsy (de Jong, 1912). The animals appear stupid and lethargic, and the muscles tend stiffly to retain any position in which they are placed. The narcosis predominates in rabbits and guinea pigs. In *man*, the postural reflexes are at first weakened, then exaggerated (de Giacomo, 1930). In *monkeys* (rhesus), small doses produce sleep, or the abstracted attitude of the "Rodin thinker." Medium doses cause the typical catalepsy. This lasts several hours. It may be measured quantitatively by the time for which the monkey remains suspended by the hand (C. P. Richter and Paterson, 1931). Large doses produce hyperkinesis with agitation and curious attitudes, and still larger doses cause an epileptoid condition (de Jong and Baruk, 1929). These phenomena are almost identical with those of clinical catatonia, the motor and psychological syndrome of dementia precox, and not with the Parkinsonian immobility (de Jong and Baruk, 1930).

Location of the Catatonic Action.—This is probably on the basal ganglia of the midbrain. Bulbocapnine does not act on the cerebral cortex (Buscaino, 1932). Electro-encephalograms show short duration volleys similar to decerebrate rigidity (A. C. Roberts and Leese, 1933). The spasticity is not antagonized by procaine in doses which relax postural rigidity. It is counteracted, however, by cocaine, 2 to 5 mg. per Kg., probably through central stimulation, especially in monkeys, which recover almost completely and immediately (Buchman and Richter, 1933). Cocaine is less effective in cats (Evrad and Spiegel, 1932). *Scopolamine* prolongs the catatonia; *carbon dioxide* inhalation exaggerates it temporarily (A. S. Peterson and Richter, 1933), or rather, it superimposes a hyperkinesis on the catatonia (de Jong, 1934). *Destruction of the optic thalami* in cats induces cataleptic phenomena and other complex symptoms (V. Neri and Chiatellino, 1939), apparently similar to those of bulbocapnine.

Antagonists.—Bulbocapnine catalepsy is inhibited by amphetamine (E. Spiegel, 1938) and by tetrahydronaphthylamine (E. F. Kerman, 1944). The latter antagonism is mutual, but bulbocapnine is not very effective against amphetamine hyperkinesis.

Peripheral Action on Skeletal Muscle.—Frog's gastrocnemius muscle, immersed in 1 per cent bulbocapnine, shortens immediately, progressing to one and a half hours and then relaxing gradually during three or four hours (Poppi, 1936).

Circulation.—Bulbocapnine lowers the arterial and venous pressure by direct action on the vessels (perfusion experiments). This is not prevented by atropine. The vasodilatation exists in all organs studied (C. E. Leese *et al.*, 1940), but is most marked in the ear, extremities and kidneys; it is slight in the intestines. It abolishes vasoconstrictor reflexes and antagonizes the pressor action of epinephrine, and the depressor action of mecholyl, but it does not decrease the response to pitressin or to histamine (H. Molitor, 1936, 1938; C. E. Leese and Fogelberg, 1937). It decreases the movements of excised *intestines*. It has no effect on blood coagulation (Molitor, 1938).

Clinical Uses of Bulbocapnine.—In man, Schaltenbrand, 1924, observed some narcosis and marked fatigue after 1 mg. per Kg. Slightly higher doses (0.1 Gm., hypodermically) have been tried in paralysis agitans, with prompt but temporary improvement (Lewy, 1926), the tremors being abolished during the administration in many cases (Mella, 1926). Others have used it in encephalitic disturbances (Hill, 1929), and in chorea (Kuttner, 1929); confirmation is needed. The plant was used against these conditions in the Middle Ages—when therapeutic observation was anything but critical. Even large cataleptic doses (to 0.6 Gm.) have practically no effect on schizophrenia (M. Ellermann, 1933) or on the catatonus in catatonic patients (de Jong, 1934). Bulbocapnine (25 to 35 mg. per Kg.) has been injected in experimental technic, to immobilize animals after operations under local anesthesia, especially on the brain (Schaltenbrand and Stanley Cobb, 1927). It may be used experimentally as preanesthetic sedative, in place of morphine-scopolamine, inducing motor sedation without impairment of respiration or circulation (H. Molitor, 1936).

Other Catatonic Drugs.—Various degrees of narcotic plastic rigidity, or at least tendency to maintain abnormal postures, occur in poisoning by cannabis indica (G. W. Henry and de Jong, 1930), by the alkaloids of *Nymphaea* and *Nuphar*, white and yellow *pond lilies* (Modrakowski, 1936), by 3-astyl 3 amino-hydrocarbostyril (N. Haysashi, 1930), and in rats and guinea pigs by morphine. Their phenomena, however, differ more or less from those of bulbocapnine, and it is doubtful whether their mechanism is the same. Harmine, barbiturates and sulfonal do not produce catatonus (Henry and de Jong, 1930).

CAFFEINE, THEOBROMINE, THEOPHYLLINE AND OTHER METHYLXANTHINES

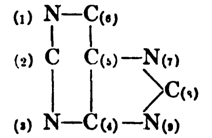
These have several distinct actions: (1) Increased irritability of the central nervous system from above downward; leading to stimulation of the psychic areas (insomnia, etc.); of the medullary centers (respiratory, vasomotor and vagus); and with large doses to heightened reflexes and tetanic convulsions. With toxic doses, the stimulation is accompanied by paralysis. (2) Increased ease of muscular contraction, progressing to loss of elasticity and to rigor; this affects all forms of muscle to a varying degree. The heart rate is thereby quickened. (3) Vasodilatation by direct action on the vessels, with moderate doses; this combines with the cardiac stimulation to quicken the circulation. (4) Diuresis results though the interaction of several factors. Caffeine is used as a psychic, muscular and respiratory stimulant; and as a cardiac tonic and diuretic. Theobromine and theophylline are relatively more effective when the peripheral actions are desired.

Members.—This group comprises the various methyl derivatives of xanthine (dioxypurine). They occur in several plants; as products of metabolism in animals; and may also be obtained synthetically. The most important are *caffeine* (trimethylxanthine), the principal alkaloid of coffee, tea, kola, guarana and maté; theobromine (3.7 dimethylxanthine), from cacao; and theophylline (1.3 dimethylxanthine), which is usually prepared synthetically. Xanthine itself, and all its other methyl derivatives, produce the principal actions of the group.

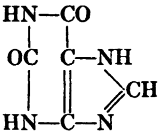
Caffeine is so feeble a base that it does not turn litmus, and the salts are dissociated by water. Its solubility is also peculiar. It was isolated from coffee in 1820 by Runge, Pelletier and Caventou, and by Robiquet. Its identity with the alkaloid of tea (sometimes called *theine*) was surmised by Berzelius and confirmed by Jobst and Mulder in 1838.

Caffeine occurs in plants of at least six families, which are scattered over many portions of the globe. These plants have nearly all been consumed by the natives as stimulants. The plants often contain volatile products or tannic acid, which slightly modify their effects. Theobromine is often associated with the caffeine; in cacao, the theobromine predominates.

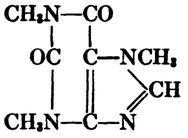
The chemical structure and derivation of the purine derivatives were elucidated by Emil Fischer. The most important are as follows:



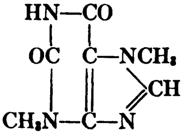
Purine (the numbers indicate the positions in which radicals may be introduced).



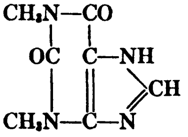
Xanthine



Caffeine



Theobromine



Theophylline

Cerebral Stimulation.—Caffeine in the form of its beverages is a popular "stimulant," tending to facilitate mental and muscular effort, diminishing drowsiness and psychic and motor fatigue, giving a sensation of comfort and cheerfulness, and relieving certain types of headache. The stimulation is apparently not followed by depression, except as it exhausts reserves. Experimental investigations indicate that moderate doses (to 0.3 Gm. in man) produce a quicker and clearer flow of thought; disappearance of fatigue; more sustained intellectual effort; more efficient appreciation of sensory impressions and more perfect association of ideas. Reaction speed is increased, especially motor, but the accuracy and delicacy of movements, particularly of acquired motor skills, is impaired, often for several days. Conditioned reflexes give precipitate reactions with a large percentage of errors, except when fatigue is relieved (Kraepelin, 1872; Hollingsworth, 1912). The central actions of theobromine are much weaker than those of caffeine (Filehne, 1886). Theophylline is intermediate. *With* *larger doses,* these effects pass into wakefulness, nervousness, excitement, tremor, palpitation and the other unpleasant reactions described under the toxicology. Still larger doses may produce delirium and temporary mania, and finally convulsions of the strychnine type. *The lower mammals* react by restlessness and excitement. The cat is said often to become frantic. Frogs do not exhibit any symptoms referable to the brain.

Hollingsworth, 1912, conducted tests on normal human subjects which led to the following conclusions: *motor speed* (tapping) is increased by small and large doses (0.06 and 0.39 Gm. of pure caffeine, respectively). With the more complicated typewriting, speed is also increased by the small dose, but retarded by the large. Errors in typewriting are fewer with all doses. *Association tests* (naming colors or opposites; calculations) are speeded by all doses. *Choice* (cancellations, etc.) seems retarded by small, and stimulated by large, doses. *Unsteadiness* (tremors) of the muscles is a frequent result. None of the stimulant effects are followed by depression. The effects start in one to three hours after oral administration and last from two to over seven hours; the mental effects are more persistent than the purely motor. The "after contraction" ("*levitation*") which occurs when resistance is removed is increased by caffeine, diminished by bromide, but little affected by barbiturate, chloral or strychnine (Sapirstein *et al.*, 1936). Caffeine causes "attacks" of rapid potential variations in the *brain action currents*. These appear identical with those produced by metrazol, cocaine and strychnine (M. H. Fischer, 1932). *Direct application of caffeine to the motor cortex* results in clonus and epileptoid convulsions similar to those caused by nicotine and strophanthin (Rizzolo, 1929).

The use of caffeine against fatigue will be discussed under the "Caffeine Beverages."

Use against Headache.—Fairly large doses of caffeine (0.5 Gm. = 7½ grains) are rather effective against certain forms of headache, such as migraine, neuralgia, fatigue, etc. The cerebrospinal fluid pressure is reported as lowered, without change of arterial pressure (W. D. Paul and Greene, 1936). The caffeine may be prescribed with acetanilid. It does not prevent the depressant effects of the latter, but rather increases its toxicity (Hale, 1909; Salant, 1912); it also increases the toxicity of alcohol and barium chloride by its circulatory action.

Use as Analeptic in Narcotic Poisoning.—Caffeine is used as an antidote against acute poisoning by morphine (Bennett, 1874); alcohol (Binz, 1878); paraldehyde (Schröder, 1887); chloral (Airila, 1913). The psychical actions are directly antagonistic, the mental and muscular coordination being immediately improved, although the effect is not lasting. The respiration (Voegtlin and Wiggers, 1918) and circulation may also be somewhat stimulated, but the effects easily become additive, so that with fatal alcohol poisoning, caffeine is actually deleterious. With morphine, the conditions are probably more favorable.

As a stimulant antidote, the caffeine is usually administered as strong, hot, black coffee, to secure the synergistic stimulant action of the heat and oils. Strongly boiled tea, through its tannin, would be a chemical antidote in poisoning by corrosive metals. Coffee has not this precipitant effect. The *mutual antagonism of alcohol and caffeine* was studied by Pilcher, 1912. He found that with the *smaller doses*, each drug tends to act qualitatively as if present alone. In alcohol sleep, small doses of caffeine cause awakening, restore the reflexes and diminish the fall of temperature. With *larger doses*, there is a qualitative change in the direction of greater depression. Light alcohol coma is intensified by moderate or large doses of caffeine; the reflexes are further depressed. With *toxic doses*, the fatality is greatly increased if both drugs are present, mainly by their deleterious action on the heart.

Spinal Cord.—Ordinary doses of caffeine heighten the reflexes (Wood, 1912; Storm van Leeuwen, 1913). Toxic doses produce convulsions of spinal origin (Bing, 1901), which agree with those of strychnine, except that the tetanus is neither as violent nor as prolonged. The exhaustion in the intervals is also less pronounced. The tetanus may produce death by fixation of the respiratory muscles. The convulsant dose is relatively large, and it is doubtful whether it has been observed in man. Ordinary toxic doses produce only tremor. The *paralytic action* of large doses can be shown in frog by protecting the muscles from rigor; *i.e.*, by ligating a leg exclusive of the nerve. Caffeine will then destroy its reflexes.

The medullary centers are moderately stimulated by caffeine. There is little or no subsequent depression, even with toxic doses. The most conspicuous effect is on the respiration. The stimulation of the vasomotor and vagus centers is interfered with by other factors, described under "Circulation."

Respiration.—In man, the respiration is scarcely affected by oral therapeutic doses (Newburgh, 1914). Cardiac dyspnea is improved by the circulatory effect. With hypodermic injection of 0.15 to 0.25 Gm., there is definite respiratory stimulation. The Cheyne-Stokes respiration of cardiovascular disease is sometimes restored almost immediately to the normal rhythm by intravenous injection of *aminophylline* (theophylline and ethylene diamine), and the effect may last for hours; 0.5 Gm. two or three times daily suffices. Theophylline in other combinations produces the same effects (M. H. Nathanson and Fitzgibbon, 1939). The respiratory stimulation by caffeine appears to be chiefly, if not entirely, central, for it occurs after denervation of the carotid sinus and aorta (Le Messurier, 1936).

The CO_2 *tension* is markedly lowered. The rate and depth of the respiration and the minute volume are increased. There is also increased gas metabolism and sometimes bronchial dilation (Higgins and Means, 1915). The respiratory response to CO_2 was not significantly altered by small or large doses in normal human subjects (Grabfield and Means, 1917).

The respiratory stimulation by aminophylline is used for the clinical *determination of circulation time,* injecting 1 cc. containing 0.24 Gm. by vein. The end point, normally in 12.4 seconds, is marked by increased depth of respiration, sometimes a gasp (Koster and Sarnoff, 1943).

Anesthetized animals respond by increased rate (Binz, 1878) and generally also increased depth of the respiration (Heinz, 1890), probably due to partial awakening from the anesthesia (Cushny, 1913). Inhibitory reflexes are less effective. *In morphinized dogs,* caffeine produces brief overventilation (two to ten minutes) with fall of alveolar CO_2; followed by normal ventilation with rise of CO_2, persisting for several hours (R. G. Smith, 1928). The respiration of *unanesthetized rabbits* may be depressed by the hypodermic injection of moderate doses, 10 mg. per Kg. (Hanzlik, 1923). *Theophylline* increases the rate and depth in chloralosed dogs and in rabbits under various narcotics. The response of normal rabbits is inconstant (Hazard and Jequier, 1938).

In respiratory paralysis by cerebral compression caffeine proved a less effective stimulant than strychnine or especially cyanide (Loevenhart *et al.,* 1918).—Breslauer-Schutz, 1921, claims useful therapeutic response from *subdural injection* in the region of the medulla.

Use in Asthma.—Prompt relief is usually obtained from intravenous injection of 0.5 Gm. of aminophylline, sometimes when epinephrine and atropine have failed. Side actions are frequent but not dangerous: vertigo, vomiting, chest pain, throbbing head (H. A. Carr, 1940). *Theophylline monoethanolamine* is effective orally with little side effects (Lamson and Bacon, 1941).

Aminophylline protects guinea pigs against the bronchial spasm of histamine and dilates excised bronchioles (R. H. Young and Gilbert, 1940; Luduena, 1942). Coffee sometimes gives relief in asthmatic attacks. The action is probably partly psychic, partly bronchial.

In guinea pigs, caffeine relaxes the bronchial spasm produced by peptone or muscarine (Pal, 1912). Bronchial dilatation is also sometimes observed in man (Higgins and Means, 1915). F. Meyer, 1915, concluded that caffeine acts mainly by stimulating the respiratory center to greater effort.

Circulation.—Caffeine acts on the heart and blood vessels, peripherally and centrally. The effects are therefore complex and vary with the dose and other conditions. The predominant action of therapeutic and moderate physiologic doses consists in vasodilatation, combined with sufficient cardiac stimulation to maintain the blood pressure, or even to raise it somewhat. Both actions combine to favor the blood flow, and would be useful in circulatory diseases; the diuretic action is a further desirable feature. On the other hand, the effects of caffeine are not as powerful or as lasting as those of digitalis, and its side actions often interfere with its use. The other methylxanthines act similarly to caffeine. Theobromine is more powerful than caffeine, and theophylline is still more active.

Intravenous injection of caffeine produces a fairly severe fall of blood pressure, with prompt recovery. The *acute fall of pressure* is presumably due to depression of the myocardium by the concentrated drug. It is not seen with other methods of administration. It is not characteristic for caffeine, but occurs as "*velocity shock*" with many other drugs. The organ volume (oncometer) falls with the pressure (indicating that the action is cardiac). Direct observation of the heart shows dilatation with diminished excursions. The heart rate is quickened and the vasomotor and respiratory centers are stimulated by the low pressure.

Stimulant Doses.—Small and moderate doses (to 20 mg. per kilogram) generally produce slight (10 to 20 mm.) rise of blood pressure, usually with more or less increase of the heart rate. The tonus of the heart is increased, and the amplitude of its excursions may be greater. This, and the faster rate, raise the output of the heart. The vein pressure is not changed (Capps and Matthews, 1913). The blood flow is increased (Landgren and Tigerstedt, 1892; Loewi, 1905). The volume of the splanchnic organs (Phillips and Bradford, 1887; Loewi, 1905) and of the cerebrum (Roy and Sherrington, 1887) increases. This oncometric change is more marked and more persistent than that of the blood pressure, and therefore indicates marked *vasodilatation.* It has been claimed that this is more powerful in the kidney than in other organs (Phillips and Bradford; Loewi), but in fact it seems to be about equal, at least in the splanchnic area (Sollmann and Pilcher). The vasodilatation is peripheral, since the perfusion method shows that the vasomotor center is actually stimulated. Decerebrate cats also show consistent stimulation of the vasomotor center (van Esweld, 1930). Ordinarily, the peripheral dilatation is more powerful than the central constriction; but under some conditions the constriction may predominate, so that the oncometer falls with the rising pressure.

The older conception of a powerful and constant constriction was based on slender and indirect evidence (mainly on the experiments of Wagner, 1885, and Schroeder, 1886). Vinci, 1895, found that caffeine gave a much larger rise of blood pressure (presumably cardiac) in animals weakened by anemia or starvation.

Depressant doses of caffeine, above 40 mg. per kilogram, progressively lower the blood pressure, until a level of 60 to 85 mm. is reached, with doses of about 140 mg. per kilogram. This level is then maintained until death approaches. The tonus of the heart is decreased, so that it gradually dilates, and the amplitude of the excursions and the output are diminished. The oncometer falls with the blood pressure, so that cardiac depression is the dominant element. It is accompanied, however, by a progressive and finally complete vasomoter paralysis, when epinephrine, splanchnic and other forms of vasomotor stimulation become less and less effective. (Epinephrine still causes a relatively small rise through cardiac stimulation.) *Death* occurs by acute cardiac failure. Caffeine serves to lower the resistance of the heart, so that the fatal dose may vary greatly in different animals.

Direct Action on Blood Vessels.—These tend to dilate when excised organs are perfused with caffeine (Cow, 1911). The effect is not great with caffeine alone, but very little caffeine suffices to counteract the constrictor effect of epinephrine (Sollmann and Pilcher). Theocin is reported to invert the constrictor action of epinephrine, ephedrine and pituitrin (R. Kohn, 1932).

Special Vessels.—The *lung vessels* are first constricted, soon ceding to dilatation (Berezin, 1914). Macht, 1914, observed dilatation of excised pulmonary artery. Theobromine was practically negative. Baehr and Pick, 1913, found no effect with caffeine on long perfusion. The *liver veins* are dilated (Berezin, 1914). The vessels on the *pia mater* and *retina* are dilated during life (Hirschfelder, 1915). The dilatation of the eye vessels may raise the intra-ocular tension even with falling systemic blood pressure (Wessely, 1915). Raphael and Stanton found no changes in the human *brain volume* (plethysmograph) after intravenous injection of 0.25 Gm. of (absolute) caffeine. (The *coronary blood flow* will be discussed after the heart.)

The Heart.—When the vagi are intact, small doses of caffeine sometimes cause slowing through stimulation of the vagus center (Ewirski, 1904) and increased vagus excitability (Fredericq, 1913). With larger doses, or always if the vagi are paralyzed, the rate is quickened. With the vagi divided, 2 mg. per kilogram increases the rate by 25 per cent; 30 to 100 mg. by 50 per cent. Beyond this there is no further increase, but the heart shows *arrythmia* and *irregularity*.

The increased rate is attributed to increased contractility of the muscle substance itself, especially in the region that sets the pace. The quickening is not due to *vagus* depression, since it occurs after atropine (Johannsen, 1869). The vagus tone is indeed lost after large doses (Aubert, 1872, and others), and the response to vagus stimulation is uncertain; but direct central vagus stimulation may still cause marked slowing. Nor is the quickening due to stimulation of the *accelerator* mechanism, for it occurs in the excised mammalian heart. Swirski, 1904, found that when the caffeine quickening had reached its maximum, a further increase would be obtained by stimulating the accelerator. (Large doses destroy the response to accelerator stimulation, Fredericq, 1913). Cushny showed that the details of the cardiac curve are different in caffeine and accelerator stimulation. Pickering, 1893, observed the quickening in embryonic chick's heart before the nervous structures become developed.

Frog's Heart.—Small doses increase the rate (Voit, 1860), excursions (Wagner, 1885), pulse volume, and especially the absolute force (Dreser, 1887). The diastole is shortened more than the systole. The refractory phase is not changed (K. Junkmann, 1925). Large doses cause slowing and weakening (Maki), with diastolic tendency (Faval). The heart beats for some time after the skeletal muscles are in rigor (Wagner). The final arrest may be either in systole (Johannsen, 1869) or diastole (Faval). When perfused in Ringer's solution, 0.025 to 0.2 per cent increases the amplitude, 0.2 to 2 per cent decreases the amplitude and produces irregularities of rhythm and automaticity (Cheney, 1935). The *terrapin's* heart responds like the frog's (Beyer, 1885). Low concentrations of caffeine, theobromine and theophylline increase the response of the turtle heart to vagus inhibition; high concentrations inhibit the response. All concentrations potentiate acetylcholine (A. Lamalle, 1941). *Perfusion of the medulla in turtles* with 0.04 per cent of caffeine has practically no effect on the heart rate, in contrast with strychnine (A. D. Bush, 1919).

In *excised and perfused mammalian heart*, caffeine and the other xanthines produce increased rate, amplitude and force of the cardiac contraction, and generally quickened coronary flow (Hedbom, 1899). The increased amplitude is first in the systole, then also in the diastole; the cardiac tonus is not increased (Plavec, 1909). The stimulation is greatest with theophylline, then theobromine, then caffeine. These experiments seem to refer only to stimulant concentrations, and they may be considerably modified by changing conditions (Lifschitz, 1907; Plavec, 1909). *Electrocardiograms from the excised mammalian heart* show that while the three principal methylxanthines agree in quickening the rate, they differ in their effects on conduction. This is depressed by theobromine, increased by caffeine and theophylline (Sakai, 1919). *Excised papillary muscle* of cats is not affected by ordinary concentrations of the methylxanthines; high concentrations, 1:5000 to 1:1000, produce brief increase of systolic tension (S. Krop, 1944).

Mammalian Heart in Situ.—The effects of the various doses were studied by Pilcher, 1912, with the results described under the general discussion of the circulatory effects.

Experimental Heart Block.—In complete block, caffeine increases the strength of the ventricular contraction. Larger doses produce ventricular extrasystoles and tachycardia. The strength of the auricles is temporarily quickened (Egmond, 1913).

Coronary Circulation.—Earlier investigators generally reported considerable increase of coronary blood flow in perfused hearts (Heathcote, 1920, bibliography; Bodo, 1928), greatest with theobromine salts, then theophylline ethylene diamine, then theophylline sodium acetate, and least with caffeine (Gilbert and Fenn, 1929). This has been interpreted as dilatation of the coronary vessels; but in the beating heart, the coronary flow is influenced not only by the tonus of the coronary vessels, but by the cardiac contractions; and in the living animals also by the aortic blood pressure (F. Meyer, 1912). In experimental animals, the increased flow does not precede but follows the myocardial stimulation (N. H. Boyer, 1943). However, dilatation plays a part at least, for caffeine and aminophylline increase the coronary flow in perfused nonbeating (fibrillating) heart (L. N. Katz and Lindner, 1939). Boyer, Wégria and Green, 1941, report some increase of coronary flow from intravenous and intracoronary injection of aminophylline in dogs. The coronary dilatation was confirmed by Lindner and Katz, 1941. Prolonged administration of aminophylline to dogs with experimental myocardial infarction reduces the size of the infarct by developing anastomoses, but it is less effective than papaverine (Mokotoff and Katz, 1945).

The circulatory effects in man correspond with what would be expected from animal experiments. With doses to 1.5 Gm. of caffeine the acute effects are inconstant and generally slight. The heart rate may be slowed, quickened or unchanged (literature, Sollmann and Pilcher). Palpitation is common, but apparently largely subjective. The blood pressure may rise (Wood, 1913); or fall (Mirano, 1906); or remain unchanged (Lucas, 1914; Newburgh, 1914). The volume of the human arm is diminished (Hewlett, 1913). The blood flow tends to improve by increased systolic output. Intravenous injection of 0.48 Gm. of aminophylline is reported to increase the cardiac output and to produce brief vasodilatation in the skin (H. J. Stewart and Jack, 1940).

A. Grollman, 1930, found that caffeine citrate in doses smaller than 0.5 Gm. had no effect on cardiac functions. With 0.5 to 1 Gm., there was generally a slight increase of cardiac output, slight or no change in the pulse rate, increase in the oxygen differential between arterial and venous blood and generally 10 to 30 per cent increase of oxygen consumption. When the caffeine caused marked subjective nervous effects, there resulted more marked increase of cardiac output, blood pressure and pulse rate and no rise in the arterial : venous oxygen differential. Hypodermic doses of 0.3 to 0.5 Gm. in resting men produce a definite increase of the total *blood flow* (Krogh-Lindhard method). The improvement occurs by increased systolic output. It does not occur during work. Means and Newburgh, 1915, attribute the rest effect to increased venous return to the heart, by some action outside the heart. During work, the venous return is adequate, even without caffeine, and is not materially increased by the drug. In advanced *myocarditis*, full and continued doses of caffeine (about 1 Gm. per day) cause a progressive and permanent lowering of blood pressure, reaching a total of 10 to 50 mm. This is parallel to the diuresis and to the relief of the edema and other symptoms (L. Taylor, 1914). Theobromine does not lower the pressure, although it is otherwise equally or more efficient.

Therapeutic Effects on Circulation.—The methylxanthines are used as cardiac stimulants in syncope, and especially in cardiac dropsies. They lack the permanent, tonic action of digitalis, but are useful as adjuvants or when a quick effect is desired. Theobromine deserves preference over caffeine. It is effective on the first day, if at all. The side actions of caffeine interfere with its employment, especially in excitable patients. In hypotension and infectious diseases, caffeine fails to improve the circulation (Newburgh, 1914; Lucas, 1914). Aminophylline does not affect improvement in peripheral vascular disease, nor does it reduce the pressure in hypertension (review, Boyer, 1943). Intravenous injections sometimes cause sudden death (G. A. Merrill, 1943).

Theobromine and theophylline (aminophylline) in angina pectoris were introduced (by Askanazy, 1895) with the object of increasing the coronary blood flow; and diethylene diamine was added to theophylline to enhance the dilatation. It has little effect, however, except to increase the solubility of the theophylline (K. H. Osterwald and Meurer, 1939). The earlier clinical reports indicated relief of cardiac pain in angina, coronary thrombosis and sclerosis; however, when methylxanthines were compared with placebos, extensive series failed to show any such effect (Evans and Hoyle, 1933; H. Gold *et al.*, 1937). Other observers report that the tolerance of some angina patients for standardized work is increased, for some twenty minutes with intravenous, longer with oral administration. Theobromine sodium acetate (0.5 Gm., four times per day) was as effective as theophylline sodium acetate (0.15 Gm., four times per day) and more economical; aminophylline was less effective; caffeine had little value (M. G. Brown and Riseman, 1937; R. L. Levy *et al.*, 1940; G. V. Le Roy, 1941). Aminophylline relieves coronary spasm from pituitrin injection in animals (P. J. Hanzlik and Moy, 1945).

The dyspnea and Cheyne-Stokes respiration of cardiac failure is often promptly improved by aminophylline (R. Singer, 1927), but no more than by theophylline or theobromine. The improvement is parallel to the decrease of venous and intrathecal pressure, and is perhaps aided by relaxation of bronchiolar spasm (J. A. Greene *et al.*, 1937). The pressure of the *cerebrospinal fluid* may be lowered without change of arterial pressure (W. D. Paul and Greene, 1936). A. Blau, 1936, reports that the fall after 0.35 Gm. of caffeine, clinically, is transient.

Pruritus in various dermatoses is reported to be relieved immediately by aminophylline, especially with intravenous injection (E. Epstein, 1946).

Effects on the Urine.—The most important therapeutic effect of caffeine consists in a considerable diuresis, but the methylxanthines have been largely displaced by the more potent mercurial diuretics. The increase concerns mainly the water of the urine. The absolute quantity of all urinary solids is also increased, but less than the water, so that their percentage is lowered. The efficiency varies with conditions, especially with the amount of water in the body (Widmer, 1914); the diuresis is most abundant in dropsical conditions, and fails entirely with dry food. It is much greater in man and in wet-fed rabbits than in dogs. Cats practically do not respond. It fails also in glomerular nephritis, but is effective in tubular nephritis unless the vessels are involved. The albumin in nephritis may be increased. Theobromine and especially theophylline are more effective. This difference is explained in part by the relatively larger doses which can be taken without prohibitive side actions. *The mechanism of the diuretic action of the methylxanthines* is chiefly, if not solely, that of increased glomerular filtration through increased blood flow and rise of glomerular capillary pressure, due to local vascular adjustments within the kidney (Phillips and Bradford). There is no evidence that reabsorption from the tubules is diminished (as suggested by Sobieranski), and it is improbable that changes in the water affinity of the tissues are involved.

Historical.—The scientific investigation of the diuretic action of the methylxanthines started essentially with von Schroeder in 1886 and 1887. He found that the increased urine flow is not conditioned on increase of the general blood pressure, and therefore concluded that it could not be due to increased "filtration," in the sense of the Ludwig theory, which he conceived to demand increased blood pressure. He therefore assumed that caffeine must directly stimulate the "vital" secretory function of the renal epithelium, according to the Heidenhain theory. The fundamental error of von Schroeder consisted in the assumption that the general blood pressure is an index of the filtration pressure in the glomeruli, without considering the probability of vasomotor adjustments within the kidney, or of an altered balance between general vascular tone and cardiac output. These conditions would be reflected in the kidney volume much more closely than in the general blood pressure; and in fact, Phillips and Bradford, 1887, and others since then, observed that the caffeine diuresis is paralleled fairly closely by increase of the kidney volume, although the agreement is not absolute. The methylxanthines cause a larger change of renal volume than other diuretics, and the dilatation lasts for two hours after intravenous injection of caffeine or theobromine (W. E. Read). Increased kidney volume implies increased filtration pressure, unless it is due to contraction of the veins; the latter was excluded by the observation of Loewi, 1905, that caffeine increases the renal blood flow. Sollmann and Pilcher, 1911, showed that caffeine produces considerable dilatation of the renal vessels if these have been previously constricted by epinephrine, while at the same time the output of the heart is increased. The renal blood flow is increased (in rabbits) even by nondiuretic doses of caffeine (Kihara, 1928). The vasodilator action is directly on the renal vessels, for it occurs in eviscerated rabbits with automatic blood pressure compensation (Ozaki, 1927). Richards and Schmidt also showed marked dilatation and increase in the functioning glomeruli by direct microscopic observation in the frog. The correspondence between the vascular changes and urine flow is not perfect (Cushny and Lambie, 1921), but some divergence might be expected in an organ of such complicated vascular topography.

Interference by Vasoconstriction.—While the stimulation of the vasomotor center has not ordinarily the importance attributed to it by von Schroeder, it may sometimes be sufficiently powerful to overcome the peripheral dilator effect. At all events, the diuresis is aided by the hydrocarbon narcotics. Curare is also said to aid the diuresis (Cervello and LoMonaco).

Denervated Kidney.—Excised and re-implanted kidney, after resumption of its normal function, responds in the normal manner (oncometer and diuresis) to theobromine and caffeine; also to urea and hypertonic saline (Quinby, 1917).

Perfusion of Excised Mammalian Kidney.—Varying results have been described (*cf.* Sollmann and Hatcher, 1907); but when positive, the effects were generally in the direction of increased vein flow and ureter flow, pointing to vasodilatation. Richards and Plant, 1915, also obtained increased ureter flow when the perfusion flow was kept constant. This has been interpreted as showing a noncirculatory factor in the diuresis; but it is doubtful whether changes in the renal circulation are excluded in this manner. *Heart-lung-kidney preparations* of dogs, perfused at constant pressure, also respond to caffeine by increased vein and urine flow. The chloride concentration in the urine increases, that of urea decreases, but the total quantity of urea increases. These changes in composition agree closely with those that occur in equal diuresis produced by rise of perfusion pressure; indicating that the changes of composition are secondary to the diuresis (Verney and Winton, 1930).

Ureter Peristalsis.—Lucas, 1907, found that caffeine has a tonic effect on the pelvic portion of the ureter.

The creatinine clearance test (Rehberg) has given results indicating increased glomerular filtration with normal tubular reabsorption (Schmidt and Leitle, 1932; Hermann *et al.*, 1933); Blumgart *et al.*, 1934, failed to demonstrate this.

Water-Affinity of Blood and Tissues.—Paul Spiro, 1918, reported that caffeine causes the blood to lose fluid even if the kidneys had been previously removed, and it was argued from this that it diminishes the affinity of the serum colloids for water and salts, and thus liberates fluid for filtration by the lymph or urine (Karl Spiro, 1920). This seemed supported by the observation of Ellinger *et al.*, 1921, that serum perfused through frog legs produced edema more readily if caffeine (1:7000) was added. However, caffeine increases the acidity of muscles, and this may account for their increased water affinity. They also reported increase in the speed of *ultrafiltration* of serum through colloidal membranes when caffeine was added, even in the dilution of 1:56,000; increased swelling of colloidal gels when placed in such serum, and aggregation of the serum colloids, observable with the ultramicroscope. Analogous results were reported by Brühl, 1929, and Szeloczey, 1929; while others obtained contradictory results (Faludi, 1928). The significance is doubtful. *The imbibition affinity of the whole frog* (*i. e.*, the quantity of water taken up on immersion, the reciprocal of the quantity lost in dry air, by winter frogs) was not increased by caffeine, although mercurials and urea increased the water retention (Molitor and Pick, 1922)

The water and salt content of the blood have been reported as diminished and as increased. The divergence is explained partly by the water and salt content of the body, but especially by the stage of the diuresis. Generally, the proportion of water and chloride in the blood diminishes during the diuretic stage, and rises to the normal during the compensating oliguria (Paul Spiro, 1918; clinically, Veil, 1922). Patients with congestive heart failure respond to aminophylline by considerable *increase of plasma volume*, persisting after the diuresis, although it may eventually fall below the control level (Calvin *et al.*, 1940).

The Chloride Level of the Blood and Urine.—In rabbits, the caffeine group may increase the plasma chlorides, without increasing the quantity of the urine (Katsuyma, 1898); in man, the chloride concentration is generally diminished (Sellei, 1912; Wuescher, 1925), and only rarely increased (for instance in diabetes, E. Meyer, 1905; drop of plasma chloride in nephritis, E. H. Mason, 1918). With rabbits, the caffeine group maintains or restores a high chloride excretion when this has been lowered by deficient salt income or by sulfate or water diuresis (Barcroft and Straub, 1910); but in dog, and in man, the chloride retention is not broken down (Sollmann and Hofmann, 1905; Saccone, 1911). Neither aminophylline nor salyrgan nor merbaphen produces a significant change in the chloride level of the human blood (Hansen *et al.*, 1931). *Bromide excretion* is accelerated in rabbits (Frey, 1910).

Source of the Chloride and Water Excretion in Rabbits.—Sasaki, 1925, found that continued administration of theobromine increased the water excretion only when the rabbits are fed on wet food; but that the chloride excretion is increased also on dry food, *i. e.*, independently of the diuresis. Analysis of the tissues shows that the water excreted in excess of the income is derived mainly from the skin; the chloride from the skin and muscles. Eventually the chloride level of the blood is also lowered.

Other Constituents of the Urine.—Increased urine flow generally lowers the concentration of urinary solids, but increases the absolute quantity, at least for a time. This holds true also of caffeine (von Schroeder, 1886). The relative increase of the different solids is not the same (salts and urea, Le Noir and Camus, 1903; Na and K, Bock, 1911; sulfate and phosphate, man, Wuescher, 1925). The phosphate concentration of the blood and urine is lowered, proportional to the diuretic efficiency of the xanthine derivatives (Bollinger, 1928). *The urea clearance test* in nephritic and hypertensive patients was not affected by caffeine, theobromine or salyrgan (I. H. Page, 1933). Caffeine, in common with other diuretics, increases the amount of benzoate that can be synthesized into *hippuric acid* (Astolfani, 1905). *Purine*, intravenously or by mouth, increases the *uric acid* clearance by more than half (Bröchner-Mortensen, 1939).

Theories of Direct Cellular Action.—The diuretic action of the caffeine group has also been attributed to direct effects on the renal cells; either to stimulation of secretion (von Schroeder), or to paralysis of reabsorption (Sobieranski), or to alterations in the glomerular filtering membrane (Cushny and Lambic). These assumptions, which are practically unsupported by positive evidence, were based essentially on the inadequacy of the earlier attempts at the more mechanical explanations. The advances that have been made may dispense with them. On the other hand, the mechanical factors can not be effective if the renal cells are too greatly altered.

Sobieranski, 1903, attributed caffeine diuresis to *diminished reabsorption* of the glomerular filtrate. His arguments were based on observations on the excretion of stains, the interpretation of which is unconvincing. Similar objections hold against the conclusions of Hirokawa, 1908, based on the osmotic pressure of the renal cortex; and against those of Greenwald, 1907, on the chloride of the cortex.

Oxygen Consumption.—Barcroft and Straub (1910) reported that caffeine produced increased oxygen consumption in the kidneys—evidence of local energy consumption that would not be needed by a physical filtration process. Other observers have failed to obtain this effect (Richards and Schmidt; Kihara, 1928); and on the other hand, the oxygen consumption of the kidney may be increased by increasing the arterial pressure (Fee and Hemingway, 1928). Indeed, there is no constant parallelism between the urine output and the oxygen consumption, in intact or excised kidneys (Van Slyke, Rhoads *et al.*, 1934). Anuria by nephrotoxic poisons may exist with increase or decrease of renal oxygen consumption (Chuta).

The *aglomerular kidney* of the toadfish does not respond to caffeine and theophylline by diuresis, but by oliguria (Bieter).

The Influence of Conditions on the Diuretic Response.—The improvement of glomerular filtration is influenced by the amount of filterable water, by the permeability of the glomerular filter, and by the patency of the renal tubules.

Excess of Fluid.—Superabundance of fluid is evident in edemas and ascites; and these conditions therefore give the largest response to the caffeine diuretics (Hofmann, 1890), provided that the conditions that caused the edemas are no longer operative. A part of the diuretic effect in cardiac edemas, however, is due to the cardiac improvement. In normal subjects, a fairly liberal water supply is necessary for continued diuresis (Sobieranski, 1895; Loewi, 1905); however, the free diuresis produced by a liberal supply of fluid is not further enhanced by caffeine (Sollmann and Hofmann, 1905; diabetes mellitus, Meyer, 1905).

Reduction of fluid interferes notably with caffeine diuresis, and is the chief reason why the large initial diuresis can not be maintained (clinically, Le Noir and Camus, 1903; animals, Phillips and Bradford, 1887; M. H. Rees, 1924), for in the proportion that the initial diuresis removes the excess of fluid, the caffeine finds it more difficult to obtain further fluid. Hemorrahge (Michaud, 1904), muscular work (perspiration) (Wuescher, 1925) and restricted consumption of liquids similarly diminish or prevent diuresis.

Habitual use of coffee or tea also confers some diuretic tolerance, so that two or three times more of caffeine, theobromine or theophylline are required to produce diuresis than when the same individual is abstinent for two months (Eddy and Downs, 1928). This habituation tolerance has also been observed in animals (H. B. Myers, 1918; Kihara, 1928).

Interference by Renal Irritation.—All forms of nephritis are likely to interfere with the diuretic response. Experimentally, the interference is greatest in glomerular and least in purely tubular nephritis.

Caffeine in Experimental Nephritis.—Hellin and Spiro, 1897, found caffeine ineffective in glomerular and general nephritis, but quite effective in pure tubular nephritis. This has been confirmed by Schlayer and Hedinger, 1907, and by Pearce, Hill and Eisenbrey, 1910. The failure of diuresis is accompanied by failure of the oncometric reaction. In *uranium nephritis*, diuretics, including caffeine, are effective during the early polyuric stage; but they become ineffective when the anuric stage is reached, although the circulatory response may be well preserved. This depends on the intactness of the renal epithelium (MacNider, 1914). In the subacutely fatal form, caffeine and the other methylxanthines did not prolong life (Christian, 1914). For *chronic nephritis*, on the other hand, theobromine and theocine were distinctly harmful, since they diminished the phthalein output and the animals died more promptly (O'Hare, 1915), although the nitrogen excretion was unchanged and the elimination of urine and chloride was increased (Fitz, 1914). Finally, the kidneys ceased to react. This is especially marked if the caffeine has been preceded by several injections of saline (Mosenthal and Schlayer, 1913).

Renal Irritation by the Caffeine Group.—Ordinary doses of caffeine do not appear to produce demonstrable injury, even in nephritic subjects. Large doses may increase the albuminuria. With theophylline the continued use even of moderate doses is considered inadvisable.

Sollmann and McComb, 1899, found that caffeine did not increase a physiologic albuminuria, and Emerson, 1903, saw no increase of albumin in acute or chronic nephritis under theobromine. Pouchet and Chevalier, 1903, claim that large doses of theophylline injure the glomerular and tubular epithelium. Animals respond to large doses of caffeine (40 mg. per kilogram), especially when long continued, by definite nephritic changes: albuminuria of 1.4 per 1000; leukocytes, epithelium and casts in the urine. The kidneys show dilated vessels, cloudy swelling, to vacuolar degeneration and necrosis of the epithelium, and slight interstitial swelling. These histologic changes may be present even when the urine appears normal. The lesions are usually transitory, disappearing a few days after discontinuance. No lesions are perceptible with doses of 5 to 10 mg. per kilogram, corresponding to 5 to 10 grains in man (Vinci, 1914).

Phenylalanine and tyrosine inhibit purine diuresis if they are injected into the peritoneum; the tyrosine by producing severe liver damage (Shambaugh, 1927).

Relative Potency of Xanthine Derivatives.—Caffeine has been largely supplanted as a diuretic by theobromine and theophylline, which are credited with a much more powerful action. With theobromine this is largely because the customary dose is four times that of caffeine; with theophylline, the superiority is genuine. For equal diuretic effect, the dosage of caffeine is to that of theobromine and theophylline as 1:1.2:0.4 (Eddy and Downs, 1928). Theophylline may be effective when theobromine fails completely (W. Goldring, 1929). Both produce less of the nervous side actions than caffeine. The drugs of the caffeine group are often administered as *double salts*, with sodium acetate, benzoate, salicylate, etc. This increases their solubility, but does not otherwise alter their actions.

Mendel and Kahn, 1913, found that most of the other methylated xanthines are not diuretic. 1:7:9 *trimethyl 2:8 dioxypurine* (Johns) was examined by Salant and Connet, 1918. It is a weak cardiac stimulant, little, if at all, diuretic for rabbits, and much less toxic than caffeine. *Tetramethylxanthine* (1.3.7.9) is reported to have much less muscular and tetanic potency than caffeine (Paderi, 1928 .

Therapeutic Use of Diuretic Action.—The methylxanthines are employed mainly for the removal of *cardiac effusions*, to supplement digitalis and mercurials. The diuresis is proportional to the effusion, sets in promptly and ceases when the drug is withdrawn. It is therefore especially useful for two or three days at the beginning of the most slowly acting but more permanent digitalis treatment. *Caffeine* is the least active of the series. It may be given in the doses of 0.3 Gm. (5 grains) of citrated caffeine, in watery solutions, three times a day, but Taylor found at least 0.5 Gm., four times daily, necessary for a full effect. *Theobromine* (1 Gm. or 15 grains of theobromine-sodium-salicylate in water, four times a day) has the advantage of producing a better diuretic response with the least side actions. It has also been used intravenously, 20 cc. of 5 per cent, Neuhof, 1913; but it is doubtful whether this is justified. *Theophylline* (theophylline-sodium-acetate, or theocin) is the most powerful, but has been charged with sometimes causing renal irritation. Its dose is 0.3 Gm. = 5 grains, three times per day, administered in hot tea. The xanthine diuretics are also useful in *hepatic effusions*. In *renal* effusions, their effect is less certain. In acute or chronic parenchymatous nephritis, there is often no response whatever, while chronic interstitial nephritis usually responds (J. Miller, 1912); but unless the dosage is very small and carefully watched, the toxic side actions may set in, and the renal condition grow worse. It would therefore be better to avoid the methylxanthines when the kidneys are acutely irritated. In anuria, the methylxanthines are generally ineffective. Christian *et al.*, 1915 and 1916, state that diuretics are generally ineffective in chronic nephritis, unless there is edema. They would therefore be of little use against nephritic toxemia.

Skeletal Muscle.—Ordinary doses of caffeine increase the functional activity of skeletal muscle so that it contracts more readily and more completely and powerfully, and is less easily fatigued (Wood, 1912). This improvement is at least in part peripheral, for it can be seen in excised or curarized frog's muscle. The relief of ordinary *fatigue*, however, is central, for ordinary muscular fatigue is itself central. Larger doses of caffeine produce gradual progressive *contracture*, with considerable tension and decreasing response to extraneous stimuli. This culminates in irreversible rigor with histologic coagulation changes, even in living animals. All the stages are accompanied by increased production of lactic acid, which is oxidized if the oxygen supply is adequate; otherwise it accumulates and contributes to the rigor. The addition of caffeine to unstimulated excised frog muscle increases its *oxygen consumption* by four to twenty-four times (Saslow, 1937). The oxygen consumption of *nerves* is increased by concentrations below 0.5 per cent and diminished by stronger solutions (Sherit, 1930).

The Stimulant Phase of Caffeine.—Smaller stimuli suffice to produce contraction (Paschkis and Pal, 1886). The latent period is shortened. The height and rapidity of the contraction are greater and a larger weight can be lifted (Kobert, 1881). Fatigue is lessened and a greater amount of work can be performed (Dreser, 1890), if the load and stimulation are optimal; but with excessive load or stimulation, caffeine diminishes the total work. The other methylxanthines affect muscle qualitatively like caffeine (Golowinsky, 1915).

The Depressant Phase.—As the dose or concentration is increased, these effects are reversed. The contraction becomes less powerful and the curve resembles that of a fatigued muscle: *i. e.*, it is lower and more drawn out. This lengthening shows first in the relaxation (Buchheim and Eisenmenger), eventually also in the contraction. The elasticity is lessened. The muscle is exhausted more rapidly by tetanus. Similar muscular effects are produced by xanthine (Paschkis) and creatine (Dreser)

Caffeine rigor was observed by Voit, 1866, and then investigated by Johannsen, and by Schmiedeberg, 1872. Its occurrence in the living body can be demonstrated by hypodermic injection in certain species of frog (the European Rana temporaria, and the ordinary American laboratory frog, R. pipiens); while another European frog (R. esculenta) is less susceptible to the rigor and succumbs to spinal convulsions. The heart may continue to beat strongly for some time. Mammals also show some stiffness after large doses of caffeine, but actual rigor results only if the alkaloid is injected directly into an artery. The coagulant action is possessed by other xanthines, being strongest with xanthine itself and progressively weaker with theobromine, theophylline and caffeine (Filehne, 1886; Dreser). The muscle in caffeine rigor is inexcitable and appears white, bloodless, stiff and considerably swollen and shortened, and is acid to litmus (Ransom, 1911). Perfusion of the muscle with saline or blood, if undertaken soon after the onset of the rigor, restores the plasticity but not the excitability (von Fürth). *Local anesthetics* tend to diminish the production of rigor, but this is attributed to a purely physical effect on the distribution coefficient (Schneller, Zips).

Microscopic Changes.—If caffeine is applied to a teased muscle under the microscope, the contents of the fiber are seen to move; the cross striations disappear and the longitudinal striae become more prominent. The sarcolemma becomes detached. The fibers shorten by half (Johannsen). These changes have been studied by Secher, 1914, through perfusion with dilute solutions of xanthine and the various methylxanthines, which all produce similar effects. The histologic changes increase with the concentration, to disorganization (caffeine, 1:2000). Short of disorganization, the changes are reversible. The disorganized fibers also eventually regenerate, provided their nuclei are intact. Similar changes are produced by chloroform and other poisons. Mammals require higher concentrations (Cheney, 1939).

Nature of Caffeine Contracture.—The spontaneous progressive contraction of muscle by caffeine is associated with the production of lactic acid (Ransom, 1911), a large consumption of oxygen (Meyerhof, 1921), and the production of heat; the total heat production corresponding closely with that of exhaustion by artificial stimulation (Hartree and Hill, 1924).

Coagulation of Muscle Extracts.—Rigor may be produced in living animals by the injection of a number of other substances in sufficient concentration; for instance, by chloroform. All of these, as well as caffeine, favor the coagulation of muscle extracts (von Fürth, 1896). However, certain substances coagulate muscle extracts even more actively, but are incapable of producing rigor during life.

Muscular Effects in Man.—Hyde, Root and Curl, 1917, in fasting subjects, found considerable increase of muscle power and endurance after 0.09 to 0.15 Gm. of caffeine, but marked depression after 0.23 Gm. (by mouth, as beverage). The increase of efficiency is due partly to a lesser feeling of fatigue (Rivers and Weber), but it is at least in part peripheral, since the efficiency is also increased when the muscle itself is stimulated electrically.

Creatine.—Caffeine increases the creatine content of the muscles even after curare. Riesser, 1916, attributes the effect to increase of the sympathetic muscular tone.

Smooth Muscle.—The effect of caffeine on smooth muscle consists in a longer and more persistent contraction curve. Larger doses prolong the period of relaxation. The tone seems to be affected differently in various muscles. The *arteries* are relaxed by relatively small doses; whereas the caffeine has a tonic effect on the pelvic portion of the *ureter* (Lucas, 1907). It has little effect on the uterus (Röhrig). *Biliary colic* is sometimes promptly relieved by slow intravenous injection of 0.25 to 0.5 Gm. of aminophylline (Butsch *et al.*, 1936; Gladstone and Goodman, 1944).

Intestines.—Caffeine has little or no effect on normal peristalsis (Nasse, 1866); but indirect contact with *excised intestine* modifies the functions. Salant and Schwartze, 1916, state that the contractions are stimulated by dilute solutions (caffeine, 1:10,000; theobromine, 1:25,000; theophylline, 1:50,000). Higher concentrations (1:2000) produce marked depression of the rhythm and tonus. The movements of the excised *stomach of frogs* are paralyzed by dilutions of 1:2000 to 1:100,000 (Agnoli, 1930).

Sympathetic System.—Fredericq and Melon, 1922, found that caffeine, theobromine and theophylline destroy the response of the heart to accelerator stimulation. They attribute this to paralysis of the accelerator endings. They also point out the *mutual antagonism between caffeine and epinephrine* in the arteries and intestines; *i.e.*, after epinephrine, caffeine dilates arteries and contracts the intestinal muscle.

Digestion.—In man, 80 to 250 mg. of caffeine stimulate acid gastric secretion, copiously with the larger dose. The stimulation is synergistic with that of alcohol and histamine. Large doses may produce nausea. Continued use of excessive quantities tends to functional hyperchlorhydria, probably indirectly through nervousness.

Similar and even greater stimulation is produced in cats by intravenous or oral administration. It occurs after atropine, and is therefore probably directly on the parietal cells, without excluding the possibilty of an additional central action (J. A. Roth and Ivy, 1945). Alternation of caffeine and histamine results in hemorrhagic erosions and "peptic ulcers" of the mucosa. Dogs do not show the increased gastric secretion (J. A. Roth and Ivy, 1944). Caffeine alone does not produce peptic ulcers in cats or rats, even when large amounts are administered daily for weeks, unless fatal doses are injected intramuscularly (G. Giddings *et al.*, 1945). In man, pepsin secretion is only mildly stimulated by pepsin or histamine. The two together are more effective than simple summation (M. I. Grossman *et al.*, 1945).

Other Peripheral Actions.—Caffeine has no action on peripheral nervous structures when it is used systemically (Aubert, 1872); nor does it cause any local irritation.

It has a paralyzing action only when it is applied in a very strong paste directly to the nerve (Pratt). It does not act on any *ganglia* or on any *glands* other than the kidney; nor on red corpuscles, nor on fibrin formation. Small doses increase the movements of leukocytes in shed blood, while higher concentrations kill them. Arkin, 1913, found *phagocytosis* unaffected, *in vitro*. *Hyperthrombinemia* is induced in dogs and other animals by single oral doses of caffeine, theobromine and theophylline, not by other purines or pyrimidines. It persists for several days and may be continued by repeated administration (J. B. Field *et al.*, 1944). *Blood coagulation* is prevented by the addition of 2.6 per cent of caffeine and sodium benzoate, even when calcium chloride is added. Caffeine changes the coagulability of the *euglobulin* and appears to be adsorbed by this fraction. It suppresses the complement of the serum (Klinka, 1929). *Milk secretion* is not affected by caffeine (Ott and Scott, 1912). The actions of caffeine on *lower organisms* are not characteristic (Brunton, 1882: oxidation of guaiac; Haskins, 1903: gas formation by yeast; Bokorny, 1894, and Korentschewsky, 1903: amebae; Romanes, 1867: medusae; Sollmann, 1906: adult and embyronic fish; Pickering, 1893: embryonic chick's heart; Ransom, 1912: germination of seeds). Concentrations of 0.1 per cent and higher depress the oxygen consumption of fertilized *ova of sea urchin;* 0.2 per cent and higher decrease the cleavage rate (R. H. Cheney, 1945). Caffeine (and less markedly, strychnine and atropine) changes the *heliotropism* of the fresh-water crustacean Diaptomus, which is naturally neutral to light, to intensely negative; this is changed to positive by carbon dioxide (A. R. Moore, 1913).

Metabolism.—The results of different investigators have been contradictory, but it appears that caffeine causes a rather small and variable increase in urea and CO_2. Both effects are probably indirect; the urea is explained by the diuresis, the CO_2 by the increased movements. This also accounts for the slight rise of temperature.

Basal Metabolism.—Means, Aub and DuBois, 1917, found in man a constant increase (7 to 23 per cent) of *basal metabolism* from doses of 0.5 to 0.65 Gm., the maximum occurring in one to three hours. The respiratory quotient was not changed. The elimination of *water* from the lungs and skin was increased. The *total nitrogen* of the urine was also increased by 6 to 37 per cent. The *pulse rate* showed no significant changes. Smaller doses do not influence basal metabolism (3 to 6 mg. per Kg., Haldi *et al.*, 1941). *Large doses of caffeine* increase the basal metabolism of guinea pigs by 40 to 75 per cent (Womack and Cole, 1934). In rats, caffeine increases the basal metabolism, but decreases the total metabolism (Chahovitch and Vichnjitch, 1928). Caffeine is reported to increase the oxygen consumption of rats in winter and spring, but to decrease it in summer and autumn. With rabbits it is increased in summer (Hindesmith and Angstenberger, 1939). C. J. Lehmann, Voit, Roux and others demonstrated increased urea excretion after caffeine; Reichert, increased heat production; Salant and Rieger, 1914, found slight changes in the excretion of creatine and creatinine.

Blood Nitrogen.—Laufberger, 1923, reported increased creatine, creatinine and calcium; no increase of uric acid or residual nitrogen.

Temperature rise was demonstrated by Binz and Peretti, 1878. It is slight in normal animals (1° to 1.5° C.). It is perhaps rather more effective in preventing the fall of temperature which occurs in light narcosis, but is ineffective in deep narcosis (Pilcher, 1912). The rise is much greater in thyroidectomized dogs (Karelkin, 1914).

Glycosuria.—During caffeine or theobromine diuresis, there is commonly a slight hyperglycemia and glycosuria, especially in rabbits fed on carbohydrate food. However, it occurs also in fasting animals (E. Hirsch, 1915). It may be induced by oral administration, also in cats, but not in dogs (Salant and Knight, 1909). The phenomenon, which is seen also with other diuretics, has not received a satisfactory explanation (Miculicich, 1912). It is not renal, for sugar appears in the urine only when there is a considerable rise of blood sugar (Hirsch). The hyperglycemia indicates increased glycogenolysis, which resembles that produced by piqûre (Nishi, 1909). Like this, it is generally (but not always; Jarisch, 1914) prevented by section of the splanchnics or excision of the suprarenals (A. Mayer, 1906) and by nicotine (Hirayama, 1911). It must therefore be usually central, perhaps through increased reflex irritability.

Absorption, Fate and Excretion.—Caffeine is readily and completely absorbed: none appears in the feces even after large doses. Only a small fraction is excreted unchanged in the urine. This excretion starts and is mainly completed promptly, but traces may continue for two or three days (Salant and Rieger, 1912). A somewhat larger fraction loses a part of its methyl group, and appears in the urine as di- and mono-methylxanthines, and with caffeine and theophylline as partly methylated uric acids. The excretion of true uric acid is not increased in man (O. H. Buchanan *et al.*, 1945). It is not known whether this is effected by oxidation or hydrolysis. The remainder—up to 80 per cent—is oxidized to urea. Theobromine does not produce this increase (V. C. Myers and Wardell, 1928); and a larger fraction (32 per cent) escapes decomposition. The greater part leaves as heteroxanthine.

Quantitative Excretion.—The quantity of caffeine which is extracted unchanged varies with the dose and with different animals: only 1 per cent in carnivora, less than 8 per cent in man and 6 to 20 per cent in rabbits (Rost, 1895; Salat and Rieger, 1912). The relative quantity of the various mono- and di- methyl-xanthines also varies in different animals, representing 10 to 40 per cent of the caffeine (Albanese, 1895). The demethylation is retarded by alcohol (Salant and Phelps, 1912). Emory and Salant, 1909, report experiments on the decomposition of caffeine in the liver. A trace appears in the stomach, intestines and in the bile. The gastro-intestinal excretion is higher when the kidneys are excised (Salant and Rieger, 1913). The loss of methyl groups occurs in pretty much all organs (J. Schmidt, 1910).

Methylated Uric Acid.—Hanzal, 1930, concluded that theophylline and theobromine are excreted, at least in part, as methylated uric acid. Methylated uric acids, when administered, are excreted for the most part unchanged. Those with CH_3 in the 7 position are not demethylated at all.

Uric Acid Level of the Blood.—Clark and Lorimeier, 1926, claim that this is increased by caffeine and by theobromine.

Passage across Placenta.—Fabre and Régnier, 1934, administering fairly large doses of caffeine to dogs, found the concentration in the fetal blood and liver as high as in the maternal.

Potentiation by Theophylline and Theobromine.—Froehlich and Zak, 1927, reported that theophylline increases the effects of a number of poisons, by facilitating their penetration into the central nervous system. Acid fuchsin, for instance, stains this more deeply and produces convulsions in smaller doses in frogs. Fluorescein stains more promptly and more intensely; ferrocyanide penetrates more rapidly. Morphine causes deeper narcosis in frogs, and magnesium in rabbits. Franceschetti and Nieland, 1928, reported that theophylline increases the excretion of arsenic into the cerebrospinal and intraocular fluids.

Theophylline on Absorption of Mercurial Diuretics.—The rapidity of absorption of mercurin and of salyrgan from intramuscular injections is materially increased by the addition of theophylline, due partly to the formation of complex nonprecipitant mercury compounds, partly to a buffer action A series of other organic substances have similar effects (De Graaf and Lehman, 1936; R. A. Lehman and Dater, 1938).

Toxicology.—The fatal dose of caffeine is so large (presumably about 10 Gm.) that fatal poisoning is rare; but doses above 1 Gm. may produce alarming symptoms, and even therapeutic doses may cause unpleasant *side actions*, especially in cardiac patients: palpitation, insomnia, nausea, vomiting, headache, vertigo, restlessness, anxiety and sometimes delirium. Theobromine is relatively free from these objections, but they may arise. They are also produced by theophylline (Widmer, 1914). The side actions occur much more violently, and with much smaller doses (0.3 Gm. of caffeine per day, or even less) in patients with *interstitial nephritis* (L. Taylor). (The doses are calculated on the basis of pure caffeine; the corresponding amounts of citrated caffeine would be twice as high.)

With *larger doses*, the pulse is full and hard, quickened or slowed, with palpitation and precordial distress (sometimes anginal attacks). The head is heavy, throbbing, confused; often intense headache and great anxiety. Restlessness and excitement, insomnia (sometimes mild delirium, aphasia, fever). Vertigo, nausea, general discomfort, fatigue, weakness (sometimes burning in the throat, gastric distress, heat flashes, perspiration, insensible pharynx, swollen tongue, ringing in the ears, flashes in eyes). Tremors of jaws, hands and feet, and muscular stiffness. Quickened, embarrassed respiration. Increased micturition (sometimes ardor urinae and erection). In *very severe cases* there is vomiting (sometimes violent diarrhea and tenesmus); violent choreic tremors. Collapse, with small, irregular arrhythmic pulse, cold extremities, dilated pupils. Consciousness is usually intact, but there may be delirium. Doses of 1 Gm. and higher have been taken to evade military service, especially by producing tachycardia (sometimes to 160 per minute). The drug is easily detected in the urine (Hollande and Thevenon, 1916).

The symptoms in animals are restlessness and increased reflexes; increased respiration, vomiting and diarrhea; muscular weakness. Then: clonic or tetanic convulsions, during which respiration may stop, with or without resumption; exhaustion and increasing paralysis; death in one to four hours. The fatal dose lies about 0.15 Gm. per kilogram. Dogs and cats are somewhat more susceptible than rabbits and guinea pigs. The dose by mouth is but little larger than the intravenous dose, except in rabbits (Salant and Rieger, 1910, 1912). Young mice are more resistant than old. The effects in *birds* are similar (Brill); in *frogs* they are modified by the onset of rigor. The toxicity for frogs is diminished by temperature above 98° F. At 45° F. the muscular effects predominate; while the convulsions become more prominent as the temperature is increased (Salant, 1913).

Recovery is usually complete within a day, even when the symptoms were violent. Some restlessness and weakness may remain for a time. It is claimed (Kunkel) that large therapeutic doses have been followed by nephritic urine, but on the other hand, daily doses of 1.25 Gm. have often been given without detriment (Becher, 1884). *Idiosyncrasy* toward caffeine is marked. Children and nervous and weakened individuals appear to be relatively more susceptible. Overdoses should be avoided, especially in *myocarditis*.

The *treatment* consists in evacuation and narcotics—bromide, alcohol, chloral or morphine. It is important to reassure the patient.

Theobromine and theophylline, in excessive doses or in susceptible individuals, may produce toxic effects similar to those of caffeine: headache, nausea, vomiting, epileptic spasms, albuminuria, gastric hemorrhage, etc. These manifestations are, however, rare. In epileptic patients, large doses of theophylline are said to have provoked attacks (Schlesinger, 1905). Two deaths from cardiac failure are attributed by Cadburg, 1918, to theophylline (about 1 Gm. in divided doses), but the patients were under digitalis treatment for heart disease and the causation is therefore rather doubtful.

The **differences in the members of the group** may be recapitulated: *Caffeine* has the most powerful central nervous action, with relatively weak peripheral effects. The strongest diuretic action is produced by *theophylline*, which also causes the most marked cardiac stimulation and coronary dilatation. Its central effects and its action on muscle approach those of caffeine. *Theobromine* acts most powerfully on muscle; its effects on the heart and urine are intermediate. It causes little central stimulation.

The pharmacology of theobromine was first investigated by Mitcherlich, 1859, and further by Filehne, 1886. It was used experimentally as a diuretic by von Schroeder, 1887, to avoid the supposed vasoconstriction of caffeine.

This led to its clinical introduction by Gram. The toxicity of theobromine to isolated muscle is one hundred and twelve times that of caffeine (Velly and Waller, 1910).

PREPARATIONS.—***Caffeine**, U.S.P. (theine, trimethylxanthine), is a feebly basic alkaloid, usually prepared from tea. It is a white, odorless powder and has a slightly bitter taste. It is fairly sol. in water (1:50) and in alc. Its solubility in water is greatly increased by heat, citric acid, benzoates or salicylates, bromides, antipyrine and a number of other substances. Incompatible with tannin. Dose, 0.12 to 0.3 Gm., 2 to 5 grains, in capsules. *Citrated Caffeine*, U.S.P., is generally used for oral administration in solution. It is a mixture of caffeine and citric acid, containing about 50 per cent of caffeine. It gives a clear, syrupy solution with a little water, but precipitates on dilution. The precipitate redissolves on the further addition of water, the solubility being about 1:32. Incompatible with carbonates. The dose is somewhat less than twice that of caffeine. The free acid renders this unsuitable for hypodermic use. *Caffeine and Sodium Benzoate*, U.S.P., is the most suitable compound for hypodermic injection. It is a mixture of equal parts of caffeine and sodium benzoate. Freely sol. in water (1:1.1) with practically neutral reaction. Dose, orally or by injection, 0.15 to 0.5 Gm., 2½ to 7½ grains. *Caffeine and Sodium Benzoate Injection*, U.S.P., is usually available as 0.25 or 0.5 Gm. in 2 cc. of water for injection.

Theobromine, a dimethylxanthine prepared from cacao seeds or synthetically, is only slightly sol. in water. It is usually administered as ***Theobromine and Sodium Acetate**, a hydrated mixture of theobromine sodium and sodium acetate, containing 60 per cent of theobromine. Freely soluble in water (1:1.5) with alkaline reaction. *Dose*, 0.5 to 1.2 Gm., 8 to 20 grains, well diluted. It gradually absorbs carbon dioxide from the air with the liberation of theobromine, becoming partially insoluble in water. It must therefore be protected against exposure to air, and is *incompatible* with acids and with chloral. It should not be given with meals, to avoid precipitation by the gastric juice. Solutions do not keep. *Theobromine and Sodium Acetate Capsules*, U.S.P.; usual sizes, 0.1 and 0.2 Gm. *Theobromine with Sodium Salicylate*, N.F. (*diuretin*), is a mixture of sodium theobromine and sodium salicylate in nearly equal molecular proportions. Dose, 1 Gm., 15 grains.

Theophylline, U.S.P. (theocin), is also a dimethylxanthine. It is sparingly sol. in water (1:120) and alc.; freely sol. in alkalis. Dose, 0.25 Gm., 4 grains, three times a day in warm tea. After two or three days it should be replaced by theobromine. *Theophylline Tablets*, U.S.P., are usually available as 0.1 and 0.2 Gm. It may be given in solution as ***Theophylline and Sodium Acetate**, U.S.P., containing about 60 per cent of anhydrous theophylline. Sol. in water (1:25) with alkaline reaction; insol. in alc. Bitter, salty taste. Dose, 0.12 to 0.3 Gm., 2 to 5 grains. *Theophylline and Sodium Acetate Tablets*, U.S.P., are usually available as 0.1 and 0.2 Gm. ***Aminophylline** (theophylline with about 13 per cent of ethylene diamine) contains about 75 per cent of anhydrous theophylline with ethylenediamine, $C_2H_4(NH_2)_2$. White or yellowish granules, slight ammoniacal odor, bitter taste. Sol. in water (1:5) with alkaline reaction; insol. in alc. Dose, 0.1 to 0.2 Gm., 1½ to 3 grains, three times daily by mouth (preferred); 0.5 Gm. per day intramuscularly; 0.25 Gm. by vein. *Aminophylline Tablets*, U.S.P., are usually available as 0.1 and 0.2 Gm. *Aminophylline Injection*, U.S.P., is usually available as ampuls, 0.25 Gm. in 10 cc.; 0.5 Gm. in 2 cc. and in 20 cc. There are generally no ill effects, even after long-continued use. It may be injected into the gluteal muscles, 1 to 3 ampuls of 0.5 Gm. in 2 cc., per day. Intravenous injection should be used only in acute emergenices, 0.25 Gm. in 10 cc. It may be administered by rectum, 2 to 4 suppositories of 0.36 Gm.

Boerhaavia diffusa, an East Indian weed (Punarnava), contains a diuretic alkaloid. It produces some rise of blood pressure, but this is not the main mechanism of the diuresis. Clinically, the fluidextract is an effective diuretic in ascites and edema, especially in early liver, peritoneal or renal disease, and more effective than other diuretics in early hepatic cirrhosis and chronic ascites; but it has relatively little effect in cardiac disease (Chopra *et al.*, 1923).

Albamyricetin, a glucoside from the blossoms of a tropical tree, is strongly diuretic, depresses excised intestine and blood vessels, and inhibits the heart (Abe and Takahira).

Caffeine Beverages.—The annual per capita consumption in the United States is about 10 pounds of coffee and 1 pound of tea (Graham, 1912). A cup of coffee, prepared from 15 to 17 Gm., or strong tea contains about 0.1 Gm. (1½ grains) of caffeine; average tea, 60 to 75 mg. (Punnet, 1942). Its effects are somewhat modified by the associated products (the volatile products causing more psychic stimulation, the tea tannin and coffee oil deranging digestion), but essentially the actions are those of the alkaloids. They consist in increased mental and physical efficiency by psychical stimulation, comfort, and relief from muscular and mental fatigue and from their attendant unpleasant sensations. These effects may be useful in certain conditions, as in those exposed to severe hardship, hunger, fatigue; but caffeine lowers performance in work requiring fine coordination, as in marksmanship (Graf and Muller, 1938). Ordinarily these beverages are pleasant luxuries which may do no harm if the consumption is kept within bounds; but nervous individuals, who are the most liable to be injured by caffeine, are most likely to exceed these bounds. The bad effects are usually not very serious, and disappear promptly if the habit is discontinued. They consist in nervousness, tremor, palpitation, insomnia, headache and digestive disturbances. The habitual consumption of caffeine confers a limited tolerance. Its withdrawal does not produce any marked abstinence symptoms. Coffee and chocolate are *useful flavors* and extemporaneous vehicles, especially for castor oil and cod liver oil.

Coffee (Caffea) consists of the dried seed of Caffea Arabica, Rubiaceae. The constituents of the "green bean" are caffeine, fat, coffalic and chlorogenic acid, saccharose, etc. The *chlorogenic acid* gives a green color with iron, similar to tannic acid, and in its impure form it was formerly called "*caffeotannic acid.*" Gorter, 1910, found it in about 100 plants. On oxidation it yields caffeic acid. It differs from tannins in that it does not precipitate proteins, and is therefore not astringent. The *percentage of caffeine* varies in different specimens from $\frac{2}{3}$ to $2\frac{1}{2}$ per cent, usually about 1.2 per cent (Koenig). It exists mainly as caffeine-potassium chlorogenate (Gorter, 1908). In the process of *roasting* (*i. e.*, heating the seed to 200° to 250° C.) a small amount of caffeine is volatilized; but since about 10 per cent of water is driven off, the percentage of caffeine is actually a trifle higher (1.25 per cent). The main change in roasting consists in the production of aromatic, brown and oily products. This oil (*caffeol* or *caffeon*) consists of 50 per cent of furfurol alcohol, and small quantities of valerianic acid, phenol, pyridine and a nitrogenous aromatic substance (Grafe, 1912). It is probably derived mainly from the hemicellulose. *The beverage, coffee,* is a decoction made with 6 to 10 per cent of the drug. Practically the entire caffeine (perhaps $\frac{9}{10}$) is thus extracted. The use of coffee arose in Arabia and Egypt about the middle of the fifteenth century. Coffee and tea were introduced into Europe about the last quarter of the seventeenth century, about the same time as the potato, cinchona, tobacco and chocolate.

Action of Coffee Oil.—The volatile aromatic constituents produce local irritation and reflex stimulation, in the same manner as condiments. The hot water contributes to this effect; and possibly the greater reactivity induced by the caffeine heightens the reflex response (Schmiedeberg). The local irritation stimulates peristalsis, and excessive use tends to nervous dyspepsia. It is doubtful whether the quantities taken in the beverage cause any direct central stimulation.

Wilhelm, Rorer and Reichert did not obtain any effects with coffee distillates. I. Lehmann, Archangelsky, Hare and Marshall, and Erdmann found, with *small doses:* pleasant stimulation; increased respiration; increased heart rate, but fall of blood pressure; muscular restlessness; insomnia; perspiration; congestion. *Large doses:* increased peristalsis and defecation; depression of respiration and heart; fall of blood pressure and temperature; paralytic phenomena. Grafe, 1915, believes that the products of roasting contribute to the action.

Decaffeinated Coffee.—In the commercial brands the caffeine has been reduced to insignificant proportions; for instance, by extracting the steamed green coffee with trichloroethylene, as in Kaffee-Hag. Such coffees produce practically no effect on the blood pressure, pulse rate, response to motor tests, or oxygen consumption (Horst *et al.*, 1934 and 1936; Haldi *et al.*, 1944). They accelerate propulsion in hypotonic stomachs less than does ordinary coffee (A. W. Bauer, 1928), but in hyperchlorhydria and gastric ulcer, they stimulate gastric secretion about like ordinary coffee (Bernay and Faure, 1937).

H. Gummel and Kiese, 1938, conclude that the motor excitement (in rats) is due solely to the caffeine, and that the effects of intravenous injection of coffee decoction on blood pressure and on isolated organs are due solely to choline and related substances, which had been isolated chemically by Li, 1937. Aubert had attributed the intravenous toxicity to potassium.

Tea (Thea) consists of the dried leaves of Thea sinensis, Theaceae. It contains caffeine (1.4 to 3.5 per cent, usually 2 to 3 per cent); tannin (1 to 30 per cent); traces of theobromine, theophylline, xanthine, adenine and volatile oil. The black and green teas differ only in the treatment to which the leaves are subjected—a fermentation with the black variety, which mainly alters the color and flavor; the green tea is rather more rich in volatile oil. The beverage is a 1 to 4 per cent infusion. A cup of strong tea prepared from 5 Gm. of leaves contains about 0.1 Gm. of caffeine (Aubert). A quick infusion extracts practically all the caffeine, but only a part of the *tannin* (which is especially abundant in the finer sorts). The customary brief infusion is therefore commendable, since the tannin may be deleterious to digestion, by precipitating proteins and albumoses, by lessening absorption and by irritating the gastric mucosa. The *tea distillate* is credited by Archangelsky with actions similar to those of caffeol. Lehmann and Tendlau found it inactive.

Cola (Kola, the seed in Cola acuminata, Sterculiaceae) is used by the natives of Africa, the fresh and often germinated seed being chewed. The dried seed, which has been introduced as a popular "tonic," contains caffeine ($1\frac{1}{2}$ to $3\frac{1}{2}$ per cent, usually $2\frac{1}{3}$ per cent); theobromine $\frac{1}{40}$ per cent); tannin (Kola red); fat, sugar, etc. In the fresh nut, the caffeine is combined with a glucosidal tannin ("kolatin," Goris, 1907). This compound, which was formerly termed "kolanin," is partly decomposed in drying, by an oxidase, into free caffeine, glucose and Kola red (Chevrotier and Vigne, 1907).

Guarana, a dried paste, prepared by the Indians of South America, consists chiefly of the dried and pounded seed of Paulinia cupana, Sapindaceae. It contains 4 to 5 per cent of caffeine, tannin, etc. Dose, 2 Gm., 30 grains. **Maté** (Paraguay tea) consists of the leaves of Ilex paraguayensis. It contains 0.13 to 1.85 per cent caffeine (2 per cent, Bertrand and Devuyst, 1910), 10 to 16 per cent of tannic acid, etc. It is used in South America for preparing a beverage.

Cacao is consumed extensively as a beverage and in the form of chocolate, a mixture of melted cacao and sugar, often with the addition of flavors, starch, etc. It contains theobromine, instead of caffeine, and therefore acts less on the nervous system. It is also rich in fat, which is nutrient. A part (about half) of this fat (Oleum Theobromatis or Cacao Butter) has been removed from the commercial powdered cacao. The name Cacao should not be confused with Cocoa (the palm yielding the cocoa nut), nor with Coca, the source of cocaine. Cacao consists of the fermented, dried and often roasted seed of

Theobroma Cacao, Sterculiaceae. It contains theobromine ($1\frac{1}{2}$ to $4\frac{1}{2}$ per cent, usually $1\frac{1}{2}$ per cent); a trace of caffeine; 50 per cent of fat; starch, tannin, etc. The theobromine is liberated from a glucoside during the fermentation. The fat is generally considered rather indigestible, but Neumann, 1906, showed that it is digested as well as other fats.

Chicory. The roasted root of this plant is used as substitute for coffee. It probably contains similar empyreumatic substances, but no caffeine. Schmiedeberg, 1912, considered it a harmless stimulant, stomachic and antiseptic. C. Reynolds, 1930, believes that it has no pharmacological significance. Still less is known about roasted malt and other cereals which are used as *coffee substitutes.*

Phenomena of chronic caffeine poisoning have been described most commonly in excessive tea drinkers (Bullard, 1886). The first symptoms are usually dyspeptic—epigastric uneasiness after meals, and a general lowering of the mental and physical tone. This is succeeded by restlessness and nervous excitability, tremors and disturbed sleep, soon followed by anorexia and by headache, vertigo, confusion. Constipation is common, but not more so than in individuals not addicted to tea. Palpitation, generally associated with irregularity, becomes distressing, and is often accompanied by dyspena. In severer cases these symptoms are aggravated and continuous. Neuralgic, sensory and hysterical disturbances are common, but it is not easy to say whether these are the cause or effects of the caffeine habit.

The quantity of tea required to develop these symptoms varies with the individual. The daily average consumption of Bullard's patients was five cups, which corresponds to about 0.6 Gm. or 8 grains of caffeine. The susceptibility is much greater in youth, anemia, weakness, insufficient food, exhaustion, and in "nervous" individuals. Children who drank coffee were reported by Taylor, 1912, to average below the normal weight, height and strength.

Differences between Tea, Coffee and Cacao.—The effects of excessive coffee consumption differ only in details from tea. Both interfere with digestion, the coffee through the irritant effects of its volatile oil, the tea through the coagulant action of the tannic acid. The caffeine itself probably contributes to the digestive derangement through its vasodilator action. This may account for the common tendency to hemorrhoids. Cacao may disturb the digestion through its richness in fat, but other symptoms are not common, partly because there is less inclination to its excessive use.

The Acute Effects on Digestion.—Caffeine causes a considerable flow of gastric juice in man, not in dogs. This effect is also produced by caffeine-freed coffee and by beverages prepared from roasted cereals. In terms of free acid the order is: Coffee, 100; Coca Cola, 90; Sanka, 75; tea, 60; coffee with cream, 60; Postum, 60 (J. A. Roth *et al.,* 1944). A liter of coffee or tea, hot or cold, taken with meals, has no definite effect on the acidity or the evacuation time of the stomach. Cacao, $\frac{1}{2}$ to 1 liter, decreases the acidity and delays evacuation (R. J. Miller *et al.,* 1920), presumably through its fat.

Chronic Caffeine Poisoning in Animals.—Salant and Rieger, 1910, found that continued administration of doses which did not cause acute effects, eventually produced emaciation, often ending in death. The stomach and, to a less degree, the intestine showed inflammatory changes. Habituation increased the tolerance to acute poisoning, the fatal dose being 15 to 80 per cent larger than ordinary. Gourewitsch, 1907, also claims a "histogenetic" habituation. Mice kept continuously under caffeine were found to exhibit less than the normal activity, but showed a normal gain in weight (Nice, 1912). Large doses of caffeine beverages decreased the growth rate of young rats, and somewhat decreased the average number of fetuses (Hamill and Miller, 1935).

◆

ADENYL COMPOUNDS

These include adenine, adenosine and other purine derivatives of nucleic acid which are contained in tea and obtained from other sources, and some synthetically. In general, they dilate the coronary vessels, depress and slow the heart, lower blood pressure, inhibit intestinal and stimulate the ureteral movements, and produce leukocytosis (reviews, Drury, 1936; R. Rigler, 1938). The relation of the adenylic system to phosphorylation is discussed under phorphorus compounds.

Adenine, a purine base, has a low toxicity, but large doses produce enteritis, and uric acid infarcts of the kidneys.

Adenylic Acid is a phosphate ester ("nucleotide") of adenine with the pentose d-ribose. It acts on the myocardium and on arterial and other smooth muscle, varying with the organ (review, R. Rigler, 1938).

Coronary Dilatation.—A. M. Wedd, 1931, reported that *adenosine* produces marked increase of coronary flow (twenty times that of nitrite) in perfused rabbit heart, independent of changes of rate or excursions, and antagonistic to the constrictor action of pitressin or barium. Similar but somewhat less potent dilatation was produced by adenylic acid, adenine and guanosine. Wedd and Drury, 1934, confirmed the increase of coronary flow by intravenous injection in dogs, notwithstanding the fall of blood pressure; but intramuscular injection was ineffective. The coronary dilatation improves the *functionation of the heart,* in intact animals or perfused, especially when it has been depressed, as by mecholyl or exhaustion (Wedd, 1935). Adenylic acid appeared beneficial in a case of clinical paroxysmal tachycardia. Adenosine produces bradycardia and A-V block in man and in rats (Kalaja, 1938). The direct action on the heart (by immersion of turtle or mammalian heart) is purely depressant (Wedd and Fenn, 1933). *Adenosine triphosphoric acid* is more active than any of its compounds in producing intererence with cardiac conduction, and increasing tone of excised guinea pig uterus (Deuticke, 1932). Its potency is diminished by deaminization. Removal of PO_4 from adenosine increases its ability to lower blood pressure and to dilate the coronary vessels. This is greatly diminished by deaminization (Gillespie, 1934). The depressor substance of blood was identified as adenosine triphosphate by C. H. Fiske, 1934. Intravenous injection of adenosine triphosphate produces the clinical features of circulatory shock; and as it is released from muscles by injury, it may play a part in shock by muscle trauma (Bielschowsky and Green, 1943).

Adenine, allantoin and hypoxanthine increase the inhibitory response of the turtle heart to *acetylcholine and vagus stimulation* (A. Lamalle, 1941).

Protection against Liver Necrosis.—*Sodium xanthine*, administered hypodermically to rats before exposure to chloroform or carbon tetrachloride, decreases the necrosis of the liver lobules and lowers the mortality rate. It does not stimulate the regeneration of the cells (Neale, 1937; O. G. Fitzhugh, 1938; J. C. Forbes, 1939). Other purine derivatives are also protective (nucleic acid, guanosine, guanine, hypoxanthine; uric acid slightly), but allantoin and alloxan increase the liver damage (R. C. Neale and Winter, 1938). Ravdin *et al.*, 1939, attribute the protection to protein cleavage products resulting from the local inflammatory action, since the effect is also produced by other irritants.

Allantoin has the same effect as living maggots on suppurating wounds and resistant ulcers, removing the infected material and stimulating growth of healthy connective tissue, and so promoting healing. The action lasts only while it is in actual contact with the granulating tissue. It is applied by soaking the bandages in 0.4 per cent solution, freshly made in hot (but not boiling) water (W. Robinson, 1935; Kaplast, 1937). However, in 1936 Robinson concluded that it does not act as such but by conversion into urea, and proposed to use this instead of allantoin, as equally effective and much more economical. Clinical reports from allantoin are scanty (review, Council on Pharmacy and Chemistry, 1938, J.A.M.A., *110*: 813). Shipp and Hetherington, 1936, obtained practically no stimulation of growth of fibroblasts with chicken heart cultures on addition of ½ per cent of allantoin.

Allantoin, glyoxyldiureid, is widely distributed in animals and plants. It is the end product of purine metabolism, by oxidation of uric acid through uricase, in animals below apes and man. It occurs as a white powder, slightly soluble in water, and is not toxic.

Alloxan produces experimental diabetes by necrosis of the islets of Langerhans (see Index).

◆

OPIUM, MORPHINE AND RELATED ALKALOIDS

Morphine and the related alkaloids of opium (the coagulated juice of the incised seed capsules of the opium poppy) have peculiar effects on the psychic functions, which render these more tolerant to discomfort and pain. This gives them a wide field of usefulness, especially in symptomatic therapeutics; but it also leads easily to their abuse, too often with tragic results. Larger doses are toxic mainly by depressing the respiration. The spinal cord is stimulated. Therapeutic doses also suppress intestinal peristalsis chiefly by peripheral action.

Origin.—The opium poppy is cultivated in Asia and Egypt; it can be raised in the United States, but the cost of labor renders the production of opium unprofitable: Thoms found that it requires 283 hours of labor to collect a kilogram of opium! The dried plant capsules (especially before ripening, Caesar and Loretz, 1902) and seed also contain the alkaloid; the poppy straw is a commercial source of morphine, but of minor importance, as it contains only 0.3 per cent of total aklaloids, while official opium contains about 10 per cent of morphine. The alkaloids are not present in the fresh plant, but are produced by the action of oxidases on the latex (True and Stockberger, 1916). The seeds yield 50 per cent of a bland fixed oil which may be used like olive oil.

Historical.—The word "mekonion" was applied in ancient Greece to three substances, (1) poppy juice; (2) Euphorbia peplus, a drastic purgative; (3) the excrement of newborn children. About 380 B.C. Diagoras of Melos describes the collection of opium by incising poppy capsules. Opium is also mentioned by Theophrastus, third century B.C. A further account of its history is given by Macht, 1915. The history of the opium preparations is interesting (Wilbert, 1916). "*Laudanum*" is said to have been originated by Paracelsus (1493–1541), but as a solid aqueous extract; "*paregoric*" by Le Mort of Leyden, early in the eighteenth century. "Sydenham's laudanum" (Vinum Opii) is derived from a formula of Sydenham (1624-1689). Tr. Opii Deodorati was originated by Robiquet (1780-1840), and Robert Hare, 1827; "Brown Mixture" by Dr. B. J. Barton of Philadelphia, about 1814.

Opium Alkaloids.—Opium contains two chemically distinct groups of alkaloids. The group of morphine, or the *phenanthrene derivatives*, is by far the more important. It comprises morphine and the esters formed by replacing the H of one or both hydroxyls of morphine. Some of these occur naturally in opium (methyl-morphine or codeine, dimethyl-morphine or thebaine). Others are produced synthetically (ethyl-morphine or dionin, diacetyl-morphine or heroin, etc.).

The second group, or *isoquinoline derivatives*, is represented by papaverine and narcotine. They are not narcotic, but act chiefly as rather feeble relaxants of smooth muscle. Similar alkaloids preponderate in other plants of the poppy family.

Chemical Structure of Morphine Alkaloids.—This is definitely established, but it has not yet been successfully synthesized. Morphine has two hydroxyls, one phenolic, the other alcoholic. Either or both of these may be replaced by other radicals, as in the derived alkaloids that occur in opium, and other changes may be made artificially. Numerous derivatives have been prepared, especially by Small and Mosettig, and investigated pharmacologically by Eddy and his collaborators for the Narcotic Addiction Committee of the National Research Council with the hope that it might be possible to obtain materially more favorable relations of the therapeutic to the addictive actions than exist in the natural alkaloids.

Absorption, Fate and Excretion.—Morphine is rapidly absorbed from all mucous surfaces and from the abraded skin, but scarcely, if at all, from the intact skin. It passes from the blood into the tissues, where it is temporarily stored. Half to two-thirds is excreted by the urine, part free and part conjugated; a much smaller amount by the feces and other secretions. The remainder is destroyed in the tissues, chiefly in the liver. Habituation and acquired tolerance do not alter the fate materially. Theories that attribute acquired tolerance to increased destruction of morphine are not tenable, in view of the fact that the tolerance is practically as great with intravenous injection, *i. e.*, before any morphine could be destroyed; and that some of the functions, for instance that of the vagus center, do not participate in the tolerance, as they would need to do if the destruction of the morphine were increased.

Isolation, Tests and Estimation of Morphine in Biological Fluids.—The results of earlier investigations on the fate of morphine have been largely discredited. Concordant results have been obtained by the modern methods as described by G. A. Emerson, 1934; J. W. Mull, 1938 (10γ in 4 cc. of blood); W. Deckert, 1936 (effective for 10γ in 1 to 10 cc. of urine); F. W. Oberst, 1943 (0.03 to 0.2 mg. in organs). It is now possible to diagnose addiction clinically by testing the urine (S. To, 1935), and even to approximate the quantity of morphine which is being taken (S. To and Ri, 1937).

Excretion.—The most satisfactory studies have been made on thoroughly habituated men and dogs, which tolerate relatively large doses, without functional disturbance. It has been contended that habituation involves alterations in the excretion of morphine, but this was based on imperfect chemical methods; there were no good studies on nonhabituated human individuals, and none on animals, with doses that did not involve toxic effects: diarrhea, coma, depressed metabolism, etc., which introduce complications that are probably much more profound than habituation.

Conjugation.—Urine hydrolyzed with dilute acid yields two to twenty times more morphine than before hydrolysis. The ratio of conjugated morphine decreases with induced tolerance (V. Thompson and Gross, 1940; Oberst, 1940). Both OH groups of morphine are involved in the conjugation. The conjugation is decreased by damage to the liver, both in habituated and nonhabituated, so that the excretion of free morphine is increased at the expense of the conjugated, the total excretion remaining unchanged (E. G. Gross, 1942). Diacetyl morphine and codeine, as well as morphine, are excreted chiefly in conjugation; dihydrocodeine and its methyl ether are chiefly free (Oberst, 1941).

Morphine Excretion by Habituated Man.—The urinary excretion of total morphine averages about 65 per cent with the dosage of 20 mg.; 43 per cent with 65 mg. (A. J. Eisenman, 1945). The unconjugated morphine averages 2.7 per cent of the oral dosage; codeine, 4.3 per cent; with hypodermic administration, the average is 5.4 per cent for morphine, 5.9 per cent for codeine. The excretion decreases promptly on withdrawal and stops in five days. Only traces appear in the feces (Himmelsbach *et al.*, 1940).

Morphine Excretion in Dogs.—E. G. Gross and Thompson, 1940, recovered 80 to 90 per cent of the injected morphine, mostly conjugated, regardless of dosage. With dogs that had acquired tolerance by habituation for one or more years, the total excretion was reduced to 35 to 65 per cent, the decrease being chiefly in the combined form.

Excretion into the Digestive Tract.—Morphine is excreted by the mucous membrane of the entire gastrointestinal tract, and may appear in the large intestine before it can be demonstrated in the small intestine, after intravenous injection (Marquis, 1896). The bile contains only traces (Kauzmann, 1868; Hatcher and Gold, 1929). It is also excreted by the saliva (Rosenthal, 1893), and by the stomach (Marmé, 1883); but only traces can be found in the stomach after hypodermic administration of toxic doses, in man as well as in animals (Hatcher, 1924; Hatcher and Davis, 1926; P. Ellinger and Seeger, 1934), so that it would be useless to treat hypodermic morphine poisoning by gastric lavage, as had been advocated by Alt, 1889, and practiced for many years (Langer, 1912; Kleiner, 1913).

Excretion by Milk.—It has been claimed that this causes morphinism in the nursling; but Koldewyn, 1910, after the administration of morphine to cows and goats, could not demonstrate it in their milk. The quantity is probably insignificant. There is no question that morphine passes through the placental circulation into the fetus, sometimes causing death in the uterus (Jung, 1913), and distinct tolerance in the newborn of animals habituated to morphine (K. Rei, 1937).

Distribution in the Tissues.—Morphine leaves the blood rapidly, although it is not destroyed by it (Cloetta, 1903). The distribution in human morphine addiction is reported by F. W. Oberst, 1943. With intravenous injection, only traces remain after two to ten minutes in cats, after thirty minutes in dogs (Hatcher and Gold, 1929), the blood being then presumably in equilibrium with the tissues. When added to shed blood, it is equally divided between corpuscles and plasma (Teruuchi and Kai, 1927). In general, the largest quantity is in the skeletal muscles; then the kidneys, liver and intestinal contents, the brain contains very little, less than the blood, even in severe poisoning (Hatcher and Gold, 1929; P. Fleischmann, 1931). The recovery after burial has been investigated by

Homburger and Munch, 1916, and by Palet, 1919. The latter obtained positive tests after seven months.

Destruction in the body proceeds rather slowly; a third or more of a large dose may be recovered from the animals, habituated as well as nonhabituated, killed twenty-four hours after the injection (Cloetta, 1903; Rübsamen, 1908). With ordinary doses the storage is not large, for the withdrawal symptoms of addicted persons appear in about twelve hours, and the amount in the urine drops promptly. Habituation does not appear to alter the destruction of morphine materially, nor does hyperthyroidism; but dinitrophenol caused a marked decrease of morphine excretion in normal dogs (O. H. Plant and Slaughter, 1937). The liver plays an important part in the destruction: liver damage increased the excretion by an average of 43 per cent in habituated and nonhabituated animals (E. G. Gross, Plant and Thompson, 1938). Defibrinated blood does not destroy morphine (Cloetta, 1903; Teruuchi and Kai, 1929); on perfusion through the liver, morphine is rapidly fixed and destroyed, the rate being the same in habituated as in nonhabituated animals (Hatcher and Gold, 1929). Cloetta, 1903, reported considerable destruction of morphine by digestion with oxygenated emulsions of lung, liver and especially brain; filtered extracts did not have this effect. Morphine and dilaudid are also oxidized by slices of rat liver, apparently at the hydroxyl group. This does not occur anaerobically or on boiling, nor by kidney or brain tissue. It is inhibited by monoiodoacetate, fluoride and cyanide (F. Bernheim and Bernheim, 1945).

Fate in Chick Embryos.—If morphine is injected into fertilized eggs, which are then incubated, no destruction of morphine or its derivatives occurs if the embryo dies before it is half developed. If the development is completed, heroin is destroyed absolutely; morphine very largely, codeine and dionine not at all. The alkyl groups protect the morphine against oxidation, as they do in the adult organism, while the acetyl groups are easily separated (Grueter, 1916).

Fate in Frogs.—In these, the destruction is small and no tolerance is acquired. The excretion is slow, extending over eight days, and occurs exclusively through the alimentary tract (B. Frenkel, 1910).

Fate of Codeine.—Codeine is excreted as such in the urine without demethylation. The percentage excreted by addicted persons is but slightly greater than for morphine (Himmelsbach *et al.*, 1940), but dogs are reported to excrete about 80 per cent, mainly in the urine, somewhat also in the feces (Tauber, 1892). Repeated administration does not increase its destruction, nor does it appear to produce tolerance in animals (Bouma, 1903).

Fate of Heroin.—The greater part is excreted unchanged in the urine; some also in the feces. A part is destroyed, and this destruction was said to be increased in habituation (Langer, 1912). Human and other mammalian tissues contain enzymes capable of splitting off the acetyl group. Their content is highest in the liver, then the kidneys (C. I. Wright, 1942).

Odorous Substances.—The substances which give the characteristic odor to opium are excreted largely by the urine and also in the breath, sweat and milk.

Central Nervous System.—The most important actions of morphine are on the central nervous system. It depresses the brain, especially its higher functions. The medullary centers are first stimulated, then depressed. The reflexes and the spinal functions are mainly stimulated. The effects are broadly identical in all vertebrate animals, although the dosage varies greatly, and the symptoms show considerable differences in the relative prominence of certain phenomena and in the time required to produce the successive actions. The descending depressant action of morphine is illustrated by the frog, in which the development of the symptoms corresponds closely to those produced by progressive removal of the brain. This is also the general course in mammals, though the symptoms are more confused. The difference is explained by the more rapid action of the drug, and by the more intimate correlation of the nervous centers.

Effects of Morphine on Frogs.—After doses of 20 to 50 mg. the symptoms start with diminution, and then absence, of voluntary movements, but the animals react normally when stimulated. (This corresponds to ablation of the hemispheres.) The frog sits quietly in the normal position; he will climb up an inclined plane and give the croaking reflex when stroked. When placed in a tumbler filled with water and inverted in a large vessel of water, it will leave the glass to seek the air. As the narcosis deepens, it will remain under the glass. Placed on the table, its leaps become more and more clumsy, and it does not avoid obstacles in jumping (corresponding to excision of the corpora quadrigemina). Then the animal fails to leap even when stimulated (paralysis of cerebellum); but when turned on its back, it will resume its normal sitting position. This reaction also becomes more and more delayed and can be obtained only by reinforcing the stimulation through pinching, etc., until finally it fails altogether (paralysis of medulla oblongata). The reflexes are weakened, but present. The respiration is decreased.

Morphine Tetanus in Frogs.—After the frog has remained in this depressed condition for some time (a few minutes to several hours; the shorter, the larger the dose), the respiration becomes spasmodic, resembling superficially the Cheyne-Stokes type; then the spinal reflexes return; and the frog passes gradually into a tetanus of the strychnine type, located in the spinal cord. The delayed appearance of this tetanus is due to the slow absorption of the effective dose, for it appears at once on intravenous injection (Stockman and Dott, 1890). The convulsions occur more promptly if the heart is tied off (Githens and Meltzer, 1911), presumably because thus a larger proportion of the morphine reaches the nervous axis (Abel, 1912). The onset is hastened and the necessary dose reduced, by cold and by removal of the cerebrum, which inhibits convulsions. The results are prompter if the medulla is not destroyed (Githens, 1913). McGuigan and Ross, 1915, found that the previous injection of morphine sensitizes frogs to *strychnine* so that strychnine tetanus develops more quickly—provided that a latent period of one-half to two hours elapses between the morphine and strychnine injections. Morphine also increases the toxicity of *picrotoxin* for white mice (Pulewka, 1927).

Death.—The tetanus is mixed with paralytic phenomena, the animal lying lax between the spasms. Eventually the paralysis becomes permanent and ends in death. The *heart* is still beating at this stage and is indeed little affected directly. The convulsive stage may be absent with very large or very small doses.

Recovery.—If recovery occurs, the depressed functions recover in inverse order to their appearance (Witkowski, 1877; this paper also gives the older bibliography of the experimental work with morphine.)

Invertebrates do not show typical morphine effects.

Narcotic Symptoms in Human Subjects.—The first effect, produced by doses too small to elicit any other symptoms (5 mg.), consists in diminished sensibility to lasting impressions, expecially such as give rise to pain, cough, fatigue, hunger, discomfort and other disagreeable sensations. This tends to produce a state of emotional tranquillity, equanimity, well-being and buoyance (euphoria), sometimes of elation and ecstasy, especially with larger doses. These vary in degree and in kind with the individual disposition and with circumstances. On repeated use, the brain learns quickly to discount the inattention, thus establishing tolerance to increasing doses. Somewhat larger doses (10 mg. or more) depress the attention and thus weaken the appreciation of other external impressions. A sudden stimulus evokes a normal or exaggerated reflex response; there is even increased acuteness of perception of external impressions (Kraepelin, 1892); but persistent or gradual stimuli are neglected. The stimuli are evidently transmitted to the brain, but do not fix the attention through the mental fog. The faculties of concentration, of judgment and of memorizing (Weygandt, 1903) are all seriously disturbed, constituting a narcosis (torpor). Through this exclusion of external stimuli, the patient is quieted, and then passes through a dreamy, apathetic, drowsy, lethargic state into natural sleep. Exceptionally, the disturbed balance of the brain leads to excitement (especially in cats) and even to delirium. *Large doses* cause a much more extensive depression, the sleep becoming so profound that the patient can be aroused only imperfectly and wiht difficulty. Eventually the coma and insensibility are complete. *The special senses* are not affected directly. They may appear disturbed through the impaired attention, or through the heightened reflex irritability.

Excitant Effects in Man.—Some individuals, particularly among women, are more excited than depressed by morphine. This can perhaps be explained by diminished restraint, rather than by direct stimulation. The same explanation probably holds true for the flights of imagination which fill the period preceding the sleep. Occasionally morphine produces violent sensations of pain, heat, and itching (C. Jacoby, 1934). It has been stated that Malays are especially liable to morphine excitement, but hospital experience in Manila demonstrates that their reaction (to 0.01 Gm. hypodermically) is not different from that of other races (Dr. Jesus Celis, personal correspondence).

Electroencephalograms show decreased height and frequency of the alpha waves, and with deep sleep these aggregate into groups (H. Berger, 1934). In addicted individuals a stabilizing dose of morphine or codeine increases the ratio of occipital alpha waves and diminishes their potency (H. L. Andrews, 1940).

Psychologic Experiments.—Macht and Isaacs, 1916 and 1917, claim that in man 4 to 8 mg. at first shorten the reaction time. This is often followed after one-half hour by delayed reaction. With larger doses the primary stimulation is short and may be absent; and the secondary depression is predominant. Association (arithmetic) is delayed more readily and mistakes are more numerous than are simpler reactions. The lethargy is illustrated by the observations of Eddy and Simon, 1932, on rats trained to run a maze: morphine lengthened chiefly the "initial delay," *i.e.*, the interval before the rat decides to start on its path for the food. The "active time" was but little increased and errors not at all. With cats, morphine, 1 mg. per Kg., causes disappearance of learned adaptive response in the order of complexity and recentness of acquisition. Neurotic behavior is generally diminished (Wikler and Masserman, 1943). The *aphrodisiac effects*, which occur in some, and the anaphrodisiac action in others, depend upon the action on the imagination. With chimpanzees, erection occurs regularly a few minutes after injection of morphine and persists for an hour or longer. Addicted males are conspicuously averse to intercourse during the withdrawal discomfort (Spragg, 1940).

The reactions of young tame *chimpanzees* to hypodermic injection of morphine are described by Spragg, 1940. With 0.1 to 0.9 mg. per Kg. sedation is not observable, nor any constant or marked change in the pupils, nor in the gastro-intestinal tract, saliva or appetite. A wheal appears at the site of injection and there is marked generalized scratching, beginning in ten to fifteen minutes and lasting an hour or more. With 2 mg. per Kg. the central effects become pronounced, drowsiness alternating with restlessness, the latter predominating. The pupils are dilated.

Narcotic Symptoms in Lower Mammals.—The cerebral effects are almost purely depressant (analgesia, lethargy, stupor, sleep and coma) in the dog, rabbit, guinea pig, rat, mouse and also in birds. The reflexes are generally exaggerated, as also postural plasticity. Dogs sometimes react with tremors and choreiform twitchings of the limbs. The *excitability of the motor areas* to electric stimulation is not altered, even by the largest doses (Hitzig, 1875). Dogs sometimes show *delirious excitement* soon after the injection and generally do so when they awaken from the morphine sleep, as described by Claude Bernard (*Anesthésiques*, p. 508): "They are often frightened, with haggard eyes, the hind legs down and half paralyzed, which gives them the position and walk like a hyena. When one calls the dogs in this condition they run away as if frightened; they do not recognize their master and try to hide in dark places. This intellectual derangement sometimes lasts at least twelve hours."

The deliriant action is especially prominent with cats and also with the horse, ass, beef, sheep, pig and goat, but intermingled in various degrees with the lethargic and analgesic effect. Cats exhibit a violent mania, racing about as if in extreme terror, with prominent eyes, widely dilated pupils and erected hair, scratching and clawing wildly. Finally they may go into fatal epileptiform convulsions. The deliriant action is on subcortical centers, in the hypothalamus, for it occurs typically after complete removal of both cerebral hemispheres, but not if the hypothalamus is removed. Local or systemic application of morphine does not affect the reactivity of the cruciate cortex or hypothalamus of cats to faradic stimulation (J. H. Masserman; W. E. Hambourger, 1937, 1940). The excitant effect on cats is produced by codeine and thebaine, while papaverine and narceine are mainly depressant (G. H. Müller). *Dilaudid* and *demerol* are also highly excitant (D. I. Macht, 1946).

Postural Rigidity.—The morphine alkaloids may produce catatonic rigidity, acting probably through the midbrain. This may be responsible for the ataxic "floating" sensation. In rats it is plastic, so that the animals tend to preserve imposed awkward positions. In mice, even small doses produce stiff erection of the tail (Straub).

The *hyenoid posture* of dogs may belong in the same category. Morphine induces a similar position in mice if pernocton is given at the same time (S. Loewe, 1938). Morphine controls the attacks of parathyroid tetany so as to prevent death (J. H. Sloan, 1926).

Straub's Mouse Test.—White mice respond to the hypodermic injection of morphine (0.02 mg.) or its esters by a characteristic S-shaped stiff erection of the tail. The same effect is produced by other convulsants, but generally only with larger doses (Rassers, 1916), for instance by nicotine, 1 mg. per 15 Gm. mouse (Jensen and Runry, 1918). It has some medicolegal importance, as it is not produced by the putrefactive bases, tyramine, cadaverine and putrescine. Codeine is about a tenth as potent as morphine. Atropine and scopolamine inhibit the morphine phenomenon (A. Juul, 1939). It has been attributed to intense tenesmus of the anal sphincter, originating in the medulla and transmitted through the pelvic nerves (Van Leersum, 1918). Heinekamp, 1922, refers it to stimulation of the spinal cord.

Curare Action.—All members of the group, when applied directly to a muscle preparation, exert a weak and slow curare action: if the motor nerve is stimulated with a tetanizing current, the muscle responds with a series of rapid separate contractions, instead of a fused tetanus. Larger doses paralyze the muscle-nerve endings completely. Diacetylmorphine acts more powerfully than morphine or codeine, but the action is too weak to be observed in intact mammals (Hale, 1909).

Spinal Cord.—Morphine and all the members of the group increase the spinal reflexes (even in tabes—Orsnato, 1918). Large doses, in frogs, produce convulsions indistinguishable from those caused by strychnine. Mammals generally die from respiratory depression before the convulsant stage can develop; but convulsions are sometimes seen in man, when toxic doses (3 grains) are taken (A. Gordon, 1915; Keen). In dogs, the intraspinal (subarachnoid) injection of morphine produces marked convulsions (McGuigan and Ross, 1915). The convulsant action is stronger with codeine and especially with thebaine, so that this is generally placed in the strychnine group.

Cisternal injection of morphine into cats provokes marked *pruritus*, with scratching reflex. This effect is also produced by codeine and paracodeine, not by dionine or heroin. It is prevented by phenobarbital and by injection of procaine into the region of the head and neck. It is not prevented by atropine and is increased by ergotoxine (Mehes, 1938; Konigstein, 1936).

Therapeutic Uses of the Analgetic and Sedative Actions.—Morphine and opium are used mainly to attenuate pain, procure sleep, check peristalsis, suppress cough, ease dyspnea, facilitate anesthesia and secure muscular quiet. These indications arise in a great variety of diseases; and since the action of the opiates is certain and highly effective, their field of usefulness is extensive and important. They must be used with discretion, remembering that the relief is generally only symptomatic and may sometimes interfere with the natural processes of repair, or obscure the observation of the progress of the disease. The danger of addiction restricts their employment in neurotic individuals and in chronic diseases (except when these are hopeless). The danger can be somewhat diminished if the morphine is not intrusted to the patient himself, but administered only by the physician, with somewhat impressive formalities of asepsis. The side actions (constipation, nausea, gastric disturbance and occasional excitement) may also interfere with the usefulness. *Demerol* has similar effects and indications, although it is not chemically related to morphine.

Against pain and extreme physical discomfort, morphine surpasses all other analgetics in efficiency, particularly in persistent and exhausting pain, such as that of trauma, inflammation or neuralgia. The therapeutic effect involves raised threshold to pain; dissociation of pain perception from the usual reaction to pain; lethargy and sleep (H. G. Wolff, Hardy and Goodell, 1940). It is generally used to dull rather than actually to abolish the pain, to render the patient indifferent or detached from the discomfort and fag, and thus to give rest and permit sleep. It should not be used as a somnifacient except when it is needed for pain, cough or dyspnea. It should be avoided in nervous insomnia or psychic excitement. *Psychic and motor exaltations,* as in delirium tremens or atropine poisoning, are controlled only by very large doses, and are better treated by paraldehyde or barbiturates. Morphine is not very effective against the *colic pains* of smooth-muscle spasms, but gives rest between the paroxysms and amnesia; this is utilized in obstetrics "twilight sleep." In *hemorrhage* the quiet induced by morphine favors arrest of the bleeding, by keeping the blood pressure low and permitting the formation of the clot. It is especially valuable when the hemorrhage is in an inaccessible situation. The depressant effect on the respiration enjoins caution in the use of larger doses, particularly in severe hemorrhage, cardiac disease and other debilitating conditions. It does not suppress *convulsions* as do the barbiturates and the aliphatic narcotics, and indeed increases spinal excitability; but it lessens the apprehension and pain. The depressant action on the respiration must be borne in mind (Dreyfus, 1914). (Codeine does not inhibit, but rather increases the convulsions of camphor; Januschke and Masslow, 1915.)

Comparative Analgetic Efficiency.—Morphine surpasses its commonly used derivatives; but codeine often suffices, with the advantage that it has less side actions, *f. i.,* it is less nauseant and less constipative, and its clinical use only rarely leads to addiction. Dilaudid also avoids the side actions (Straud, 1934), but is not proof against addiction. This holds also for demerol. Carefully controlled clinical tests indicate that the actions of the mixture of opium alkaloids ("*Pantopon*") are indistinguishable from those of the morphine which it contains, the $\frac{1}{3}$ grain tablet of pantopon corresponding to $\frac{1}{4}$ grain of morphine sulfate in analgetic efficiency and in all the side actions. It has therefore no advantage (J. M. Hayman and Fox, 1937). The same relation holds for critical experiments in animals (Barlow, 1931).

Analgetic Dosage.—Severe acute pain requires 8 to 15 mg. ($\frac{1}{8}$ to $\frac{1}{4}$ grain) of morphine hypodermically; larger doses are usually not materially more effective unless tolerance has been acquired, and this must be carefully avoided. In lighter grades of pain, codeine should be used, 0.015 to 0.06 Gm. ($\frac{1}{4}$ to 1 grain) by mouth, preferably with 0.3 to 0.65 Gm. (5 to 10 grains) of acetylsalicylic acid. This suffices for many cases of cancer. Morphine is used more economically in chronic cases if moderate doses (10 to 15 mg.) are given by mouth at intervals of three to four hours, than with larger doses at longer intervals; but routine intervals favor addiction (E. M. Daland, 1936).

The stress and excitement involved in *battle casualties* require 30 mg., $\frac{1}{2}$ grain. This is safe, but must not be repeated until after six hours. *In shock,* 10 to 15 mg. may be injected by vein, to avoid delayed absorption. It allays pain and apprehension, although it has no direct effect on the shock.

Quantitative measurements of the *pain threshold* in man show that the analgetic effect of morphine increases markedly with the dose to 10 mg. intramuscularly; and but little more between 15 and 30 mg. With codeine, the analgesia is near its maximum at 60 mg., but increases somewhat to 120 mg. (J. D. Hardy *et al.*, 1940). The potency of pantopon is that of its morphine content. The potency of 30 mg. of morphine is equaled by 3 mg. of dilaudid or 6.6 mg. of metapon. *Addition of acetanilid,* amidopyrine or acetylsalicylic acid potentiates the morphine analgesia (Fellows and Cunningham, 1943). Sensations other than pain are not affected by therapeutic doses of morphine or codeine or other analgetics, such as acetylsalicylic acid, evipal or alcohol (Wikler *et al.*, 1945). *Neostigmine* was reported to potentiate the analgetic effects of morphine in man and in animals, perhaps by diminishing its urinary excretion (Slaughter *et al.*, 1943, 1946); but Andrews, 1942, failed to find significant potentiation. *Methods for determining analgetic potency on animals* are described by Knowlton and Gross, 1943 (electric threshold, dogs), and by D'Amour and Smith, 1941 (heat on rat tails). The results agree with the clinical.

Local application of opiates to bruises, etc., is not rational, for morphine has practically no action on the sensory endings or on the peripheral sensory nerves. A weak local analgesic effect was reported by Macht, Johnson and Ballinger, 1916, and confirmed by Sollmann, 1917 (endermic method). This, however, is so slight, brief and superficial that it is doubtful whether it has any part in the therapeutic analgesia. Practically, the site of application is no more affected than other regions of the body (Jolly and Hilsmann, 1874). Any apparent success is largely imaginary; although there may be some central analgesia, since morphine is readily absorbed from wounds and mucous membranes and to a slight extent even from the unbroken skin. With the antiquated "Lead and Opium Wash," the precipitate formed by the lead with the gums and meconic acid furnishes a soothing protection. The morphine is not precipitated by the lead.

For Pre-Anesthetic Sedation.—Morphine, 10 mg. or $\frac{1}{6}$ grain hypodermically half an hour before inhalation anesthesia, lessens apprehension and gives a smoother anesthesia, with a smaller quantity of the anesthetic agents, diminishes the discomfort on awakening and reinforces the postanesthetic sleep. It is often used in conjunction with barbiturates or avertin to build up a "basal anesthesia," to be completed by a relatively small amount of inhalation anesthetic. It is *synergistic with pentothal* and may produce deep coma unless proper allowance is made in the dosage (S. L. Lieberman, 1945). It is used with scopolamine (see Index) for "twilight sleep" in obstetrics. Its use involves a tendency to respiratory depression, which must be watched. Morphine is similarly used in connection with local anesthesia, to allay nervousness and distract attention. Codeine is considerably less effective for preanesthetic medication. Experimental data on the relative efficiency of preanesthetic medication are given by O. W. Barlow and Stormont, 1932, and Barlow and Duncan, 1933.

Sedative Action in Cough.—The morphine alkaloids check cough chiefly by diminishing attention to the irritative reflex. They also decrease the quantity of bronchial secretion, partly by a direct action (Rossbach, 1882) probably central, and partly by the drying of the mucus as it stays longer in the air passages. Opiates as "sedative expectorants" in bronchitis and phthisis are useful when the cough is mainly irritative; and contraindicated when required for the expulsion of excessive mucus. Even then, however, they may be needed to secure sleep. Small doses suffice, and *codeine,* 10 to 30 mg. ($\frac{1}{6}$ to $\frac{1}{2}$ grain) orally, should be preferred. The average patient obtains relief from 10 mg. every four hours (L. F. Davenport, 1938). The anti-tussive dosage of morphine is 2 to 5 mg. ($\frac{1}{30}$ to $\frac{1}{12}$ grain); Tr. Opii $\frac{1}{2}$ cc. or 10 drops; dionin, 15 mg. or $\frac{1}{4}$ grain; heroin, 5 mg. or $\frac{1}{12}$ grain.

Heroin is effective, but has no material advantage. It is extraordinarily addicting and much more toxic than morphine (Harnack, 1899).

Respiration.—Small and moderate (non-narcotic) doses of morphine (3 to 15 mg. in man) quiet the respiration. The rate is generally moderately slowed (Gscheidlen, 1869), markedly so if it had been rapid; the depth is often rather increased, especially if it had been shallow; the minute volume is usually somewhat decreased, but may be unaltered or even increased; the response to carbon dioxide and asphyxia is greatly diminished. Spasmodic irregularities, dyspneas and air hunger are removed or allayed. The regular deep respiration thus induced is more favorable to air exchange, so that the respiration is more efficient even when it is slower. *Toxic doses* produce progressively serious depression of the respiratory center: marked decrease of excitability, rate, depth and efficiency; periodic respiration (Filehne; Barbour, 1914) resembling the "Cheyne-Stokes type" (but probably not typically so; Krongliakoff-Blanc, 1928), and finally arrest of respiration, before the heart is seriously injured.

The mechanism of the respiratory depression is presumably analogous to the psychic effects, *i. e.,* inattention to the stimuli that normally influence and entertain respiration. This would be most marked toward persistent stimuli, such as those of cough and carbon dioxide; while the response to abrupt stimulation, for instance of the sciatic nerve, may even be increased (S. J. Cohen and McGuigan, 1924). With toxic doses, the apathy would gradually abolish all respiration. In habituation, the organism learns to adapt its indispensable functions to the apathy, and the toxicity is greatly diminished. Different degrees of apathy would explain the wide variations in the fatal dose for different animals.

Relation to Dosage.—With dogs and rabbits, Macht, 1915, found that small doses (0.1 mg. per Kg.) markedly slowed the rate, but somewhat increased the minute volume and alveolar ventilation; but the response of the center to CO_2 was somewhat decreased. Full doses (1 to 5 mg. per Kg.) diminished the rate, minute volume alveolar ventilation and response to CO_2.

Quickening of respiration is seen occasionally with therapeutic doses in man (Higgins and Means, 1915) and occurs at certain stages in animals: *in the dog,* the hypodermic injection of morphine first causes quickening of respiration (perhaps through nausea) followed in fifteen minutes by the typical slowing (Mayor, 1908). In *frogs*, the slowing is succeeded by quickening, just prior to the convulsive stage. A *secondary quickening* is also seen in rabbits (Filehne, 1879; Cerna, 1892) but never in man.

Diminished Sensibility to Asphyxia.—In normal animals, excess of carbon dioxide and deficiency of oxygen increase the depth and rate of respiration. Morphine dulls this response (A. Loewy, 1890; Cushny and Lieb, 1915); apnea is easily produced and very persistent (Filehne, 1879); the blood becomes very venous (Filehne and Kionka, 1895). Schmidt, 1924, attributes the diminished response to CO_2 to slowing of active expiration. The average concentration of blood at high altitudes is not altered by 15 mg. of morphine (E. W. Peterson *et al.*, 1945).

Respiratory Reflexes.—The effects of morphine vary for the different reflexes. In general, it tends to increase the sensibility to inhibitory and spinal reflexes, and has little effect on acute augmentory reflexes (Cushny, 1913; Cohen and McGuigan, 1924).

Other Opium Alkaloids on the Respiration.—The effects of the morphine derivatives, codeine, heroin, dionine, etc., are essentially the same as those of morphine (Issekutz, 1911). In rabbits and rats respiratory depresssion equivalent to that of morphine requires about double the dosage for pantopon, four times for codeine, four to eight times for narcotine, seven times for papaverine (Barlow, 1933), seventeen times for dilaudid (C. J. Wright and Barbour, 1934). Barbiturates (especially those with lasting action) potentiate the respiratory depression more than avertin, chloral or urethane (Maloney and Tatum, 1930). *Diacetyl-morphine (Heroin)* was introduced by Dreser, 1898, with the claim that therapeutic doses lessen the cough reflex and slow the respiration; but that the inspirations are deepened and more powerful, so that the alveolar air is more effectively ventilated. Independent workers have shown that there is no real difference from morphine (Fraenkel, Harnack, Lewandowsky, Santesson, Winternitz, 1899; Issekutz, 1911; Cushny, 1913). In man, the respiratory effects of 5 mg. of heroin correspond almost quantitatively to those of 15 mg. of morphine (Higgins and Means, 1915). *N-allyl normorphine* and the corresponding codeine compound stimulate respiration and antagonize the morphine depression (E. R. Hart, 1943). *The alkaloids of the papaverine group* generally stimulate the respiratory center, so that opium is rather less depressant to the respiration than would be expected from its morphine content (Macht, 1915).

Use in Asthma and Dyspnea.—Morphine (15 mg. or $\frac{1}{4}$ grain, hypodermically) may relieve, by quieting the patient and allaying the "air hunger" and anxiety. It may even improve the efficiency of the respiration, rendering shallow breathing deeper, and convulsive respiration regular. It is likely to become dangerous, however, by suppressing the effort to drive the air through the narrowed passage (Balyeat, 1939). Morphine should be avoided in bronchial asthma, for fear of habit-formation. It might also lead to addiction in cardiac dyspnea. It is useful in acute respiratory disease, for instance pneumonia or pleurisy; deleterious depression need scarcely be feared from therapeutic doses.

Morphine in "Gassing" by Chlorine and Other Volatile Irritants.—Morphine not only dulls the agonizing "air hunger," but tends to save life by quieting the patient and thus diminishing the use of oxygen and the production of carbon dioxide. Hjort and Taylor, 1919, claim that it also prolongs the maintenance of alkali reserve.

Bronchial muscles are slightly relaxed by small therapeutic doses of morphine, and more powerfully by papaverine and narcotine (Pal, 1913; Macht, 1915); large doses of morphine, codeine, dionine, and especially heroin, narcotine and thebaine, produce marked constriction. Higgins and Means, 1915, observed bronchial constriction in man with 15 mg. of morphine or 5 mg. of heroin. The relaxation may play a part in the relief of bronchial spasm (*asthma*); while the constriction may contribute to the asphyxia of toxic doses.

The effects are peripheral, for they occur on excised bronchial muscle (relaxation, Trendelenburg, 1912) as well as in pithed (constriction, Jackson, 1916) and in intact animals (relaxation with small, constriction with large doses; Brodie and Dixon, 1903). The constrictor action is not antagonized by atropine or ergotamine. It can be overcome by powerful dilator (sympathetic) stimulation, epinephrine, hordenine, cocaine (Swanson, 1929).

Autonomic System.—The peripheral effects of morphine are complicated by its inhibitory action on choline esterase, resulting in cholinergic stimulation; and by increased output of epinephrine with resultant adrenergic stimulation.

Choline esterase inactivation by morphine was demonstrated by Bernheim and Bernheim, 1936, and studied by G. S. Eadie, 1941. Analogous effects of morphine esters and derivatives are described by C. I. Wright and Sabine, 1943.

Iris.—In man (not generally in animals) even small, scarcely analgetic doses of morphine constrict the pupils, and toxic doses result in pin-point miosis. This has diagnostic importance. The action is central, for it does not occur on local application or in excised eyes. It is due to a stronger constrictor (oculomotor) tone, for it disappears when the oculomotor endings are paralyzed by atropine. It is somewhat diminished by section of the sympathetic supply (Amsler, 1927). The miosis appears analogous to that of sleep or of general anesthesia, namely, extinction of the centripetal sensory impulses which in the waking state restrain the tonus of the oculomotor center (Meyer and Gottlieb). It requires intactness of the optic nerve (McCrea *et al.*, 1942). Morphine also produces a fairly lasting rise of intra-ocular pressure (Myashita, 1913). The rise is shorter with ethyl-morphine.

Pupil Changes in Animals.—In *cats*, the pupils are dilated by morphine in conformity with the inhibition of the oculomotor tone by the psychic excitement. Dilaudid and demerol also produce maximal mydriasis in cats. Codeine and papaverine do not change the pupil (D. I. Macht, 1946). The pupils of morphinized *dogs* are contracted with internal strabismus, during the sleep, but if they are wakened the pupils dilate and the strabismus disappears (C. Bernard). *In albino rats* morphine produces no perceptible change in the pupil, but greatly increases the mydriatic response to sympathetic stimulants, cocaine, epinephrine, ephedrine (Koppanyi, 1932).

Circulation.—Therapeutic doses of morphine or its derivatives do not affect the circulation materially. In man, there is generally an (indirect) increase of *pulse rate* immediately after an injection; this is quickly followed by persistent moderate slowing, with increased fulness and force (stimulation of vagus center). The blood pressure, after a short rise, may remain level (Anderes, 1913), or falls slightly (Guinard, 1895), through the slowing, and perhaps through incipient depression of the vasomotor center. The cutaneous vessels are markedly flushed, and sometimes also those of the oral mucous membrane and conjunctiva. With *toxic doses,* fall of blood pressure is more marked (central vasomotor depression) and the pulse becomes weak, varying in rate, and often arrhythmic (stimulation of vagus center and disturbed cardiac conduction). The heart muscle suffers indirectly, by the low blood pressure and asphyxia (hence danger in cardiac insufficiency, especially when combined with dyspnea). Ordinarily the circulation remains fairly good, until death occurs by paralysis of respiration. Direct depression of the heart is produced only when morphine, or especially its derivatives, are perfused directly through the heart. Hering, 1915, believes that the increased vagus tone resulting from large doses may indirectly produce ventricular automatism, or even fibrillation, especially in pathologic hearts tending in that direction.

Vagus Center and Cardiac Conduction.—Dogs show the above phenomena in more marked degree. The preliminary acceleration is due to nausea. The typical slowing is not seen after section of the vagi, and is therefore central. It occurs with small doses, increases with larger doses and passes into arrhythmia (van Egmond, 1911; Anderes, 1913); and sino-auricular and auriculo-ventricular heart block, separate or combined, removable by atropine (Eyster and Meek, 1913). The reflex excitability of the vagus center is also increased (Jackson and Ewing, 1914). The action is probably on the medulla, not on the cerebrum (B. H. Robbins *et al.*, 1939). Electrocardiograms also show central vagus stimulation (Cohen, 1913). The effect on the pulse rate is inconstant in cats, absent in rabbits (Egmond). Anderes found constant slowing in rabbits, the vagus stimulation being partly central, partly peripheral through decrease of the negative thoracic pressure. Morphine sensitizes the vagus center to epinephrine (Heinekamp, 1919). The cardio-inhibitory center of the turtle is stimulated by perfusing morphine through the medullary circulation (Bush, 1920).

Cardio-inhibitory reflexes from the carotid sinus and aortic arch are intensified by morphine, in dogs (Van der Linden, 1932). Hering and Koch, 1931, concluded that the ordinary morphine bradycardia is due to this cause; but Heyman *et al.*, 1931, found that it occurs also after denervation of these zones, so that morphine must stimulate the inhibitory center directly.

Blood pressure fall on intravenous injection occurs with doses of 1 mg. or more per Kg. in dogs and cats, not in rabbits, rats or guinea pigs. Tolerance is rapidly acquired (C. F. Schmidt and Livingston, 1933). It is perhaps a "flocculation shock."

Cardiac Muscle.—Morphine and all its derivatives first increase the rate and amplitude of perfused *mammalian heart.* This is followed by decrease and finally systolic standstill (Gruber and Robinson, 1929). The rate of the perfused atropinized *frog's heart* is quickened by dilute, slowed by more concentrated solutions of all the papaveraceous alkaloids, morphine being the least deleterious (Hale, 1909). The refractory phase is prolonged by morphine (Junkmann, 1925). Lippins, 1908, found peronine highly toxic for the turtle's heart. Narcotine is the most toxic of the opium alkaloids, for the heart (Macht, 1915). Papaverine lowers the cardiac tone (Pal); this is followed by considerable tachycardia (Rennon and Desbouis, 1914). The *tonus waves of turtle's auricles* are augmented by morphine, depressed by papaverine and benzyl alcohol (C. D. Snyder and Andrus, 1919). The *cardiac ganglia* show degenerative histologic lesions, similar to those of alcohol or chloroform (Lissauer, 1914). Gscheidlen, 1869, found that the *vasomotor endings* were not completely paralyzed even in advanced poisoning; stimulation of the spinal cord still gives a rise. The venous *pressure* is not changed by moderate doses, and is slightly lowered by toxic doses, indicating vasodilation (Capps and Matthews, 1913). The *coronary circulation* is quickened by dilatation of the coronary vessels, by most of the opium alkaloids. The action is most marked with narcotine and papaverine, slight with morphine, very slight with codeine, heroin or pantopon, and absent with narceine and thebaine (Macht, 1915; Gruber and Robinson, 1929).

Cerebral Circulation.—The effects are small and inconstant with ordinary doses (Aliprandi, 1905). Frankfurther and Hirschfeld, 1910, describe an initial increase of brain volume, followed by decrease, the latter probably due to the fall in general blood pressure.

Action on Skin, Diaphoresis, Use against Colds.—Morphine and its esters have a direct mild irritant action on the skin, resulting in erythema, itching and wheals. These effects are especially marked with local application to the scarified skin, but the internal administration of therapeutic doses produces flushing (extending also to the oral mucosa, Claude Bernard), a sensation of comfortable warmth and diaphoresis; sometimes skin rashes in the over-susceptible. With toxic doses the skin becomes pale (splanchnic vasodilatation) and cyanotic (asphyxia). The diaphoretic action is used to treat and perhaps abort incipient colds, preferably as codeine (30 mg., ½ grain, in morning and afternoon, and double this dosage at night, for not more than two days). The addition of papaverine has been patented, but its usefulness is questionable. "Dover's powder" (Pulvis Ipecacuanhae et Opii), 0.5 Gm., was formerly used for this purpose.

Wheals.—The local application of solutions of morphine or any of its esters to the scarified skin results in the production of an urticarial wheal (Philippson, 1899; Toisk and Hari, 1903; Jadassohn and Rothe, 1914; Sollmann, 1917). Contact dermatitis in personnel manufacturing morphine has been reported (Brit. J. Derm. and Syph., 1944, *56*:151). Similar wheals are produced by histamine, peptone, emetine and calcium chloride (Sollmann and Pilcher, 1917). The susceptibility to wheal formation is the same in addicts as in normal individuals; so that tolerance is not acquired by habituation (Pilcher and Sollmann, 1923). This wheal formation is responsible for the itching and probably for the sneezing that are sometimes noted in morphine poisoning. The pruritus was described by the Greeks, but seems to have been forgotten until quite recently (Francis Adams, 1830; Edinbrgh. Med. and Surg. Jour., *1*:315).

Conjunctival Reaction to Ethylmorphine (Dionin).—The direct application of a 1 to 5 per cent solution or ointment produces burning pain, hyperemia, and then acute edema of the lids and conjunctiva (chemosis), with prolonged analgesia. The edema is absorbed without ill effects. This reaction is used in ophthalmology for analgesia and treatment in conjunctivitis, corneal ulcer, acute glaucoma, iritis and other inflammatory conditions of the uveal tract.

The edema appears in a few minutes and lasts for several hours. There is some local anesthesia. The pupils are at first constricted, and the intra-ocular tension is raised (Toczyski, 1912). The edema does not occur in rabbits, but readily in dogs or cats (Axenfeld, 1905). Benzol-morphine (peronine) is said to act in the same way; but the effect does not occur with morphine, codeine, heroin or any of the natural opium alkaloids.

Suppression of Saliva.—Therapeutic doses of morphine produce dryness of the mouth, and thirst, by abolishing the reflex secretion of saliva. Claude Bernard showed on dogs that it does not hinder secretion on peripheral stimulation of the chorda tympani nerves, but suppresses the reflex secretion of placing acid in the mouth, or of stimulation of the central end of the divided lingual nerve. The action is therefore central (V. E. Henderson, 1910).

Nauseant and Emetic Action.—Morphine tends to produce nausea and vomiting. The appetite is diminished through the lesser perception of hunger and through the gastric derangement. The effect is independent of the mode of administration, the action being central. The severity varies in different individuals; in some cases it is so serious, and accompanied by so much depression, as to preclude the use of the drug. It may sometimes be diminished by bromide or by atropine (I. Simon, 1907). Codeine is distinctly less nauseant than morphine. The action of the mixed opium alkaloids (pantopon, etc.) appears to correspond essentially to their morphine content (Hayman and Fox, 1937).

Site of the Emetic Action.—This is essentially central; for it occurs when all afferent impulses from the digestive tract are excluded; and it is also evoked when small quantities of morphine or acetylmorphine are applied directly to the floor of the fourth ventricle (Hatcher and Weiss, 1923). It may conceivably be aided by reflexes from the gastric spasm; for atropine appears to diminish the emetic tendency. There is no evidence of local gastric irritation. Vomiting occurs more readily with hypodermic than with intravenous injection; probably because the latter depresses the vomiting center too rapidly. *Nausea salivation* is profuse in dogs. Repeated injections establish a strong conditioned salivation reflex, which does not diminish as the habituation progresses but rather increases with the dosage. (Pilocarpine does not establish a conditioned reflex and inhibits that of morphine; Krylov, 1930.)

Antiemetic Action.—With large doses of the morphine alkaloids, the emesis is followed by diminished susceptibility to vomiting. This action is also mainly central (Leake, 1922). Morphine is prescribed against vomiting, but the doses which can be safely prescribed are often ineffective.

Dogs, after the primary emesis, do not respond to irritant emetics or apomorphine, probably because of depression of the vomiting center, although morphine, codeine or heroin are antemetic in doses which are not narcotic, while chloral or urethane, to prevent vomiting, must be exhibited to full narcotic action (Ruth, 1913). Contracture of the cardial sphincter, which was postulated by Magnus, 1908, may prevent the emptying of the stomach, but would not arrest emetic movements (Hatcher). Papaverine is not antemetic (Ruth).

Gastric Tonus and Sojourn of Food.—Morphine causes prolonged spastic contraction of the prepyloric and pyloric sphincters, delaying the passage of food through the stomach to five and a half hours (Gordonoff, 1925), which correspondingly defers absorption (*f. i.*, of iodide; Baas, 1904). This plays a part in the constipating action of morphine.

These actions have been confirmed by roentgen examination and by examination of stomach contents, in man as well as in animals (Magnus, 1906; Gruber, Thomas *et al.*, 1936; Veach, 1937; review, H. Krueger, 1937). Similar results were obtained by transfusion *in situ;* papaverine relieved the spasm (H. Schroeder, 1933). Discordant results were reported by Plant and Miller, 1928, for gastric fistulas.

Gastric Secretion.—In fasting human subjects, morphine (0.01 Gm. hypodermically) decreases gastric secretion, the volume being diminished more than the acidity. The decrease seems parallel to the mental depression, being least marked or absent if the subject becomes talkative or excited. The inhibition is easily overcome by stimulation, such as the sight of food, and by histamine (K. C. Wang *et al.*, 1936). The decrease is greater in normal than in habituated animals (P. Ellinger and Seeger, 1934).

Several observers have reported increase of secretion by morphine in fasting animals (Chiari, 1915; Smirnow and Schirokij, 1927). In dogs with a Pavlov stomach, Riegel, 1900, obtained first a decrease, then an increase of volume and acidity. Claude Bernard reported that digestion in the pigeon's crop was arrested by morphine when injected into the crop, but not on hypodermic injection, indicating a local action. *Pancreatic secretion* is decreased by morphine, as is also the response to secretin (O. Cohnheim and Modrakowski, 1911).

Constipative Action.—Morphine produces constipation, even with small doses, delaying the passage of the contents through every part of the digestive tract, chiefly by spastic contracture of the gastric sphincters, and through decreased propulsive efficiency by tonic spasticity of the intestinal musculature. The action is directly on the muscle and persists also in habituated individuals. It is an undesirable side effect of its analgetic use, but is valuable for arresting diarrheas and for quieting peristalsis in acute inflammations of the intestines and peritoneum. In acute intestinal catarrh, if the intestines are first cleared of toxic and irritant material by a cathartic, the rest afforded by opiates favors the subsidence of the inflammation. Tincture of opium by mouth (0.5 cc. or 10 drops) or a teaspoonful of paregoric deserves preference. Opium is only moderately effective in the colic of lead poisoning. In peritonitis it relieves the pain, both directly and by lessening peristalsis; but the disguise of the symptoms may be surgically objectionable. In biliary and renal colic, morphine (15 mg. or $\frac{1}{4}$ grain) is given hypodermically, to lessen the suffering (usually with 1 mg. of atropine to relax the ducts).

Codeine, dilaudid and acetylmorphine (heroin) produce qualitatively identical effects, both on the stomach and on the intestines; codeine and dilaudid being considerably weaker, and heroin somewhat stronger, than morphine (Plant and Miller, 1923). Mixtures of the alkaloids give simple summation (Gordonoff, 1925). Opium as a whole is therefore somewhat more constipating than would correspond to its morphine content (Zunz, 1921). Papaverine and the other isoquinoline alkaloids do not cause gastric spasm. They depress the intestinal tone, but their action is evidently overcome by the morphine.

The relative delay at various levels of the digestive tract varies with conditions, such as the degree of distention and the presence of irritation, in each of the regions. *In normal man,* Zehbe, 1913, found the total time of passage through the digestive tract nearly doubled by morphine. The chief delay was in the colon and rectum; the gastric and intestinal passages were each lengthened by a third. Pancoast and Hopkins, 1915, reported the delay as chiefly in the small intestines and but little in the colon. If morphine is administered with the test meal, the delay is confined largely to the stomach, because the food does not enter the intestines until the effects of the morphine have practically passed off (Gordonoff, 1925). E. H. Fell, 1938, found no characteristic delay in the emptying time of the stomach and small intestines, but the emptying of the colon was delayed by eight to thirty-one hours and the total sojourn in the intestines by four to twenty-four hours. He attributes the constipation to the difficulty of expelling the hard, dry feces against the increased tonus of the anal sphincters.

In dogs, M. Krueger, 1937 (review), found that 6 mg. of morphine per Kg. delay the evacuation of feces about twenty-four hours, distributed about as follows: *sojourn in stomach,* thirteen hours, chiefly by closure of the pylorus and constriction of the prepyloric sphincter; *sojourn in small intestines,* seven hours, chiefly by decrease of biliary and pancreatic secretion, decrease of propulsive activity, increased viscosity of contents; *sojourn in colon,* four hours, chiefly by drying of contents, difficulty of passing through the contracted sphincter.

Historical.—The mechanism of the morphine constipation has been much disputed (the bibliography of Uhlmann and Abelin, 1920, cites 314 titles) chiefly because the quieting of peristalsis was supposed to require depression of the intestines. The older workers (reviewed by Magnus, 1910) assumed depression of the local reflex which was assigned to the plexuses of Auerbach and Meissner, or central stimulation of the inhibitory splanchnic fibers (Nothnagel, 1882). This postulated depression could not be confirmed; the constipative action occurs after section of the intestinal nerves and after atropine; and excised intestines show chiefly stimulation. The explanation of spastic arrest did not readily suggest itself, because other spastic agents generally pass through a stage of increased peristalsis and colic, which is absent with morphine. The cause of this peculiar difference is not known. The credit for demonstrating the importance of the intestinal spasticity belongs to Plant and Miller, 1923, 1925.

Antagonism to Cathartics.—Magnus, 1906, 1908, found that the constipative action in the milk diarrhea of cats is due almost entirely to the gastric action. The diarrheas of senna, castor oil and magnesia were resistant to morphine; but the inflammatory diarrhea of colocynth was arrested by a direct intestinal action (Padtberg, 1911). Later experiments on animals with permanent fistulas of the small intestines show that morphine arrests the powerful peristaltic waves induced by the emodin cathartics and by podophyllin, converting them into the spastic tonus (C. M. Gruber, Bryan and Richardson, 1931). Morphine and codeine also increase the tonus of exposed intestine when it has been depressed by magnesium sulfate (N. B. Dreyer, 1929). *Papaverine* and the chemically related chelidonium alkaloids are depressant to the intestinal movements, and relax the colic of acetylcholine and pilocarpine, and of phenoplhthalein, podophyllin and senna (L. Alkan, 1928).

Tonicity of Small Intestines.—Various methods of observation show that intestinal muscle shortens and develops increased tension, more prolonged contraction phase with slowing of the rhythm (to a fourth; Krueger and Samwalt, 1936), and marked slowing of propulsion. The spasticity may be observed in man through the thin skin of herniae (Plant and Miller, 1925), and by intubation; in animals by pressure changes in permanent fistulas (Plant and Miller); by propulsion of a bolus in an intestinal loop; and by artificial abdominal windows (Gordonoff, 1925). It occurs also in excised intestines, both with perfused lumen (Baur, 1925) and with Magnus segments (references, Uhlenhuth and Abelin, 1920). It is not prevented by atropine; the action is therefore entirely peripheral (review, Krueger, 1937).

Intubation studies on human small intestine permit observation under clinical conditions. Hypodermic injection of 10 to 30 mg. of morphine produces within a few minutes tonic contraction of the duodenum practically obliterating the lumen, followed by dilation lasting several hours. The ileum shows marked decrease of the contraction waves, with slow rise of tonus, and later, stationary tonus rings. The effects were detectable for three days (W. O. Abbott and Pendergrass, 1936). In an externalized loop of the lower ileum, in man, 8 mg. of morphine caused decrease in propulsive activity, more frequent mixing waves and, often, an increase of tonus (A. C. Forster, 1938).

Pressure Changes in Unanesthetized Dogs with Thiry-Vella Fistulas.—Plant and Miller, 1923, first showed the stationary tonus effect by this method. The rate of the contractions is slowed and the amplitude may be increased. Large doses abolish peristaltic activity. Repeated intravenous injections decrease the general tonus and may increase the force of the contractions (Gruber *et al.*, 1929 and 1932, and H. Krueger *et al.*, 1934 and 1938). The *progress of a bolus* through the Thiry-Vella loop gives truer information as to propulsion than does the balloon pressure. In the ileum and jejunum of unanesthetized dogs, morphine briefly augments the propulsive activity, but this is followed by high tonus with marked and prolonged slowing or arrest of propulsion (J. P. Quigley, Highstone and Ivy, 1934; Weisel *et al.*, 1938; papaverine and atropine also decrease propulsion; pitressin and pitocin usually slow it; pilocarpine has little effect). The *derivatives of morphine*, natural and synthetic, act qualitatively alike, but codeine produces less tonus increase than morphine in equivalent dosage, and dilaudid still less (Krueger and Hoover, 1934). *Papaverine* depresses the tonus, but sometimes increases the tonus waves (Gruber and Robinson, 1929). On segments of excised intestines, dilaudid acts like morphine, increasing the tonus for the cat and relaxing it for guinea pigs (Gruber, Brundage *et al.*, 1935). *Physostigmine* partly potentiates the morphine action on the intestine (Slaughter and Gross, 1940).

Colon.—By the fistula and the balloon method Plant and Miller, 1928, observed that morphine produced increase of tonus and spastic contractions, during which peristalsis was abolished. These effects lasted much longer than the central narcosis. Roentgenologic observations on cats showed that morphine rendered the normal deep segmenting peristaltic contractions very shallow (Schwenter, 1912). The rectal tonus is increased in cats; this is followed by relaxation in several hours (G. N. Myers, 1940). The *anal spincter* is also contracted (Koppanyi and Murphy, 1933).

Defecation Reflex.—In addition to the muscular action, the morphine apathy diminishes the attention to the rectal sensations and therefore the responsiveness to the defecation reflex (Schapiro, 1913; Mahlo, 1913). It furnishes prompt relief to the tenesmus of diarrhea.

Purgative Action in Dogs.—Morphine increases the motility and tonus of the colon, with strong propulsive movements. Atropine prevents the propulsion but does not inhibit the tonus and nonpropulsive motility (A. F. Adler and Ivy, 1940). Hypodermic injection of large doses of morphine is generally followed by defecation. Intravenous injection of morphine, codeine, heroin (or ergotamine) causes prompt straining and defecation, through central action, for the effect does not occur if the floor of the fourth ventricle has been injured (Theo. Koppanyi, 1932).

Bile Flow.—Therapeutic doses of morphine (10 mg. hypodermically) diminish the flow of bile (Paven *et al.*, 1929) through spasm of Oddi's sphincter (Reach, 1914). After removal of the gallbladder this may raise the pressure in the common bile duct sufficiently to produce biliary colic. It may be relieved by nitrites. Papaverine has no effect (W. Walters *et al.*, 1937). Lieb and McWhorter, 1915, state that the musculature of the gallbladder is not affected; but Macht, 1917, claims that the gallbladder reacts to the opium alkaloids like the ureter, *i. e.*, that it is stimulated by morphine, depressed by papaverine. The *secretion of bile* is greatly decreased by heroin, but not by morphine (Balteceano and Vasilu, 1935).

Uterine contractions are little affected by morphine, in either direction, in clinical labor (Dodek, 1932) and in gravid and nonpregnant animals (D. Slaughter and Gross, 1937). Labor may be somewhat slowed and prolonged (Bourne and Burn, 1930) by failure to reinforce the labor pains with voluntary contractions of the abdominal muscles (Barbour and Copenhaver, 1915). The chief danger in the use of morphine is depression of the respiratory center of the child, and it should not be employed after the first stage of labor (see under *Scopolamine*).

It has been observed in rabbits that the prolonged labor tends to injure the fetus, resulting in a high ratio of still-births. This is not due to poisoning of the fetus, for it survives if removed by hysterectomy (F. F. Snyder and Lim, 1941).

Ureter.—Morphine and the derived alkaloids (including dilaudid, but to a less degree) increase the tonus of the ureter and the rate and force of its contractions (Gruber, 1936). This may conceivably interfere with their use in ureteral colic. *Papaverine* depresses the ureteral tonus and contractions (Macht, 1916), but it has not proved effective against colic.

Urinary Bladder.—Toxic doses of morphine produce spasm of the vesical sphincter, leading to distention of the bladder and constant but ineffective desire to micturate. This sometimes occurs in the therapeutic use (Czapek and Wassermann, 1914). It is diminished by habituation (Ikoma, 1924).

In guinea pigs the distention may rupture the bladder (Tappeiner, 1899). The effect is apparently the result of a depression of a detrusor center in the sacral cord, which produces reflexly a reciprocal spasm of the sphincter. Larger doses inhibit the bladder tonus (Hirano, 1938).

The other phenanthrene alkaloids also cause powerful contraction on intravenous injection in dogs (D. E. Jackson, 1916). Larger intravenous doses are inhibiting in rabbits (Hirano, 1938). The isoquinoline alkaloids (papaverine) relax (Macht, 1918). The capacity of the bladder in unanesthetized dogs is decreased by morphine, mecholyl and atropine, increased by ephedrine (Winters, 1940).

The *seminal ducts* react like the ureter (Macht, 1916). The *retractor penis* muscle of the dog is stimulated by morphine (Edmunds, 1920).

The **urine output** is diminished by morphine, clinically and in animals, including diminished response to water administration (Klemt, 1934). The chloride and nitrogen excretions are not changed except in so far as morphine may diminish food consumption. The decrease of urine volume is due to the diaphoresis; but the inhibition of water diuresis is apparently affected through liberation of antidiuretic hormone from the hypophysis, for it does not occur after destruction of the neurohypophysis (de Bodo, 1944). Morphine also hinders the transfer of injected saline solution from the blood to the tissues (Bogert, Underhill and Mendel, 1916).

Temperature.—Toxic doses of morphine lower the temperature below normal, chiefly by diminished heat production. Small doses are somewhat antipyretic by the diaphoresis.

The fall (which is sometimes preceded by a slight rise, especially in cats and guinea pigs; Helfrick, 1935) may be 2° C. with large doses. The cooling is particularly great if the animal is kept in cold surroundings. With small doses, the fall may be explained by increased heat loss from cutaneous vasodilatation; but with large doses it is due mainly to diminished heat production and finally to circulatory collapse. The heat production may be reduced by 80 per cent in extreme cases, reaching its minimum in the third hour. The heat loss is diminished (up to 20 per cent), partly through the effort of the heat centers to compensate for the diminished production, partly through the depressed circulation (Reichert, 1901).

Malaria.—Opium gives symptomatic relief, but has no curative or prophylactic value; nor does narcotine affect the parasites of any of the malarias in the peripheral blood (Chopra and Knowles, 1930).

Protozoa.—The papaverine group is toxic to these organisms, whereas the morphine group is relatively ineffective (Bills and Macht, 1924). Trypanosoma brucei is killed *in vitro* by both groups, but especially by the papaverine group. *In vivo* (rats) both groups are ineffective (Macht and Weiner, 1918). The amebicidal action of emetine, which is also an isoquinoline derivative, prompted Pick and Wasicky, 1915, to suggest the trial of papaverine against *amebic dysentery;* but it has not been successful.

Leukocytes are diminished in acute and chronic morphine poisoning (Cloetta, 1903). The injection of morphine inhibits the migration of leukocytes in inflamed frog's mesentery (Ikeda, 1916). Morphine also diminishes phagocytosis *in vitro* (Arkin, 1913); but the concentrations are different from those obtaining clinically.

Tissue Cultures.—Morphine has unfavorable effects (Kamon, 1928).

Basal Metabolism.—Morphine, even in ordinary clinical doses (H. H. Anderson, 1929), diminishes the oxygen consumption and the CO_2 output, as the result of the muscular quiet. This tends to disappear in habituation (Schoen, 1924). Cats which are excited by morphine show increased CO_2 output (Boeck and Bauer, 1874), as do other animals with the more stimulant morphine derivatives. With *codeine*, the oxygen consumption is decreased by small doses, increased by larger doses; some of the codeine derivatives produce only increase (Eddy, 1933).

Acidosis.—Large doses of morphine diminish the sensitivity of the respiratory center, increase the CO_2 content of the plasma and produce asphyxial acidosis, with marked and rapid decrease of the alkali reserve and of the *p*H of the blood. The lactic acid of the plasma is not increased (Rakieten *et al.*, 1934). Smaller doses (10 mg. per Kg. for dogs) appear to increase the alkali reserve for several hours (Hjort and Taylor, 1919). The *urine* becomes strongly alkaline, by the excretion of carbonate, after narcotic doses in dogs; rabbits' urine does not show any change of reaction (Underhill *et al.*, 1917).

Morphine Hyperglycemia.—After large doses of morphine, the *urine* often contains *reducing substances*, partly morphine-glycuronic acid (P. Mayer, 1899), partly dextrose from the asphyxia.

Clinical doses raise the blood sugar level for some hours in 10 to 15 per cent of fasting individuals. This response disappears in a few weeks if the administration is continued (Bahler, 1930). In dogs, the hypodermic injection of 10 mg. per Kg. increases the blood sugar, on the average, by 60 per cent in one-half hour and 77 per cent in one and one-half hours (E. L. Ross, 1918). A peculiar reducing substance in human urine is described by Spitta, 1908. The morphine hyperglycemia is much greater after partial destruction of the pancreas (Auer and Kleiner, 1917). *Insulin* lowers the blood sugar level as much as in other hyperglycemias (Stewart and Rogoff, 1923). *The mechanism of the hyperglycemia* appears to be a stimulation of autonomic centers which involve areas of the posterior hypothalamus. Decerebration through a midcollicular region, performed twelve to twenty-four hours previously, prevents morphine hyperglycemia and excitement in cats (C. M. Brooks, Goodwin and Willard, 1941).

Relation to Adrenals.—Morphine hyperglycemia differs essentially from asphyxial, piqûre and ether hyperglycemia in that the reaction to morphine is decidedly less if the adrenal glands have been removed or if epinephrine liberation is prevented; while this does not affect the other hyperglycemias (Stewart and Rogoff, 1922; Bodo *et al.*, 1937; Houssay and Lewis).

Antiglycemic Action.—The opium alkaloids have no effect on the hyperglycemia resulting from the conversion of hepatic glycogen (epinephrine or piqûre), but they have an inhibitory action on alimentary hyperglycemia (Klercker, 1914). This indicates that the action is on the alimentary canal, presumably by the gastric delay slowing the digestion and absorption of the carbohydrates, and thus preventing the sudden flooding of the organism with sugar (Macleod, 1914).

Relief of Diabetes.—Opium, morphine and codeine diminish the discomfort, the thirst, hunger and itching, and in moderate cases sometimes also the glycosuria, but not the hyperglycemia. The action would, therefore, appear to be on the renal threshold. The influence on the course of the disease is unfavorable and therapeutically inadvisable, even apart from the addiction danger (Chopra and Boxe, 1930).

Toxicology.—*Acute Symptoms of Morphine and Opium Poisoning.*—Suicidal and accidental poisonings by these agents are common. Prompt diagnosis is important for proper treatment. Coma is the most conspicuous symptom, and its gradual development is characteristic. In advanced poisoning it may be difficult to distinguish the morphine coma from other forms. The symmetrical pin-point pupils are important, but it must be remembered that these dilate as death approaches (asphyxia). The odor is distinctive for opium poisoning. The following description of the morphine effects applies equally to opium (with ten times the dose), except that the symptoms do not appear as promptly.

Moderate Therapeutic Doses (5 to 15 mg., $\frac{1}{12}$ to $\frac{1}{4}$ grain of morphine).—The symptoms set in five to ten minutes after hypodermic, fifteen to thirty minutes after oral administration. They begin with slight flushing of face, sensation of warmth and comfort, lassitude, giddiness, dreamy state, with free imagination but confused intelligence; mouth dry and thirsty. The patient then becomes sleepy; skin pale; respiration and pulse slowed; pupils constricted. Nausea and vomiting are exceptional with this dosage. In a short time—the sooner, the larger the dose—a natural sleep sets in, lasting six to eight hours or more; the patient commonly awakens refreshed. *Intravenous injection* may produce immediate tinnitus, tachycardia and brief fainting.

Larger Therapeutic Doses (20 to 30 mg., $\frac{1}{3}$ to $\frac{1}{2}$ grain).— The initial symptoms are the same. Sleep occurs more promptly and is more profound. On awakening there is usually some confusion, nausea, anorexia and constipation.

Toxic Doses (100 to 300 mg., $1\frac{1}{2}$ to 5 grains). —The initial symptoms are as described. The somnolence deepens rapidly into sleep and coma; severe symptoms are generally conspicuous in five to ten minutes after hypodermic, or fifteen to forty minutes after oral administration; rarely delayed for one or two hours. In the earlier stages of the coma the patient can be partially aroused to a confused consciousness, but relapses promptly into lethargy. As the coma deepens (*i. e.*, almost always within two hours, and often in half an hour after taking the poison), the patient can not be roused, the reflexes disappear, the muscles relax, the jaw drops. The miosis becomes extreme ("pin-point pupil"); the skin cyanotic; the temperature falls; respiration is very slow, irregular, often Cheyne-Stokes; pulse slow, feeble and often irregular. Convulsions are rare in adults, more common in infants; they are sometimes violent, but rarely if ever tetanic. The respiration stops before the heart. The pupils almost always dilate as the terminal asphyxia sets in. (With heroin, death is due to the convulsions; Langer, 1912.) The *time of death* is usually seven to twelve hours; but sometimes two hours or even less. Survival over twelve hours indicates a good prognosis. *Autopsy findings* are merely those of asphyxia: cerebral and meningeal congestion, sometimes with serous effusion; lungs hyperemic and sometimes edematous; general venous congestion; rarely intestinal or cerebral ecchymoses.

Recovery may occur even after asphyxial convulsions. The respiration and pulse improve, the coma becomes lighter and passes into a prolonged sleep, often lasting one or two days. On awakening, the patient is troubled with headache, constipation and digestive disturbances, often vomiting, itching, impotence of the bladder, exceptionally excessive depression. Sometimes the recovery is interrupted by a serious relapse, perhaps through the reabsorption of morphine from the intestine.

Ordinary Fatal Dose.—With morphine, this is 0.2 to 0.4 Gm. (3 to 6 grains); with opium, 3 Gm. (45 grains). There is considerable idiosyncrasy, and 60 mg. (1 grain) of morphine must be regarded as dangerous. With 250 mg. (4 grains) the prognosis is unfavorable, even under treatment, although patients have been saved after 4 Gm. (60 grains) of morphine.

A few cases of death from ordinary doses of opium have found their way into the literature, but their significance is doubtful; E. E. Smith in 1854 reported in the "Lancet" the death of a two-day-old infant from 5 mg. of opium; and cites from a Mr. Dendy that 8 mg. of opium had produced dangerous poisoning in a child of two years. Lewin (Gifte und Vergiftungen, p. 612) states that death of adults has been reported from 0.3, 0.5 and 0.6 Gm. of opium.

In *acute heroin poisoning*, the animals are killed by the convulsions; if these are prevented by etherization, almost double the fatal dose may be survived (Langer, 1912). The literature of fatal heroin poisoning is reviewed by McNally, 1917.

Relative Toxicity for Different Animals.—The tolerance for morphine differs remarkably. Comparisons of the toxicity of morphine and its derivatives (M. Osman, 1929) can, therefore, not be transferred from animals to man. Man is by far the most susceptible to morphine, the fatal dose for man being no greater than that required for a frog of but $\frac{1}{2000}$ the weight. Pigeons, goats, rabbits and pigs require nearly one hundred times the human dose, per kilogram; dogs and cats about fifteen times; horse and cow two to four times. The toxic levels for *hamsters* are given by D. B. Houchin, 1943.

Idiosyncrasies.—*Infants* are highly susceptible to morphine; there is difference of opinion as to older children. Women and patients weakened by disease succumb relatively easily. *Myxedema* lowers the tolerance, so that 15 mg. of morphine may put a patient into deep coma (Lund and Benedict, 1929). In *uremia* there may be synergistic coma with magnesium, if this is administered as cathartic (Hirschfelder). On the other hand, large doses are well tolerated in *diabetes, delirium tremens, tetanus, hydrophobia* (Cl. Bernard), and during the severe and persistent pain of *biliary or renal colic*. *In shock*, the poor absorption may delay and so diminish the response to hypodermic injections of morphine. If it is attempted to compensate for this by repeating the injection, the whole amount may be absorbed at once when conditions improve, and produce dangerous poisoning (H. K. Beecher, 1944). In *fever*, morphine is sometimes exciting; in neurotic patients it may cause insomnia and delirium instead of sleep. Nausea and vomiting are pronounced in some individuals. Persons with high parasympathetic excitability react even to small doses with severe and prolonged vomiting and fall of blood pressure, sometimes with collapse. Urticaria has been observed. *Itching of the skin*, especially of the nose, is a rather common symptom in poisoning. These idiosyncrasies should be remembered in the therapeutic use of the drug.

Hypersusceptibility of Infants.—Young animals are said to be more susceptible than adults, with the exception of cats. Doebeli, 1911, from a clinical and experimental investigation, concludes that the hypersensitiveness, both in the human and in animals, applies only to the age before weaning, older children following the ordinary rule. The hypersusceptibility exists only for the narcotic action and is, therefore, less significant for codeine. The experimental findings are confusing. Chesler *et al.*, 1942, report that fetal and adult rats are equally susceptible to acute respiratory failure, and that the newborn are more resistant. Gibbs and Bobb, 1938, found the toxicity of morphine for newborn rats ten times that of adults; it then decreases steadily to the twenty-first day, when it reaches the adult level. In rabbits, the susceptibility to the convulsant and fatal effects of morphine decreases to about the twelfth week of life, and increases from the twelfth to twenty-fourth week. Morphine derivatives do not give the same curve (Eddy, 1939). The special susceptibility of sucklings is perhaps explained by the observation of Hunt, 1910, that a *milk diet* greatly increases the toxicity of morphine (for mice). *Rachitic diet* renders cats less susceptible to the depressant and more susceptible to the stimulant action (Amsler, 1937), probably because calcium deficiency renders the central nervous system more excitable. Hunt, 1905 and 1907, found that *feeding with thyroid or iodides* increases the susceptibility of mice, rats and guinea pigs to morphine. Githens and Meltzer, 1913, find in rabbits that iodide increases the morphine depression but lessens the tetanic effect, and therefore the fatality. It has been claimed (Lewis and Scott) that *adrenalectomy* renders rats much more susceptible to the lethal effects of morphine, but Rogoff, 1925, showed that this was based on inadequate estimates of the natural mortality after this operation, and that the susceptibility to morphine is not altered. *Double nephrectomy* is said to increase tolerance for morphine (E. M. McKay and McKay, 1930)

Treatment of Acute Morphine and Opium Poisoning.—If the opiate was taken by mouth, the first indication is to *empty the stomach*. If narcosis has already set in, emetics may act too slowly and the stomach tube should be used. The best *chemic antidotes* are activated charcoal (a tablespoonful or more, stirred into water) or potassium permanganate, 0.5 Gm. per liter by lavage; or orally, 0.1 Gm. in a tumbler of water. Tannic acid is not very effective. The patient should be *kept awake* as far as possible, by talking, hot strong coffee and constant movement, to counteract the lethargy. Reflex stimulants may be employed, such as cold ablutions and the inhalation of ammonia in the form of smelling salts. The patient should be kept *warm*. Metrazol and nikethamide are generally considered the most effective respiratory stimulants in morphine poisoning (Schübel and Gehlen, 1928); Handley *et al.*, 1944, report amphetamine, 5 to 25 mg. hypodermically, more effective. If the breathing shows signs of failing, artificial respiration should be supplied. *Oxygen* inhalation is also useful in the later stages (periodic respiration and anoxemia); it increases the rate of respiration and improves the blood pressure (Clark and Hamill). When the danger is over, the *constipation* which usually follows should be relieved by cathartics and enemas.

Permanganate.—De Busscher (1904, 1905) found this effective in rabbits, even when it was administered three hours after the morphine; it was much less successful with dogs. It was quite ineffective if the morphine was given subcutaneously.

Respiratory Stimulants.—If the morphine asphyxia is interpreted as inattention to the CO_2 stimulus, a removal of this psychic fog would be required to restore permanently the excitability of the centers. No drug has yet been found quite successful for this purpose; the "improvement" is usually confined to an acute and temporary reaction. The discordant conclusions of a few workers may be quoted in illustration: *Voegtlin and Wiggers*, 1918: caffeine, moderate doses, marked improvement; atropine, slight improvement; camphor and epinephrine, doubtful. *Meissner*, 1923 (rabbits): improvement by ether or atropine hypodermically, camphor or cocaine intravenously. No improvement by caffeine, strychnine, epinephrine and aspidospermine. *Schmidt and Harer*, 1923 (dogs and cats): caffeine, marked increase of rate and depth of respiration; aided by digitalis; camphor, variable; atropine, ineffective; CO_2 inhalation, dangerous. *Haskell et al.*, 1924: caffeine, in wide range of doses, unfavorable. In *human subjects*, with respiration depressed by morphine, the increase of minute-volume averages 102 per cent for amphetamine, 37 for nikethamide, 30 for ephedrine, 21 for metrazol, 17 for caffeine (C. A. Handley, 1945).

A general antagonism exists also between morphine and small doses of *cocaine*, especially as regards the effects on temperature and metabolism. Larger doses are synergistic.

Atropine has been used extensively and somewhat indiscriminately in the treatment of morphine poisoning. It may be a dangerous remedy. The most conspicuous antagonisms of the two poisons are on functions of subordinate importance to life, on the pupils, heart rate and secretions. The more important effects on respiration, circulation and metabolism are antagonistic only with certain stages; while more severe grades are actually synergistic. The later paralytic effects of atropine coincide with those of morphine; while in the last stages of morphine poisoning the centers are too greatly depressed to respond to the slow and weak stimulation of atropine. *The usefulness of this antidote exists therefore only if moderate doses of atropine are given in moderate morphine poisoning* (or *vice versa*). This conclusion is supported by several series of experiments on animals. As a practical deduction, the atropine should be given hypodermically in the dose of 1.5 mg. ($\frac{1}{40}$ grain) and should *not* be repeated. It is fair to add that this is not the universal opinion. For instance, Roch, 1907, advises 2 mg., frequently repeated, until the pupils begin to dilate.

Comparison of Morphine Derivatives.—The complex chemical structure of morphine lends itself to innumerable modifications. Some of the more simple are represented in the opium alkaloids. More profound alterations have been produced artificially (including related synthetic derivatives of phenanthrene, carbazol and dibenzofuran), especially by L. F. Small and Mosettig, and investigated experimentally by Eddy and clinically by Himmelsbach and their collaborators, for the Narcotic Addiction Committee of the National Research Council, 1938 to 1941. Such investigations require objective methods and critical interpretation to guard against premature enthusiasm which has often characterized the commercial exploitation of morphine substitutes. The modern investigations have confirmed that unless the changes involve rather profound dislocation of the structure, the actions of the derivatives are qualitatively identical with those of morphine, but they differ in potency and in the relative effects on various organ systems, and these differences are of practical importance. Considerable is now known as to how these correlate with the chemical structure.

Muzzling the *phenolic OH* of morphine by alkyl or aryl groups almost invariably increases the convulsant action and sometimes the toxicity, and decreases all other morphine effects, regardless of what other modifications may be made elsewhere in the molecule. Covering the *alcoholic OH* tends to increase *all* the morphine actions, but generally to shorten their duration. Spatial shifts in the alcoholic OH have irregular effects Saturation of the C 7.8 double bond tends to increase the potency and duration of action (summary, C. K. Himmelsbach, 1941).

It is questionable whether any of the derivatives that have been investigated surpass morphine and codeine in therapeutic adaptability. The distinctive features of the more important agents may be recapitulated.

Morphine produces the strongest narcotic, analgetic, hypnotic and intestinal effects, and has the weakest convulsant action. It causes the greatest derangement of digestion, and, next to heroin, is most liable to induce addiction. It could cover all therapeutic indications. The chief objections are the addiction liability; and to a minor degree the nausea, constipation and occasional idiosyncrasy. If it is properly dosed and spaced it is probably more satisfactory for analgesia than its derivatives (E. L. Lee, 1942).

Opium produces essentially the effects of the morphine it contains (10 per cent), except that the gum and other extractives somewhat delay absorption, and render it unsuitable for injection. The modifications induced by its other constituents are slight and not especially important. This applies also to mixtures of opium alkaloids such as *pantopon* (J. H. Hayman and Fox, 1937; Barlow, 1937). The differences which are reported by various observers are so contradictory that they were probably accidental.

Pantopon (pantopium hydrochloricum), introduced by Sahli, consists of the isolated alkaloids of opium in their natural proportions. Its effects are essentially those of its morphine content. The earlier pharmacologic data on pantopon are reviewed by Barth, 1912. Severe poisoning from 50 mg. is reported by Voigt, 1911. *Artificial mixtures* of opium alkaloids have been proposed, such as the *laudanons* of Faust, 1912, and the *narcophine* of W. Straub and Caesar, 1912, with claims that they represented optimal potentiations of the phenanthrene and isoquinoline alkaloids; but the claims were not substantiated by other workers (Weissner, 1914). *Potentiation of Toxic Action:* Issekutz, 1912, found that the toxicity of mixtures of morphine and its esters corresponds to simple addition, but that mixtures of these with the isoquiniline alkaloids show marked potentiation. This has been confirmed by W. Straub and Caesar, 1912, who claim that doses of narcotine, which are in themselves inactive, double the toxicity of morphine for mice.

Codeine (methyl morphine) is less narcotic and especially less nauseant and constipative than morphine. It is much less likely to induce addiction (chiefly because it gives less abrupt elation, and is expensive and more difficult to inject in large dosage). It should be preferred whenever possible. It is adequate against cough, discomfort and moderate pain, not against severe pain or against diarrhea. Increase of dosage is liable to produce restlessness instead of quiet. Infants are not hypersusceptible (Doebeli, 1911).

Codeine was isolated by Robiquet in 1832, but did not come into general clinical use until 1880. In animals, codeine increases the spinal reflexes distinctly more than morphine (v. Schroeder, 1883), and it may be more toxic through the convulsions. Cl. Bernard reported that it never puts dogs as completely asleep as does morphine, but that the chief difference is in the awakening, which is not accompanied by the fright, hyenoid posture and dementia that characterize morphine recovery in dogs. Frankfurter and Hirschfeld, 1910, claim a greater dilation of the *cerebral vessels* (without rise of blood pressure).

Convulsant Narcotic Series.—In general, the narcotic actions on the brain, on the one hand, and the stimulant action on the cord and medulla, on the other, are in inverse ratio: morphine is the most narcotic and least convulsant, and thebaine the most convulsant and least narcotic, the other morphine esters and the isoquinoline alkaloids being intermediate. Buergi, 1914, places them as: morphine, papaverine, codeine, narcotine, narceine, thebaine. *Thebaine* (dimethyl-morphine) is so markedly convulsant that it may be placed in the strychnine group (Cl Bernard; Stockman and Dott, 1890).

Ethyl-morphine (*dionin*) is used chiefly for its local edemic effect on the conjunctiva. Its central actions are in all respects intermediate between those of morphine and codeine.

Diacetyl-morphine (*heroin*) stands closer to morphine, of which it shares all the disadvantages, without any serious advantages. It is more addictive. Its manufacture and importation are prohibited in the United States.

Dihydromorphinone (*dilaudid*), an artificial derivative, is more potent than morphine, producing equal narcosis with $\frac{1}{5}$ to $\frac{1}{4}$ of the dosage. It is perhaps less nauseant and constipating, but as it is fairly addictive (clinically, King, Himmelsbach and Sanders, 1935; experimentally, E. J. Stanton, 1936), its usefulness is questionable (review, N. B. Eddy, 1933). The dosage averages about a fifth that of morphine; for cough, 1.3 mg., $\frac{1}{40}$ grain; as analgetic, 2 to 2.5 mg., $\frac{1}{32}$ to $\frac{1}{24}$ grain. The action is somewhat less lasting.

Dilaudid was introduced clinically by Krehl, 1926, after a rather brief pharmacologic study. The superiority as to digestive disturbance (Gottlieb, 1926) may be questioned. King *et al.* found it clincially just as constipative as morphine; Krueger and Holmes, 1934, report vomiting in dogs and obtained the same effects as with morphine on Thiry-Vella fistulas in unanesthetized dogs. Like morphine, it is deliriant to cats (J. Schmitt, 1929) and excitant for horses, and somewhat for dogs (F. Oehme, 1928).

Methyl dihydromorphinone (*metopan*) is the most promising of the derivatives so far developed by Small and Mosettig. Its nauseant action is less, its toxicity greater, its analgesia somewhat more potent than with morphine and distinctly more persistent, and tolerance seems to be less readily acquired (N. B. Eddy, 1938). It satisfies the craving of morphine addicts and is, therefore, potentially addictant, but there is probably less danger since tolerance is not readily acquired, so that the dosage need not be increased. It is especially suited for controlling chronic pain, like that of cancer, with about half the dosage of morphine. It is less suitable as preanesthetic sedative, being less somnifacient, and sometimes produces respiratory depression (E. L. Lee, 1942). *Dihydrodesoxymorphine* (*desamorphine*), one of the derivatives devised by Small and Mosettig, appeared to have favorable therapeutic ratios, its toxicity (in animal experiments) being four times that of morphine, analgetic potency ten times, gastro-intestinal action, only $\frac{1}{20}$ (Small and Eddy, 1934). However, the action lasts only three-fourths as long as morphine, requiring frequent administration, and this increases the addiction liability. It is adequate for preanesthetic sedation, but its advantage is questionable (Lee, 1944). *Eukodal* was reported by Dixon as especially addictant and dangerous.

Synthetic phenanthrene derivatives acquire marked analgetic actions, especially by substitution of OH and NH_2 groups. Some derivatives synthesized by Mosettig cause a veratrine-like prolongation of relaxation in muscle (Small *et al.*, 1938). In Straub frog hearts, they disturb the ventricular rate without changing that of the auricles. The block is not modified by atropine (E. E. Nelson, 1939).

Other Constituents of Opium.—The isoquinoline alkaloids are discussed under Papaverine (see Index).

Meconic Acid has no effect in the doses which would be administered in opium. Larger doses produce narcosis, muscular fibrillation, medullary convulsions, diarrhea, curare action (Barth, 1912).

Regulations for the Prescribing of Narcotics.—In the United States, physicians who prescribe narcotics must be registered with the Department of Internal Revenue, and comply with regulations furnished by that department, which are designed to restrict the illegitimate supplies of these drugs. Severe penalties attach to violations.

Form of the Prescriptions.—These are written on ordinary blanks, *not* on special forms. They must contain: (*a*) The full name and address of the patient; (*b*) the full name, address and registry number of the prescriber, and (*c*) the date of issue. The signature must be in ink or indelible pencil. Narcotic prescriptions can not be given over the telephone. They can not be refilled or partly filled. A physician is permitted to prescribe only for patients whom he attends in person.

Prescriptions for continuous use must have further inscriptions explaining the facts or the "exception" under which they come; for incurable diseases they may be marked, "Exception I, Article 117"; if for addicts under the special restrictions provided in "Exception II, Article 117" (Treasury Decision 342).

Scope of the Regulations.—These include opium or coca leaves, or any compound, manufacture, salt or preparation thereof, even though they are not narcotic, for instance apomorphine and papaverine. Synthetic local anesthetics are not included.

Exemptions.—Certain articles are specifically exempted and may be prescribed without formality or bought without prescription, for legitimate uses. The more important of these exemptions are: Tr. Opii Camph.; Mist. Opii et Glycyrrh. Co.; Lotio Plumbi et Opii and all preparations for application on the skin, if they contain ingredients that would render them unfit for internal use.

Conditions against Which Narcotics May be Prescribed.—These include, (*a*) all acute conditions, at the discretion of the prescriber; (*b*) incurable diseases (cancer, advanced tuberculosis, etc.) under certain restrictions; (*c*) the treatment of addicts, narrowly restricted.

Dispensing and Administration of Narcotics by Physicians.—Subject to the preceding paragraph, physicians may personally administer single or occasional doses away from their office, without formality or record. Otherwise a record must be kept, in the manner provided in the regulations.

PREPARATIONS—OPIUM

***Opium,** U.S.P. (*Meconium,* Thebaicum), is the dried milky juice exuding from the incised unripe seed capsules of the poppy, Papaver somniferum. Brown masses or powder of peculiar odor and bitter taste. Contains a number of alkaloids, the most important being morphine (not less than 9.5 per cent). Prescribed as *Powdered Opium,* U.S.P. (Opium Pulveratum), a light brown powder, yielding 10 per cent of anhydrous morphine. Dose, 0.03 to 0.2 Gm. ½ to 3 grains. The usual percentage of the other alkaloids in opium is: Codeine, 0.2 to 0.7 per cent; Thebaine, 0.15 per cent; Narceine, 0.02 to 0.7 per cent; Narcotine, 1.3 to 10 per cent; Papaverine, 1 per cent (absent in some sorts; Van Italie and Kerbosch, 1910). The development of these alkaloids in the growth of the plant is interesting (Kerbosch, 1910). Opium also contains a number of other minor alkaloids: meconic acid (2.5 to 5.5 per cent), lactic acid, gums. resins, fats, odorous principles. No starch or tannin. The most important preparation is **Opium Tincture,** U.S.P. (*Laudanum*), 10 per cent of opium or 1 per cent of morphine. Miscible with water or alcohol. Dose, 0.6 cc., 10 minims. The ***Camphorated Opium Tincture,** U.S.P. (*Paregoric*), is a weak (0.4 per cent of opium) aromatized preparation, forming a milky mixture with water. It is used especially against diarrhea and for children. Dose, 2 to 4 cc., ½ to 1 drachm. Four cc. contain 16 mg., ¼ grain, of opium or 1.6 mg., 1/40 grain, of morphine, U.S.P. (20 mg., ⅓ grain, of opium or 2 mg., 1/30 grain, of morphine, B.P.). ***Compound Mixture of Opium and Glycyrrhiza,** U.S.P. (*Mistura Opii et Glycerrhizae Composita; Brown Mixture*), is used as sedative expectorant. Ten cc., 2½ drachms, of this mixture contain 1.2 cc. of paregoric or 5 mg., 1/12 grain of opium; and 2.5 mg., 1/24 grain of tartar emetic, also a little Sp. Aeth. Nitrit. It is needlessly complex, but the tartar emetic effectively prevents increase of dosage. Dose, 4 cc., 1 drachm, U.S.P.

Pantopon (*Pantopium Hydrochloricum*) is a purified mixture of opium alkaloids, containing 50 per cent of morphine. Sol. in water. Dose, 5 to 20 mg., 1/12 to ⅓ grain, by mouth or hypodermically.

Dover's Powder, U.S.P. (Pulvis Ipecacuanhae et Opii), containing 10 per cent each of ipecac and opium, has only historical interest. It was introduced by Thomas Dover, 1742, as a diaphoretic in gout. Dose, 5 to 10 grains.

PREPARATIONS—MORPHINE

***Morphine Sulfate,** U.S.P. (Morphinae Sulfas), *Morphine Hydrochloride,* B.P., and other morphine salts occur as odorless, bitter, white feathery crystals. They are incompatible with alkalis, tannin, iodides and other precipitants of alkaloids. The sulfate is soluble in 16 parts of water (the hydrochloride in 17.5; free alkaloid in 3340 parts). The B.P. lists a 1 per cent Liquor Morphinum Hydrochloride. Average dose, 10 mg., ⅙ grain. The rectal dose is the same; the hypodermic about two-thirds of the oral. Maximal single dose, 30 mg., ½ grain. The usual dosage for special indications is: 2 to 5 mg. for cough and diarrhea; 5 to 15 mg. for pain and insomnia; 10 mg. for preanesthetic and in hemorrhage; 15 mg. in dyspnea, colic, peritonitis. Solutions are said to decompose rather readily when heated above 60° C. (Welmans, 1908). Moulds in solutions of morphine often come from the cork. They are prevented by adding a small piece of camphor (Norgaard, 1920). *Morphine Sulfate Tablets,* U.S.P.; the usual sizes contain 5, 8, 10, 15 and 30 mg. (1/12, ⅛, ⅙, ¼ and ½ grain). *Morphine Injection,* U.S.P., a morphine salt in water for injection; usual sizes 10, 15, 20 and 30 mg. (⅙, ¼, ⅓ and ½ grain) in 1 cc.

The *dosage of opiates for children* is best adjusted to the weight: with children above ten months, the weight (in pounds) is divided by 150; below ten months, by 300. The adult dose is multiplied by the fractions thus obtained (Doebeli, 1912). H. E. Irish, 1935, concludes that the effects on infants are simply proportional to the body weight.

PREPARATIONS—MORPHINE DERIVATIVES

These resemble morphine salts in physical characteristics and incompatibilities.

***Codeine Sulfate,** U.S.P., is soluble in 30 parts of water (*Codeine Phosphate,* soluble in 2.5 parts, is also official in the U.S.P.). Dose, (15 to 60 mg. ¼ to 1 grain). *Codeine Phosphate Tablets,* U.S.P., and *Codeine Sulfate Tablets,* U.S.P.; the usual sizes contain 15, 30 and 60 mg. (¼, ½ and 1 grain).

Dihydromorphinone Hydrochloride, U.S.P. (*Dilaudid*), N.N.R., differs from morphine by the substitution of a ketone group for one of the hydroxyls and the removal of the adjacent double bond by hydrogenation. Soluble in water (1 Gm. in 3 cc.). Marketed as tablets of 2.5 mg.; hypodermic tablets of 1, 2, 3.2 and 4 mg., and ampuls of 2 mg. in 1 cc. Dose, as sedative and analgesic, 2.5 mg. orally or 2 mg. hypodermically. In mild pain or cough, 1.3 mg. by mouth. *Dihydromorphinone Hydrochloride Tablets,* U.S.P.; the usual sizes contain 1, 2 and 4 mg

Ethylmorphine Hydrochloride, U.S.P. (*Dionin*), is soluble in 10 parts of water. Dose, 15 mg., ¼ grain; locally, 10 to 20 per cent. *Diamorphine Hydrochloride,* B.P. (*Heroin,* Diacetyl morphine), is soluble is 2 parts of water; dose, 2.5 to 8 mg , 1/24 to ⅛ grain.

OPIATE ADDICTION

Opium, morphine and its derivatives, especially heroin, and to a less extent cannabis and cocaine, may lead to serious addiction, based on the euphoria which they produce, the feeling of well-being, relief and contentment, of stimulation and freedom of imagination, and of ease and facilitation of mental effort. These grateful actions vary in kind and degree for different individuals, as also the will and the ability to resist the temptation, and therefore all do not fall victim to them with equal readiness; adolescents, women, emotionally unstable, neurotic and dissipated individuals are especially in danger if they become acquainted with the effects of these drugs. The greatest number begin their addiction at the age of 20 to 29 years; next come the adolescents; few start after fifty (Pescor, 1938). Drug addiction is generally a symptom of psychologic maladjustment, "an attempt to escape the unhappiness of a losing battle with life." The elation itself is largely the relaxation afforded by relief from an incubus and is therefore proportional to the burden or boredom. The majority of the heroin and cocaine addicts belong to the criminal classes, thrill-seekers and hedonists, who begin the use through curiosity or dissipation (Kolb and Ossenfort, 1938; Treadway, 1930; J. R. Rees, 1932; Felix, 1939); next comes the medicinal use, especially against pain (U. S. Treasury Report, 1931); and next perhaps those who are tempted to occasional use in times of stress and fatigue. The expense and the difficulty of obtaining the drugs have largely eliminated the casual users. Before the restriction of the Harrison Narcotic Law, "patent medicines," cough, consumption, diarrhea, and catarrh "cures," were responsible for many cases. Infants have become addicted through paregoric and "soothing syrup." Addiction in pregnancy produces addiction phenomena, tolerance and withdrawal symptoms in the newborn, in animals as well as in the human (K. Rai, 1937). Physicians must be on their guard when prescribing these drugs in acute conditions. Their frequent use for minor discomforts leads easily into temptation. The continued administration is justifiable only in hopeless painful diseases, such as cancer. They are detrimental rather than helpful to the cure of tuberculosis. It is safest to assume that daily use will soon lead to addiction—ten days may suffice in susceptible individuals, and twenty to twenty-five days in those with normal emotional stability (Hubbard, 1920). All morphine derivatives may do so, including codeine, although this is unusual in practice. The liability is greater with the drugs and methods that give the promptest euphoristic "kick." It is therefore greater with intravenous than with hypodermic injection, and with this more than with oral use; with heroin more than with morphine, and with this more than with codeine. Frequent repetition is more habituating than larger doses farther apart. Increase of dosage is especially dangerous.

Prevalence of Opium Addiction.—While the therapeutic use of opium goes back beyond Hippocrates, its habitual use seems to be of more recent origin and was at first confined to the Orient. The first authentic records fall in the beginning of the sixteenth century. The Mohammedans learned it through the conquest of India. Their acquaintance with Cannabis indica was much earlier. Its introduction into Europe and America is of modern date. In the United States it was rare until after 1860. It increased greatly until it was checked by the Harrison antinarcotic act of 1915, which makes addiction illegal, inconvenient and expensive. The average addict now uses less than a grain of morphine per day (Anslinger, 1940). Further improvement in the narcotic situation depends on the success of police in dealing with smugglers and illegitimate dealers; on a popular understanding of the seriousness of starting the addiction; and on methods of treating confirmed addicts.

Accurate appraisal of the *number of opiate addicts* is not possible. Official estimates place the proportion in 1877 as 1:400 of the general population in the United States; in 1922 as 1:1000; in 1938 as 1:3000 (Anslinger, 1940), but it may not be more than 1:10,000, which is about the same as in Germany. The proportion is highest in the urban centers, and among young people. Nearly half the addictions start before twenty-four years of age (W. L. Treadway, 1930). Physicians have a considerably higher ratio; estimates run as high as 1 per cent (Anslinger; for Germany, Kurt Polish, 1931).

By far the largest proportion of drug habitués start as abnormal personalities who become addicted by choice, through associates or curiosity. Of about a thousand patients at the Lexington Narcotic Hospital, over half had a hedonistic personality, another fifth had inebriate histories, nearly a fifth were frankly psychoneurotic and psychopathic, and less than 4 per cent could be classed as normal (Pescor, 1939).

The legal consumption of opiates in the United States shows a distinctly favorable trend. Between the years of 1931 and 1935, the per capita annual consumption of the more addictant alkaloids decreased 20 per cent (from 2.8 to 2.3 grains, expressed as opium), while that of the less addictant codeine and dionin increased 2.3 per cent (from 2.85 to 3.5 grains, as opium). *Cocaine* decreased 13 per cent (from 6.84 to 6.06 grains) (U. S. Treasury Report, 1935). The total legal consumption in the United States in 1931 was (in ounces), codeine, 164,000; morphine, 90,000; cocaine, 32,000 (U. S. Treasury Report, 1931).

Forms of Opium Habit.—The drugs are introduced by all possible channels: by the mouth, hypodermically, intravenously, by smoking, by suppositories; and heroin, like cocaine, by snuffing. The effects are essentially similar. Addicts in the United States chiefly use heroin by snuffing, and this and morphine hypodermically or intravenously (since 1920), probably because of the more abrupt and therefore more noticeable response. Those who have become accustomed to injections do not readily change to the oral use. The needle may be attached to a medicine dropper; sometimes the alkaloids are rubbed in the scarified skin. The satisfaction of addiction involves something more positive than the mere suppression of physical discomfort. A "stabilized" dosage, which suffices to protect completely against active withdrawal symptoms, does not achieve the emotional tranquilization and "lift" for which the patient strives, and leaves a feeling of dissatisfaction (Himmelsbach *et al.*, 1940).

Smoking.—Smoking opium (chandoe) is prepared by the Chinese by a complicated process of roasting and repeated extraction and evaporation. Its morphine content is about the same as that of ordinary opium. Pott, 1912, and Nakajima and Kubota, 1927, proved that morphine is indeed the active constituent of the smoke. It has been said that Orientals are less injured by opium; but this is mainly because smaller quantities are consumed in smoking with longer intermissions. The hypodermic method has now become more popular, and with it the Chinese present the same phenomena as Europeans (A. S. Rochester, 1909). The Chinese government made serious and fairly successful efforts to suppress the opium evil. In *India*, where the use of opium was very prevalent but is rapidly diminishing, the dose is generally kept small, three to five grains of opium per day by mouth, which does not produce marked addiction phenomena. Those who take larger doses become addicted like Europeans (R. N. Chopra, 1928).

Addiction by Heroin.—All morphine esters may be presumed capable of producing addiction, but practically the difference between them is large. Heroin is more powerful than morphine, and the addiction is consequently more easily acquired and more difficult to break. It also causes more acute fatalities. Although its sale is prohibited in the United States, a considerable amount is smuggled, and the Atlantic seaboard addicts use it more than morphine (Treadway, 1930). The League of Nations Expert Committee (J.A.M.A.; *97:* 273, 1931) agrees that the objections to heroin are greater than its field of usefulness.

Addiction to codeine is relatively rare and generally easily broken; or else the patients go over to the other more effective and cheaper alkaloids (L. F. Davenport, 1938). Really narcotic doses would be inconvenient to administer, and disproportionately expensive, so long as its sale is restricted. If restrictions were removed so that it could be procured in unlimited quantities, the situation would become different. Large quantities were smuggled from Canada when its sale there was unrestricted (Commissioner of Narcotics, Report, 1936).

With medicinal doses of codeine, the psychic effects are so slight that they would scarcely be recognized by the patient; there is therefore little temptation to increase the dosage; and the codeine can be withdrawn without notable reaction. Relatively large doses over long periods appear necessary to establish addiction. Experienced addicts do not easily take to codeine, for while it removes the discomfort of the acute withdrawal symptoms (with about 5.2 times the dosage of morphine), it "leaves them cold," they do not achieve the euphoria, do not receive the "kick," even when the dosage is raised so as to produce narcotic confusion (Himmelsbach, Andrews *et al.*, 1940). Practically no fatalities from codeine are on record, and the fatal dose is not known. Small doses may cause symptoms if there is idiosyncrasy. *Derivatives of codeine* with more marked narcotic action produce addiction ("*eukodal*" and "*parakodin*"; Biberfeld, 1920 and 1921; P. Wolff, 1928). The acquired tolerance does not extend to the convulsant action.

Of fifteen *morphine derivatives* tested, all proved effective in satisfying the craving and other symptoms of morphine withdrawal in addicted patients and therefore possess addiction liability. Complete satisfaction occurred with dihydromophine, desomorphine and desocodeine; incomplete with metopon. Changes in the chemical structure alter the addiction liability in the same direction as other morphine actions, but perhaps not to the same degree. Clinically (Himmelsbach, 1941) as well as in animals (Small, Eddy *et al.*, 1938), methylation of the phenolic OH reduces the potency and prolongs the action. Replacement of the alcoholic OH by H or O increases the potency and shortens the action. Saturation of the C 7-8 double bond tends to increase both potency and duration. Isoquinoline derivatives, including perparine, are not addicting (Himmelsbach, 1939).

Effects of Opiate Addiction.—Continued use of opiates leads to the development of tolerance, to diminished response to its narcotic actions or, perhaps more correctly, to functional adaptation to the "fog," so that progressively larger doses must be used to secure the narcotic effects. Along with this, a craving for these effects develops, constituting the addiction; and if this craving is not satisfied, withdrawal symptoms set in, largely psychical but partly physical, which increase for several days, and then decline, so that the subject returns to a quasi-normal condition. Qualitatively, this is much like the course of other habitual indulgences, such as alcohol, tobacco, coffee or chewing gum; but the craving is so much stronger and the withdrawal reactions are so much more violent, that it is generally believed that a "physical dependence" is created. This is probably true, although it is difficult to prove and the concept is not very clear. However, animals (even completely decorticated dogs, A. Wikler, 1946) also develop the phenomena of opiate addiction, including tolerance, craving and withdrawal symptoms. The differentiation of "addiction" from "habit," and this from "habitual use" of a drug, is not sharply defined. Addiction and habit both involve an active desire, a hunger for the drug if it is withdrawn; they are generally held to differ in the degree of the acute ill effects of withdrawal, which are more serious with addiction. This distinction is of course arbitrary. "Tolerance" is not an essential part of addictions or habits, although it is frequently the case that experience dulls the reaction so that progressively larger doses must be used to produce equivalent effects.

Habituation of cold-blooded animals has not been adequately studied. Frogs are said to become hypersusceptible with repeated administration. An interesting reaction has been described for gold fish (not minnows): when placed in a "graduated tank," they rapidly develop preference for water containing alcohol, morphine and certain other substances (Shefford, 1918). However, this is probably a sensory skin phenomenon, and not analogous to the psychic craving of human drug habits

Acquired Tolerance.—The continued use of morphine or its derivatives leads to the gradual development of considerable tolerance to the narcotic and toxic effects. This starts before addiction becomes confirmed. Addicts who desire euphoria are therefore driven to the use of ever-increasing doses, sometimes 10 or 20 times more than would be fatal to an unaccustomed individual. The tolerance is never absolute, and accidental or intentional overdosage is a frequent cause of death for morphinists. Patients who take morphine as a stimulant may not increase their dosage beyond a definite, more moderate amount, soon ascertained by experience, and find it possible to resist or discontinue temporary increases beyond this point (Bishop); precisely as some smokers keep themselves on a fairly definite allowance while others are constantly increasing their indulgence. The daily consumption of morphine or heroin ranges between 0.3 and 4 Gm.; it is generally above 0.4 Gm. and would usually be between 1 and 2 Gm., if supplies were obtainable (McIver and Price, 1916; Kolb and DuMez, 1924; Wholey, 1912, heroin). Even larger doses are claimed by patients; but their statements are often unreliable, since they are made in the hope that the drug will be withdrawn more gradually. The tolerance diminishes if the drug is discontinued, but can be reacquired within ten days (Biberfeld, 1917). Some degree of tolerance persists indefinitely, so that the normal doses of morphine depress the pain threshold much less than with normal individuals (H. L. Andrews, 1943).

Mechanism of the Tolerance.—With the possible exception of rabbits (Van Dongen, 1915), all mammals and birds that have been tried acquire tolerance readily (Cloetta, 1903), and these have extended the possibilities of experimentation (review, Tatum and Seevers, 1931). The tolerance does not extend to all the actions, but only to those that involve conscious or subconscious psychic activity, including the respiratory center, which indeed acquires the highest tolerance (in dogs, 1800 times the initial minimal effective dose). Next comes the tolerance to narcosis, and then in descending order, defecation, emesis, and pupils (van Egmond, 1911). Cats also acquire some tolerance to the deliriant action (H. Gold, 1929). No tolerance is acquired by the cardiac vagus center, by the convulsive centers (Langer, 1912), or by the peripheral actions, the skin reaction (Pilcher and Sollmann, 1914) or the intestinal tonus and constipation (G. H. Miller and Plant, 1928). The undiminished response of the unconscious functions indicates that the tolerance of the conscious centers is functional, and not due to destruction or "antitoxic" inactivation of the alkaloid. The habituation may be interpreted as an education of the conscious centers to discount the morphine fog; possibly reinforced by the central hyperirritability which is an after-effect of morphine, conspicuous in the withdrawal symptoms.

The theory of hyperirritability was advocated by Tatum and Seevers, 1930, on the basis that monkeys with abstinence symptoms are hypersusceptible to cocaine excitement; and that animals habituated to morphine are tolerant not only to morphine derivatives, but also to depressants of other groups, such as barbital. The latter, however, is apparently not beyond the limit of error, for discordant results have been reported by other workers, also with chloral and scopolamine (Plant and Pierce, 1928). In any case, it would not be strange that adaptation to the morphine fog could be applied to barbiturate fog. On the other hand, habituation of cats to the deliriant action of morphine could not be explained by hyperirritability; nor the cross tolerance and emetic action of morphine and apomorphine, described by Tui, 1931; nor the fact that some degree of tolerance may persist for a considerable time. Indeed, C. F. Schmidt and Livingston, 1933, found that a single large dose of morphine renders dogs resistant to the narcotic effects of subsequent small doses. An erroneous hyperexcitability theory had been proposed by Marmé in 1883. He believed that morphine is transformed in the body into *oxydimorphine* (dehydromorphine), to which he attributed actions precisely the reverse of those of morphine. It would thus explain both the tolerance and the abstinence symptoms. Donnath, however, 1886, Marquis, 1896, and Schmidt and Livingston, 1933, showed that oxydimorphine is not formed; and, moreover, the properties of this substance do not agree with the assumption of Marmé. Another theory which may be dismissed is the formation of an *antitoxin.* Hirschlaff, 1902, claimed that the serum of habituated animals is protective; but his experiments are discredited by the negative results of Morgenroth, 1903, of Cloetta, 1903, and of Pellini and Greenfield, 1920, 1924. The blood of habituated animals (or man) contains neither protective nor toxic substances. *Increased destruction* of the alkaloids by habituated animals was reported by several workers, first for morphine by Faust, then for heroin by Langer, but later investigators found the destruction rate the same as for nonhabituated animals (Hatcher and Gold, 1929; Plant and Pierce, 1933), so that the apparent differences may lie within the experimental error. In any case, the destruction is so much slower than the absorption of the alkaloids (Cloetta, 1903; Ruebsamen, 1908) that it could not play an important role in the tolerance.

Psychic Effects of Opiate Addiction.—The immediate effects of morphine are essentially the same as in unhabituated individuals; but the response varies quantitatively, and somewhat qualitatively, because of acquired tolerance and of the imminence of "abstinence symptoms." These differ as regards the occasional opiate debauchee, and the steady addict. The *occasional user*, for instance the opium smoker, usually pushes the dosage to the toxic point, and thus obtains the dreams and the deep sleep. The steady consumer does not carry the dosage to that stage; partly because he has acquired tolerance; partly because of the side effects; and partly because it would be impossible for him to work while under the toxic influence. Most patients whose addiction started with the therapeutic use of opiates have never experienced the imaginative toxic effects, but only the analgesia and euphoria; their first recognition of the addiction dates often from the withdrawal symptoms. *Confirmed addicts* generally use opiates rather as stimulants, or as a means of escape from the intense discomfort, nervousness, depression and violent craving that follow the withholding of the accustomed dosage. These are analogous to intense hunger or thirst, and increase in intensity for several days to a degree beyond the unassisted strength of most patients, especially when the means of relief, further dosage of the opiates, is available to them (E. L. Bishop, 1913, 1920).

Apart from the dependence on the daily allowance of opiate, the imminence of craving and withdrawal symptoms when this is withheld, and the fear of detection, the condition of the addicted individual is quite normal even after long addiction to large doses (A. B. Light and associates, 1930) except for some tendency to constipation and alternations of moods of irritability and placidity or apathy, and corresponding changes in the pupils, coincident with the intervals of administration. The skin shows needle marks, and perhaps abscesses, if the drugs were injected. Intravenous injection with a common syringe has transferred *malaria* (Faust, 1933) and syphilis. A hundred fatal malarial infections from this source were reported in New York within four years. *Definite diagnosis* rests on failure to respond to therapeutic doses (15 mg., $\frac{1}{4}$ grain), and on the occurrence of withdrawal symptoms when access to the drug is prevented. It is also feasible to demonstrate morphine in the urine.

If the patient has difficulty in obtaining the drug, the picture is dominated by the withdrawal symptoms and their dread, and often by the consequences of the economic distress, especially in old cases which require large quantities of the drug. Such patients are emaciated and anemic, from starvation and bad hygiene. The skin appears cachectic, waxy pale, dry and rough; the nails and teeth are also often diseased from neglect. If the food is not restricted, the patients may be well nourished. The *basal metabolism* may have rather wide fluctuations, presumably because of the alternation of irritability and apathy. The abnormal life of extreme addiction is likely to accentuate the *neurotic tendency* which is usually inherent in these individuals. The *sexual functions* are often diminished (amenorrhea, functional impotence), chiefly by malnutrition, but libido is not completely abolished until the daily dosage of morphine reaches 1 to 2 Gm., 15 to 30 grains (Pescor, 1938); they generally return after withdrawal (Wholey, 1912). The estrous cycle and fertility of rats are not affected by morphine or cocaine addiction (H. B. Myers and Flynn, 1928; A. Forster, 1928).

Opiate debaucheries doubtless accentuate the weaknesses of *moral character* from which they originate. They tend to make their victims slothful, apathetic and unreliable. They do not lead to the more active crimes, as cocaine may, except in so far as crime may be necessary for obtaining the drug. (The relations of narcotic addiction and crime are reviewed by P. O. Wolff, 1943.) Those of inherently good character, if they take the drug solely to ward off the intolerable depression, are not so seriously affected. Their will power and self reliance are weakened, as by any other enslaving self indulgence, and the agony of drug deprivation drives them to deception and more serious crimes when their supply is threatened; but aside from this, their character and mental faculties remain practically unchanged. This is certainly the case in the legitimate continued use of opiates, as in cancer. A large part of the traditional depravity of the addicts exists in the minds of the public more than in life. This pariah attitude makes it more difficult for the addicts to lead a normal existence, and thus tends to drive them into the vices of which they are accused (Bishop). Drug addicts are patients with a nervous disease. Like other mentally ill patients, they must be treated with firmness, but also with sympathy and kindness.

The phenomena, as studied in *planned re-addiction* of former habitués, include *increase* of body water, erythrocyte sedimentation rate, carbohydrate intake, and of nocturnal activity; and *decrease* of body weight, pulse rate, basal metabolic rate and diastolic blood pressure. Respiration generally remains subnormal during addiction. *Efficiency,* as judged by psychologic tests, is lowered by slowing of responses, although not sufficiently to disrupt working efficiency seriously. Psychical stimuli produce less disturbance. Slight withdrawal symptoms begin within three weeks unless the dosage is progressively increased (E. C. Williams and Oberst, 1946; R. H. Brown, 1946).

Brain Potentials.—These show a high alpha index during addiction, persisting during and sometimes after withdrawal. Delta activity is present in severely addicted subjects, and is greatly reduced after withdrawal (H. L. Andrews, 1941).

Differential Action on Sensations.—In individuals not accustomed to morphine, this diminishes pressure and pain sensations about equally. Heat and cold appreciation are not impaired. The potency against pain declines with habituation, but that against pressure is not decreased. The analgetic potency returns on withdrawal. The discrepancy between the appreciation of pain and pressure therefore reflects the degree of active opiate addiction (P. Hoefer, 1929).

Suggestibility.—When tested by the "postural sway" suggestion, individuals addicted to opiates are distinctly more suggestible; this fades to normal on withdrawal (V. H. Vogel, 1937).

Hyperglycemic Tendency.—The blood sugar level is normal (except early in addiction, when it is high; Asho-Ro, 1934; H. Jacoby, 1930), but dextrose administration produces marked alimentary hyperglycemia in addicted individuals, both human and dog, levulose only in the human and not in the dog. Both tolerate high doses of insulin without hypoglycemia. It is suggested that this is related to liver pathology (Anton and Birk, 1934). On the other hand, the hyperglycemia reaction which follows the injection of morphine in normal dogs disappears after repeated injections, in two to four days (Pierce and Plant, 1928).

Water Balance.—In a series of addicts with marked physical dependence, the blood was found hydrated during addiction, less hydrated during withdrawal, returned to the addiction level after recovery from the withdrawal symptoms and later remained at the normal level (E. G. Williams, 1939). It is practically normal in moderate addiction, including the blood count (and blood picture) (Morat, 1911, human; Pierce and Plant, 1928, dogs). Barbour *et al.,* 1929, report slight hydration of the blood in dogs. They also found distinct hydration of the blood and tissues early in the addiction of rats by large doses of morphine, but this tended to return to normal as the addiction progressed. Rats addicted to morphine for six weeks develop moderate tissue edema, especially in the skin. This tends to disappear on the first day of withdrawal, but to recur during the second and third day. Parathyroid injections together with high calcium diet increase the water loss on withdrawal, tend to prevent the relapse, and diminish the withdrawal symptoms (Detrick and Thienes, 1941).

Metabolism in Animals.—Rats subjected to chronic morphinism, or to heroin or codeine, may be better nourished than the controls, probably because they are less active (Sollmann, 1924). They behave somewhat like thyroidectomized animals, showing a decrease of gas metabolism, increased respiratory quotient and increased sensitivity to oxygen deprivation (F. Hildebrandt, 1922). Excessively prolonged administration of morphine produces increased metabolism and progressive emaciation (Hildebrandt, Sollmann). The basal metabolic rate of addicted dogs is increased by about 10 per cent (Barbour *et al.,* 1939).

Effectiveness of Cocaine Anesthesia.—It has been claimed that the susceptibility of the cornea to local anesthesia is abolished during morphine addiction in humans and animals (Amsler, 1933), and that it is restored on dis-habituation, and also by milk injection even when the morphine is continued (rabbits, Bertschik, 1934). Others have failed to confirm the insusceptibility (Oelkers, 1935), and it did not exist in a man under active morphine addiction (Himmelsbach).

Withdrawal Symptoms.—The withdrawal of opiates from those habituated to their use is followed by craving and a train of severe nervous symptoms; the intensity varies with the individual, increasing with the stabilizing dosage (H. L. Andrews and Himmelsbach, 1944), the duration of the addiction, the dosage used, the rapidity with which the drug is withdrawn and being inverse to the general resistance, vigor and will power of the patient, much as with other ingrained habits. (The Philadelphia Committee, Light *et al.*, 1930, and King, Himmelsbach and Saunders, 1935, report comprehensive clinical studies.) In the early stages of addiction, withdrawal results in more or less restlessness, weakness and depression. These are endurable, and disappear in a few days if the drug is withheld. With more confirmed addiction, the symptoms take in general the following course: *Irritable temper*, uneasiness; *spasmodic yawning* and *sneezing*, lacrimation, coryza and hoarseness; *restlessness* and *weakness;* sweating, hot flashes and chills; leukocytosis (generally in the human; pronounced in dogs, Pierce and Plant, 1928); *severe functional digestive disturbances*, refusal of food and drink; vomiting and diarrhea, *concentration of the blood* and negative water balance, resulting in *loss of body weight* and shrunken skin; "*cramps*," muscular twitchings and violent pain in the legs, sometimes in the arms and abdomen; *headache* and other neuralgias; complaints of extreme *weakness*, tremors; *persistent insomnia*, excessive irritability, often culminating in hysteric attacks in women or in *delirium* and acute mania, sometimes suicidal; marked pilomotor activity. The most dangerous phenomenon is sudden circulatory *collapse*, starting with irregular and weak pulse, alternately fast and slow, cold sweat, general prostration, rarely ending fatally with heart failure. This collapse, if severe, demands the prompt injection of 10 mg. ($\frac{1}{6}$ grain) of morphine, which generally relieves all symptoms completely within five to thirty minutes; except that the concentration of the blood, and the cramps which probably depend upon it, may last for several hours until the water balance is restored.

With the abrupt and complete withdrawal, the symptoms are generally moderate on the first day, severe on the second and third, moderate on the fourth and fifth, mild on the sixth and seventh and absent on the eighth day. After ten to fourteen days, the patient generally begins to gain weight and appears well, although insomnia may persist for some time.

This grading is by the classification of Himmelsbach, 1936, as follows: *Mild grades* are characterized by yawning, lacrimation, rhinorrhea, sweating; *moderate grades* by gooseflesh, mydriasis, anorexia, tremor; *marked grades* by insomnia, restlessness, air hunger, rise of blood pressure (11 to 15 mm.), rise of basal metabolic rate, hyperglycemia, slight hyperpyrexia (0.5° C.); *severe grades* by exaggeration of the preceding, emesis, diarrhea and weight loss exceeding five pounds in twenty-four hours. Collapse is rare.

The withdrawal symptoms are largely, perhaps entirely, psychical, of the same nature as hunger, thirst or other intense craving, *i. e.*, quasi-hysterical reactions to a balked, imperative desire, more or less beyond volition. Those who have had much experience with treating addictions generally believe that there is also a "physical" dependence characterized by the physical withdrawal symptoms, which differentiates opiate from other addictions. The symptoms are stronger, however, if the patient expects, perhaps unconsciously, to arouse sympathy, and thus obtain the relief of the drug; they are practically absent if the patient is rendered delirious by scopolamine (Wagner and Riewel, 1905). Animals also react more or less to withdrawal (Plant and Pierce, 1928), with individual differences (Collins and Tatum, 1925; Sollmann, 1924), probably as they would to hunger and thirst

Intestinal Disturbances.—Roentgenologic examinations by Nishigiski, 1926, showed increased tone and peristalsis of the small intestines, or irregular progress of the contents, and spasticity of the large intestines; they are relieved by morphine, but atropine has little effect. Similar diarrheic withdrawal phenomena were observed by G. H. Miller and Plant, 1926, on dogs with permanent intestinal fistula. *Anorexia* is probably due to the malaise. In marked grades it decreases the caloric intake by 40 to 55 per cent.

The basal metabolic rate is increased in clinical withdrawal 21 to 30 per cent in marked grades (Himmelsbach), perhaps chiefly by the nervous unrest. It may exexplain the slight *hyperpyrexia*. In animals, Barbour *et al.*, 1930 and 1935, found the basal metabolic rate increased during withdrawal. Sudden withdrawal of morphine causes a marked temporary *rise of blood sugar* by 41 to 55 mg. per cent in marked clinical grades (Himmelsbach; Philadelphia Committee). It occurs also in rabbits (Asho-Ro, 1934) and dogs (Cohen). Clinically, the withdrawal illness is uniformly accompanied by *dehydration*, due chiefly to refusal to drink, together with the profuse sweating and diarrhea. It is partly responsible for the *loss of weight* (E. G. Williams, 1939); anorexia and increased metabolic rate are the other factors. Dehydration may also be a cause of the *muscle cramps*. These are not due to lowering of plasma calcium (E. G. Gross and Slaughter) In animals, morphine withdrawal may lead to increased water content of the blood (10 per cent) and of the brain (14 per cent), liver, muscle and skin (J. M. Pierce and Plant, 1928; Barbour *et al.*, 1928 and 1929). This is more marked on a carbohydrate than on a fat diet. Purging results in blood concentration (Morat, 1911). Thienes and Detrick, 1939, report that the tissue hydration of rats falls below normal during withdrawal. *Leukocytes* change in three phases: (1) a relative and usually absolute increase of neutrophils, generally with absolute lymphopenia and hypoeosinophilia; (2) near the middle or end of the first week, repeated fluctuations of the neutrophils and lymphocytes, and reciprocal, sometimes considerable eosinophilia; (3) restoration to the normal, sometimes requiring sixty days (M. Rinkel, 1933).

Nervous Withdrawal Symptoms in Animals.—Dogs, and especially monkeys, that have been addicted to opiates manifest satisfaction when these are injected, and abstinence symptoms when they are withdrawn, quite similar to the human. *Chimpanzees* resemble the human very closely. The addicted animals become introversive, less sociable, less playful, more cyclical in moods, restless when the time of injection approaches. Within two and a half to seven weeks of addiction they show definite withdrawal signs; yawning and a combination of restlessness and lethargy when the injection is deferred. They reach their maximum in forty-eight hours. Tolerance is also lost rather rapidly after this time and changes to hypersusceptibility. An important difference from human addiction is that the one animal studied two weeks after complete withdrawal apparently lost all interest in opiates, which it had sought strenuously during the active withdrawal symptoms. The time required to establish addiction was materially shorter when the dosage was increased (Spragg, 1940). *Macaca monkeys* are also well suited for showing addiction liability. Seevers, 1934, found the central depression more prolonged with morphine and dilaudid than with codeine and heroin. Tolerance developed most with morphine, then dilaudid, then heroin, then codeine. Withdrawal symptoms were least with codeine. *Completely decorticated dogs* may be addicted, much like normal dogs, becoming more resistant to the analgesia and sedation. They react to withdrawal by motor restlessness, rise of temperature, increased heart rate and rhinorrhea. These subside after three days (A. Wikler, 1946). *White rats* develop tolerance. They show no signs of satisfaction; but their struggle-response to the discomfort of restraint (tying to a board, in supine position) is greatly increased by withdrawal, progressing with the degree of the latter (Himmelsbach, 1934). This is a simple index of addiction liability, which is positive for dilaudid and codeine as well as for morphine and heroin. It is negative for barbiturates, acetanilid and cocaine (Himmelsbach, Gerlach and Stanton, 1935; E. J. Stanton, 1936, 1937). Joel and Ettinger, 1926, found that morphine habituation does not change the reactions of rats to the chloral group, or to picrotoxin, strychnine or cocaine.

Clinical appraisal of addiction liability may be done on addicts (stabilized for two weeks on a constant dosage of morphine) by the abeyance of withdrawal symptoms during the administration of the substitute, and their outbreak on its withdrawal. This has confirmed the addictant qualities of dilaudid, codeine and the various new derivatives (Himmelsbach *et al.*, 1940). It has also been attempted to test addiction by administration to hopeless cancer and tuberculosis patients as part of the regular treatment, but the results in such patients are equivocal.

Treatment of Opium and Other Drug Habits.—The primary indication is the withdrawal of the drug. This must be done under medical supervision, best in special institutions, for the patients have neither the will power nor the physical resistance to carry it through unaided; attempts at self treatment are rarely successful. Indeed, the closest surveillance of the patient is indispensable, both to prevent clandestine continuance of the drug and to control the withdrawal symptoms. When the drug has been completely stopped, for a few days, the intense craving for it disappears, and the patient may be considered as provisionally cured, although still in need of tonic treatment. Contrary to the popular impression, the withdrawal is a fairly simple problem. The chief difficulties are subsequent relapses. Re-orientation of the psychopathic personalities can not be accomplished in a few weeks, and often not at all, and the cure therefore is often not permanent. The memory of the morphine euphoria remains, and any stimulus associated with the former use of the drug is likely to evoke the old desire, and every unpleasantness suggests the means of escape (Pescor, 1938). The patients are likely to succumb again, sooner or later, and if the drug is resumed the addiction develops rapidly. It is necessary to be especially cautious in the therapeutic use of opiates on ex-addicts. About a fifth of any large group of addicts have been through repeated treatments (L. Kolb, 1936). The average duration of the "cure" is a little over two years. Only 2.5 per cent abstain for more than five years (Pescor, 1938). Those who were treated against their full consent naturally relapse with the first favorable occasion. These remarks apply also to cocaine and other serious drug habits, the treatment of which is identical. The withdrawal requires energetic and decisive procedures. It is important first to put the patient into good physical and mental condition (E. S. Bishop, 1920); then the drug should be withdrawn abruptly, or reduced rapidly, under confinement in special wards or hospitals. Gradual reduction causes probably more suffering by prolonging the struggle, and is generally unsuccessful. "Insensible" withdrawal does not exist; the sensations of the patients recognize even small reductions of dosage. Ambulatory treatment is so often inefficient, and is so liable to fraud, that it is rarely justified (S. D. Hubbard, 1920). Advertised "morphine cures" generally contain morphine and are used by addicts to supply the drug. Abrupt withdrawal and rapid reduction are equally successful, and the total suffering of the patient is about the same. The abrupt method is more extensively used for its simplicity (P. Wolff, 1928), but the preference depends considerably on the special experience of the physician. In the rapid reduction, the withdrawal is completed in five to ten days. Bishop advises to begin by reducing the number rather than the size of the doses. The details require individualization, especially if any opiate is given. Restlessness and insomnia call for sedative baths, paraldehyde, barbiturates or bromide; pains for salicylates; dextrose injections (1000 cc. of 10 per cent by vein) may be given if the patient refuses food. Purgatives and other special adjuvants are not necessary and are often harmful (Kolb, 1936). The enthusiasm of their advocates is based on inadequate controls; the majority of patients go through simple withdrawal with surprisingly little difficulty, especially when supported by the confidence of the physician.

The clinical relief of the withdrawal symptoms by drugs has been tested systematically by Himmelsbach and Andrews, 1943. Codeine was ineffective in the dosage of 26 mg., effective with 52 mg.; demerol was effective with 100 and 200 mg.; morphine with 5, 10 and 20 mg., more effective and more sustained by vein than hypodermically. *Thiamine, neostigmine, pentobarbital* and *atropine* were ineffective in ordinary doses; nor did neostigmine prevent or modify clinical morphine addiction in any manner or degree (Himmelsbach and Oberst, 1942; H. L. Andrews, 1942).

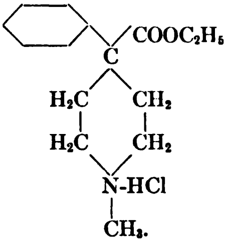
Thiamine was reported by O. G. Fitzhugh, 1939, to decrease the withdrawal irritability of addicted rats, the administration being started two days in advance. Chronic morphinism as such does not increase the requirements for thiamine in dogs (Cowgill, 1939). *Insulin* was advocated by M. Sakel, 1930 and 1933, and Anton and Jacobi, 1930, with the claim that twenty to thirty units per day permit rapid withdrawal of morphine without emesis, diarrhea and restlessness, and with diminution of the psychic symptoms. The clinical evidence is not convincing, and controlled experiments on monkeys (Seevers and Stormont, 1936) and on rats (Stanton, 1937) are quite negative. Thienes and Detrick, 1939, claim that *parathyroid hormone* hastens the dehydration and mitigates the withdrawal symptoms in rats. "*Rossium*," an antipyrine derivative, was introduced by Ostromislensky, 1935, on the basis of his unsubstantiated "anaphylactic theory of morphinism." Critical clinical tests show it to be without demonstrable benefit on the abstinence syndrome (Himmelsbach, 1937). The *scopolamine (hyoscine) and atropine treatment* was introduced by M. K. Lott, 1901 (Wagner and Riewel, 1905), to secure amnesia of the withdrawal. Kolb claims that it actually increases the suffering, leaving the patient more or less shaky for days, and with an indefinite craving that prompts relapse. It also has a high mortality, in one institution six deaths in 130 treatments. The *Lambert-Towns routine* (A. Lambert, 1913) also utilizes belladonna, with active purgation. Kolb states that it increases the suffering and is dangerous, and that its chief use is so to disable the patients that they can not escape. *Purgation*, generally by magnesium sulfate, is used in several routines, originally with the idea of eliminating some hypothetical toxic agent. It distracts the attention, but is otherwise detrimental by contributing to dehydration, as are also *nauseants*, pilocarpine and milk injection fever (P. Wolff, 1928). The withdrawal itself usually results in diarrhea, sometimes severe, for several days (Kolb).

Experimental Control of the Withdrawal Symptoms in Monkeys.—Seevers and Stormont, 1936, found that only oxygen inhalation and intravenous hypertonic glucose or sucrose gave relief. Administration of calcium, parathyroid, magnesium, potassium and insulin was ineffective. Sodium thiocyanate (advocated by Bancroft) made the animals more sick.

The *after-treatment* includes physical rehabilitation and the more difficult problems of mental and emotional stabilization and sociologic placement. It is highly important that the patient rest for several weeks or, better, months, preferably in a sanatorium. Insomnia should be relieved with bromide and barbiturate, guarding against the acquisition of a habit. The "recovered" patient must be protected as much as possible against pain and all conditions that would tempt him to resume the drug. Psychotherapy may be useful to prevent recurrence.

DEMEROL

This substance also known as *Meperidine, Isonipecaine*, and abroad as *Dolanthin* and *Pethidine*, a synthetic phenylpiperidine derivative, is a clinically satisfactory substitute for morphine, except against cough and diarrhea. The effects are not as lasting. It is not constipating, but tends to relax spasm of smooth muscle, similarly to atropine, to which it is chemically related. It produces euphoria similar to that of morphine, and prolonged administration may lead to addiction (Anslinger, 1946), but with less dependence than morphine (Batterman and Himmelsbach, 1943; Samter, 1946; Wieder, 1946; review, J.A.M.A., *132:* 43, 1946). *The provisions of the narcotic act must be observed in prescribing demerol.*



Demerol, ethyl-1-methyl-4-phenylpiperidine-4-carboxylate hydrochloride, was introduced as an analgetic by Eisleb and Schaumann, 1939.

Urinary Excretion.—Patients excrete 2 to 21 per cent, average 9 per cent, of the amount administered (300 to 800 mg.); about three-fourths within seven hours after a single dose (F. W. Oberst, 1943). It is *hydrolyzed* by liver *in vitro*, but not by the other tissues tested. The hydrolysis is inhibited by physostigmine and by fluoride (F. Bernheim and Bernheim, 1945).

Clinical Analgesia.—Oral or intramuscular administration of 30 to 150 mg. is successful and safe for practically all conditions which are ordinarily subject to morphine analgesia, including postoperative pain, preanesthetic medication, parturition, and colics. Its brief action, lasting two or three hours, renders it less convenient against cancer. *Side actions* are unimportant: Dizziness, perspiration, dry mouth are frequent, nausea and vomiting exceptional, drowsiness is brief and not followed by confusion. There are no visceral lesions. *Addiction* is frequent, and is broken more easily than morphine addiction (Batterman and Mulholland, 1943).

For preanesthetic medication, 100 mg. of demerol, hypodermically, are equivalent to 15 mg. (¼ grain) of morphine. Excessive depression occurs only half as frequently with demerol. It may be administered with 0.4 to 0.6 mg. of scopolamine (Rovenstine and Batterman, 1943). In *patients with intracranial lesions,* demerol, like morphine, may slow the respiration to an alarming degree (S. A. Guttman, 1944).

In *parturition,* demerol produces good analgesia and is relatively free from untoward effects on mother or child (W. Sonnek, 1941). The progress of labor is not disturbed, but rather accelerated by increased uterine force (Solomons and Widdess, 1943).

Demerol also has considerable local anesthetic action (E. L. Way, 1946).

Spasmolytic action has been described clinically for intestinal, biliary and ureteral colic and bronchial spasm, but the reports are discordant. In intact animals, Gruber, Hart and Gruber, 1941, observed marked contraction of the intestines; excised smooth muscle gave variable results, including slight relaxation. Fellows and Cunningham, 1942, found that several *phenylpiperidine derivatives* relax smooth muscle and inhibit histamine, pituitary and barium spasm similarly to papaverine.

Circulation.—Intravenous injection of demerol generally lowers the blood pressure by vasodilatation, even with relatively small doses (Gruber *et al.*, 1941).

Habituation.—*Tolerance* to the analgetic effects develops in patients with continued use over eight weeks, and persists for at least four weeks after withdrawal. A patient used 3 Gm. daily, hypodermically (Wieder, 1946). The response is sufficiently pleasurable and the withdrawal sufficiently uncomfortable to discourage voluntary discontinuance (H. L. Andrews, 1942). The withdrawal syndrome, typically like that of morphine, but milder and shorter, can be evoked after ten days of continued use. Demerol administration satisfies the drug hunger of stabilized opiate addiction (Himmelsbach, 1942).

PREPARATIONS.—***Demerol Hydrochloride** (Isonipecaine, Meperidine, Dolanthin); marketed as tablets of 50 mg. and as ampuls of 100 mg. in 2 cc. *Average dose:* preoperative, 100 mg. intramuscularly; postoperative, 50 to 100 mg. orally or by injection.

1,1-diphenyl-1-(dimethylamino isopropyl)-butanone-2 is a potent analgetic agent in man and in animals. It resembles morphine also in respiratory depression, slowed heart and mouse tail erection. It acts weakly on intestine and is not emetic. Dogs do not develop tolerance to the analgesia. The therapeutic oral dose, 5 mg. for man, does not produce significant side actions or euphoria (C. C. Scott and Chen, 1946).

Betahydroxy-alphabeta-diphenyl ethylamine ("*M4*" of Dodds, Lawson and Williams, 1944) has morphine-like analgetic properties and may replace morphine in cancer (200 mg. every four hours). It has a low toxicity and does not produce undesirable side actions, except some mental confusion. Like morphine, it dilates the pupils of cats and produces hyperglycemia in rabbits

PAPAVERINE AND PERPARINE

Papaverine is the most important isoquinoline alkaloid of opium. Its actions are quite unrelated to those of morphine. It is not narcotic, and is but slightly analgetic. It does not produce tolerance or addiction. It tends to relax the tonus of all smooth muscle, without interfering with the normal contractions (Pal, 1913, 1914). It was therefore suggested against spastic colic of various organs (30 to 80 mg. by mouth or hypodermically, 5 to 30 mg. by vein, Pal), but proved rather ineffective. Its toxicity is low: Bouchet claimed that 1 Gm. produced no effects on man. It decreases the tendency to cardiac fibrillation and may be used instead of quinidine.

Perparine is derived from papaverine by substituting ethoxyl for a methoxyl group. It was introduced for the same therapeutic field, but probably has little value, although it is claimed to be three times more potent in depressing smooth muscle tonus, and one-third to one-half as toxic (Pouchet, 1933). It is nonaddictant and has no effect on morphine withdrawal symptoms (Himmelsbach, 1937).

Gastro-Intestinal Tract.—Papaverine lowers the tonus level of the stomach, slows or suppresses its normal peristalsis and counteracts physostigmine stimulation. Perparine is up to twice as potent. Their effects on the intestinal movements are relatively slight and inconstant, as is also their antagonsim to the morphine tonus; but they decrease phenolphthalein diarrhea in cats (Gross and Slaughter; von Issekutz *et al.*, 1936). Stoerk, 1915, employed papaverine (60 mg. three times daily) against the tenesmus of bacterial dysentery. Excised rabbit intestine is depressed by 1:1,000,000 (Mulinos, Shalman and Pomerantz, 1939). L. W. Rowe, 1942, reports a *morpholine compound* that proved twice as potent as papaverine for relaxing excised intestine.

Ureteral Colic.—Macht, 1916, reported that papaverine relaxes the tone of the ureter, without inhibiting the peristalsis. Geraghty and Macht, 1916, suggested its injection by ureteral catheter against the colic of ureteral calculi (5 cc. of 2 per cent solution of the hydrochloride). The gallbladder and the seminal ducts are also relaxed (Macht, 1919).

Heart.—Papaverine produces dilatation of the coronary vessels and renders the dog heart less susceptible to ventricular fibrillation by faradic stimulation (Lindner and Katz, 1941) and by coronary ligation (McEachern *et al.*, 1941). It depresses auriculoventricular conduction and removes ventricular extrasystoles. Excessive doses cause intraventricular block, paroxysmal ventricular tachycardia and a peculiar ventricular fibrillation (L. N. Katz *et al.*, 1941; Wégria and Nickerson, 1942). *Clinically,* 0.1 Gm. by mouth, three or four times daily, produces significant improvement on over three-fourths of patients with anginal symptoms; 0.2 Gm. four or five times daily is useful against premature beats. It is less toxic than quinidine and has the advantage of coronary dilatation. It is not addicting (Elek and Katz, 1942; E. E. Swanson, 1945). Prolonged administration to dogs with experimental myocardial infarction reduces the size of the infarct by increasing the anastomotic channels (R. Mokotoff and Katz, 1945). It has been proposed as a *test of circulation time,* injecting 40 mg. of the hydrochloride into a cubital vein in one second. The signal is a deep inspiration, normally in sixteen to twenty-seven seconds. This is commonly followed by nitritoid symptoms (Elek and Solarz, 1942). L. Berk and Sapeika, 1945, find this test unsatisfactory. Pal reported that small doses of papaverine lower abnormally high *blood pressure,* while much larger doses are required to lower the normal pressure. Macht, 1916, claimed that it lowers blood pressure mainly by peripheral vasodilator action, especially in the splanchnic area, and that the coronary circulation is increased. The perfusion rate through frog legs is increased (Mulinos *et al.*, 1939). On the basis of these claims, papaverine was tried against *hypertension, angina pectoris* and *thrombo-angiitis obliterans,* but it appears to be unreliable (Littauer and Wright, 1939). With intravenous injection into dogs, the initial fall of pressure is succeeded by hypertension and renal vasoconstriction (Mercier, 1931); but large doses neutralize the pressor action of epinephrine (Mercier et Delphant, 1932).

Local Anesthesia.—Papaverine is somewhat anesthetic and has been used on the cornea as 4 to 10 per cent solution.

Fate of Papaverine.—It is probably extensively destroyed in the body, since neither papaverine nor any immediate decomposition products have been recovered from the organs or excreta after its hypodermic administration (Zahn, 1915).

Papaverine Hydrochloride, U.S.P., is soluble in water (1:30). Dose, by mouth or vein, 30 to 100 mg., ½ to 1½ grains. *Papaverine Hydrochloride Injection,* in water for injection; usual size, 30 mg. in 1 cc. Commercial papaverine contains considerable cryptopin, to which most of its chemical tests are due (Pictet and Kramers, 1910). In general, however, the quality of commercial opium alkaloids is satisfactory (Warren, 1915).

Tetra-Hydro-Papaveroline.—Laidlaw, 1910, found that this inhibits the tone of unstriped muscle, dilates the bronchioles and blood vessels and lowers blood pressure, at the same time stimulating the heart. It is relatively nontoxic. Marshall, 1912, tried it clinically in arteriosclerosis, but found it practically inefficient—probably because it is too easily oxidized. Exfoliative dermatitis and extensive alopecia have been reported as consequences of the prolonged use of a papaverine derivative ("*cyverine*") as antispasmodic (O. L. Levin and Behrmann, 1942).

Narcotine and Narceine are related to papaverine in composition, and their effects are similar but weaker (Pal, 1914). Narcotine prolongs the emptying time of the stomach and inhibits the movements of the intestines, but it could not be used against colic, as effective doses upset digestion (Dikshit, 1932). Its addition to morphine has probably no advantage. Macht, 1915, found, contrary to Straub, that it is quite toxic to the heart, respiration and other functions. M. Hayashi, 1931, reports on its peripheral actions and claims that it has some central depressant effect. Cooper and Hatcher, 1934, conclude that it does not appear to exert the therapeutic effects of morphine. The toxicity varies with the rate of absorption and is sixty times higher intravenously than for oral administration. Only traces are excreted by the urine, in cats.

PROTOPINE GROUP

Curare and muscular actions were described by v. Engel, 1890, for the protopine group—certain unimportant alkaloids (protopine, crytopine, chelidonine, homochelidonine and chelerythrine) which occur in opium, but especially in other Papaveraceous plants (Sanguinaria or Bloodroot); and Chelidonium or Celandine; Bocconia.

Chelidonine is the most promising member of the protopine group. It is chemically related to papaverine, containing the benzyl-isoquinoline group. It therefore depresses all smooth muscle and has a low toxicity. Hanzlick, 1915, suggested its clinical trial against spasm and colic of smooth muscle. The sulfate is freely soluble in water; it is incompatible with chloride. The dose is 0.2 Gm., 3 grains. H. Meyer, 1892, found that it produces, in frogs, descending depression of the *central nervous system,* similar to morphine, but without spinal stimulation. Mammals also respond by analgesia and sleep, without marked depression of reflexes. The respiration is unaffected by therapeutic doses; moderately slowed by larger doses. *Toxic doses* cause coma, without nausea or vomiting; finally, the vasomotor center becomes paralyzed. *Peripheral actions of chelidonine* have been investigated especially by Hanzlik, 1921. Like other isoquinoline alkaloids (narcotine, papaverine), it depresses all kinds of *smooth muscle*. The effect appears to be directly on the muscle substance, since it antagonizes not only pilocarpine, but also histamine, peptone, anaphylaxis, epinephrine and even barium; while these do not remove chelidonine depression. Anan, 1929, claims that low concentrations raise the tonus of excised intestines and uterus, while higher concentrations depress. Large doses depress *cardiac muscle*, slowing and dilating the heart. *Skeletal muscle* is also depressed (Hanzlik), and Meyer described paralysis of sensory and motor endings. It has no effect on nerve trunks, even in high concentrations.

Chelidonium juice is an acrid irritant, applied in folk medicine to remove warts. The acrid principle has not been isolated. Chelidonium also contains berberine.

Sanguinaria (Bloodroot) has been used as a nauseant, usually as the 10 per cent acidulated tincture (dose, 1 cc., 15 minims). It contains sanguinarine (reports, Council on Pharmacy and Chemistry, 1911, 60) and other alkaloids (Kozniewski, 1910). It is irritant, but requires further pharmacological investigations.

◆

HYDRASTIS

Hydrastis (Golden Seal), the rhizome and roots of Hydrastis canadensis, has few, if any, rational indications. It was employed empirically as a bitter stomachic; to check internal hemorrhage and locally in catarrhal conditions, especially of the genito-urinary tract.

Hydrastis was used by the Indians, mainly as a pigment, but also as medicine. It was introduced by the eclectic physicians. The plant is becoming rare, but is easily cultivated (Henkel and Klugh, 1908). The dose of dried Hydrastis is 2 Gm.; that of *hydrastine hydrochloride* is 10 mg.; *hydrastinine hydrochloride*, 30 mg. Both salts are water soluble. The alkaloids are also used locally for conjunctivitis or gonorrhea, 0.1 to 0.5 per cent. Dilute solutions of hydrastinine give a blue fluorescence.

Constituents.—Hydrastis contains at least three alkaloids: berberine, 1.5 to 4 per cent; hydrastine, at least 2.5 per cent (U.S.P.), and canadine, a derivative of berberine. There is also some resinous matter, etc.

Hydrastine is an isoquinoline derivative, closely related to some of the minor opium alkaloids, narcotine, laudanosine and papaverine. Narcotine is methoxyhydrastine, an H of hydrastine being replaced by OCH_3. Oxidation splits off opianic acid and forms analogous artificial alkaloids, *hydrastinine* from hydrastine, *cotarnine* from narcotine. *Berberine*, $C_{20}H_{17}NO_4$ (structure, Faltis, 1910), is an intensely yellow and bitter alkaloid, of wide occurrence, which gives the color and taste to a large number of "golden" roots and bark (Berberis, Xanthoxylon, Coptis, etc).

Actions of Hydrastis.—The effects of the drug and its different alkaloids are qualitatively similar.

Central Nervous System.—Hydrastine produces convulsive effects analogous to those of strychnine. These are also obtained with the fluidextract. The derivatives hydrastinine and cotarnine have a purely depressant action, producing death by respiratory paralysis (Laidlaw, 1910). There is no narcosis.

Circulation.—Experimental results indicate that the effects of hydrastis and its alkaloids and derivatives on the circulation are too uncertain to be therapeutically useful. The clinical evidence also appears insufficient to establish their value. Frey, 1909, found that hydrastinine had no effect on pulmonary hemorrhage; and Hanzlik, 1918, showed that hydrastis and its alkaloids, including hydrastinine, are not styptic on ordinary wounds, either with local or systemic administration, but rather tend to increase the bleeding. The effects of hydrastis on the circulation are variable and the descriptions of different investigators are discordant. Williams, 1908, obtained no effects with hypodermic or oral administration, even with large doses. Intravenously the fluidextract, hydrastine and berberine produced the same results: considerable fall of blood pressure, followed with small doses by a slight and short rise. With large doses, the pressure remained low. These effects were predominantly cardiac. The vasomotor center is not directly affected by moderate doses of hydrastis, hydrastine, berberine, hydrastinine or cotarnine, but may be stimulated indirectly through respiratory depression, convulsive phenomena or cardiac unrest. With toxic doses, there is vasomotor paralysis and paralysis of vagus endings. Excised organs show some vasodilation. On the scarified skin, hydrastine (1:1000) produces some blanching (Sollmann and Pilcher, 1915). *Hydrastine* is related to the protopine group and therefore depresses the cardiac and skeletal muscle, and has a weak local anesthetic action. *Hydrastinine* also causes some primary fall of blood pressure, but a larger rise (about 15 mm.) maintained for over fifteen minutes; the heart rate is slowed. This rise is also predominantly cardiac, but there is a stimulation of the arterial muscle, not prevented by paralyzing the nerve endings with ergotoxine. Kurdinowski, 1904, interprets its actions rather differently.

Uterine Actions.—Fellner, 1906, Kehrer, 1907, and Lieb, 1914, showed that hydrastis, hydrastine, hydrastinine and cotarnine increase the tonus and excite rhythmic contractions of the uterus, both in the excised organ and in living animals. This has been confirmed by the subsequent workers; also for the surviving human uterus (Rübsamen and Kligermann, 1912). High concentrations relax (Wendling, 1915). Berberine has similar effects (Marek, 1911). La Torre, 1912, examined histologically the uteri of animals treated with hydrastinine. The muscular layers were contracted and thickened, compressing the larger vessels, and thereby probably decreasing the blood supply of the mucosa. Laidlaw found the stimulant action of hydrastinine and cotarnine constant in the excised organ, but varying with conditions during life. Hydrastis does not act on the intestine and very slightly on the bladder. Synthetic hydrastine appears to be rather more stimulant than the natural alkaloid (Wendling, 1915). The *bronchioles* are not markedly affected in pithed animals (D. E. Jackson, 1914).

Actions of Berberine and Canadine.—Berberine acts as a simple bitter in small doses. Its bitter taste and the yellow stain which it produces on linen render it objectionable in the therapeutic use of hydrastis. Berberine is about seven times as active as hydrastine on the circulation; and as hydrastis contains about one and one-half times as much berberine, about 85 per cent of the circulatory effect is due to this alkaloid. Large doses lower the temperature, increase peristalsis and kill by central paralysis (Curci, 1892). It is not excreted, being probably oxidized completely (Berg). The actions of berberine have been reviewed experimentally by R. N. Chopra, Dikshit and Chowhan, 1932. It is a feeble local anesthetic. Intraspinal injection produces motor paralysis. Intraperitoneal injections into trypanosome-infected rats prolong life somewhat (Seery and Bieter, 1940).

Canadine resembles morphine somewhat in its action. It is present in too small a quantity to be of practical importance. It occurs also in xanthoxylum, where its actions have been studied by Laidlaw, 1913.

◆

COTARNINE

Cotarnine salts (marketed under the name of *stypticine* and *styptol*) were tried locally and systemically to arrest bleeding, especially in menstrual disorders. Their employment was based on weak clinical and experimental data, which do not stand critical examination.

Use against Hemorrhage.—Hanzlik, 1918, showed that cotarnine is not a local hemostatic. Systemically, it tends to lower blood pressure, and thus somewhat decreases bleeding.

General Symptoms.—K. Mohr, 1905, found that small doses produce only some lassitude and drowsiness. Larger doses had a pronounced sedative action, especially in cats and dogs. Ataxia was also marked. With fatal doses, these effects were followed by some excitement, then progressive paralysis till death. Toward the end, the respiration became slow and shallow, sometimes interrupted by asphyxial convulsions. Laidlaw, 1910, describes indefinite depression of the central nervous system and death by paralysis of the respiratory center. Relatively small doses slowed the respiration without change of depth.

The *fatal dose* ranges from about 0.1 Gm. per kilogram for guinea pigs (Laidlaw) to 0.3 to 0.4 Gm. per kilogram for rabbits, and even higher for dogs and cats (Mohr).

Uterine Contractions.—Kehrer, 1907, reported that cotarnine stimulates the uterus, excised and *in situ*, pregnant or nonpregnant, increasing the contractions and tonus. This has been confirmed for the excised organ by all subsequent workers (Lieb, 1914). The results *in situ* are contradictory. Chiappe and Ravano found that the pregnancy of guinea pigs was not affected by toxic doses; and that even fatal doses produced no uterine abnormalities. The *clinical data* are in harmony with these negative results.

Other Smooth Muscles.—Offergeld quotes contraction of the intestines and bladder; but Laidlaw found the bladder irresponsive.

Systemic Circulation.—Intravenous injection produces variable changes in the blood pressure; sometimes a fall; or a momentary fall followed by a slight rise (Kehrer, 1907; Laidlaw, 1910; Lieb, 1914). If the vagi are divided, the rise is more prominent (Pilcher and Sollmann, 1915). The vasomotor center is not affected directly, but may be stimulated by the slowed respiration (Pilcher and Sollmann); this probably accounts for the rise. The fall of pressure appears to be cardiac; for the Langendorff heart is slowed and weakened (Laidlaw). This diminished output of the heart has been credited with causing a hemostatic effect; there is no evidence that it occurs with therapeutic doses; and even with the experimental doses it is too slight and too evanescent to influence a persistent hemorrhage.

Direct action on systemic arterioles seems to be absent, either with systemic administration or on perfusion with reasonable concentrations (Laidlaw; Mohr).

Coagulation of blood is not affected, whether the cotarnine is added directly to the blood or injected into the animal (Laidlaw; Marfori).

Dosage and Administration.—The cotarnine salts are used by mouth or hypodermically. The intramuscular dose is 0.25 to 0.5 Gm., as 10 or 20 per cent solution, repeated daily as needed. The injections are not irritant. By mouth, the dosage is from 0.05 to 0.1 Gm. four to five times daily.

Side Actions.—None have been reported from oral administration or from hypodermic injections of 0.5 Gm. Offergeld found some lassitude with 0.7 Gm. and a single case of temporary collapse with 0.65 Gm. by intramuscular injection.

◆

BENZYL BENZOATE AND OTHER BENZYL ESTERS

Benzyl benzoate and acetate were found by Macht, 1918, to *relax excised smooth muscle* from various organs. They were tried clinically in colics or spasmodic conditions of smooth muscle (1 to 10 cc. of a 20 per cent alcoholic solution in cold water, three to four times daily), especially in functional dysmenorrhea (Litzenberg, 1919) and in hypertension. Thorough investigation showed that clinical doses, by mouth, are entirely without effect (Gruber, 1924). Larger doses (also of benzyl alcohol) produce only local irritation, *i. e.*, vomiting and diarrhea (Gruber, 1923; bibliography). If injected parenterally, the benzyl compounds depress the heart and the respiration, and increase the urine flow (Gruber, 1925), without depressing the smooth muscle in those organs against whose overactivity the drug has been especially advised, *i. e.*, the uterus, intestines, stomach and bronchi (Mason and Pieck, 1920). The *toxicity* of the benzyl esters is low, since they are converted into hippuric acid. Dogs tolerate considerably more, by mouth, than do rats, rabbits and cats (B. E. Graham and Kuizenga, 1945).

The earlier reports of beneficial results in dysmenorrhea can probably be explained by suggestion. The application of a mixture of equal parts of benzyl benzoate, soft soap and isopropyl alcohol against *scabies* has been advised (Kissmeyer, 1937; A. H. Slepyan, 1944). D. C. Daughtry, 1945, reports rapid cures with 25 per cent emulsion. It may produce local irritation, and patients should be warned to discontinue the treatment if the rash or itching becomes worse. Persistent sensitization to wool follicular dermatitis not infrequently follows repeated (not single) treatments (S. J. Shane, 1946). A 5 per cent emulsion applied to clothing protects against the mites of scrub typhus.

The soluble sodium salts of the benzyl esters (sodium benzyl-succinate and sodium di-benzyl-phosphate) are also ineffective by mouth, in clinical doses. Larger doses, administered parenterally to animals, generally depress the respiration and raise the blood pressure (Gruber, 1925). The rate of *hydrolysis* by alkalis would be of some importance for the local effects in the intestines and for absorption. Volwiler and Vliet, 1921, found the amount of hydrolysis in four hours to be 3 per cent for the salicylate; 15, 18 and 23 per cent for the benzoate, stearate and cinnamate; 40, 50 and 60 per cent for the acetate, succinate and fumarate.

Benzyl Benzoate, U.S.P., $C_6H_5COOCH_2C_6H_5$, is a colorless, oily liquid, of faint odor and disagreeable, sharp taste. Insol. in water or glycerin; freely sol. in alc. and fat solvents. Best prescribed as the commercial 20 per cent alcoholic solutions or emulsions, usually flavored with aromatics (Spir. Anise). Dose, 1 to 10 cc. (¼ to 2 teaspoonfuls) of the 20 per cent solution, in cold water, three or four times daily. *Benzyl Benzoate Lotion,* U.S.P., a 25 per cent emulsion, with triethanolamine.

Benzaldehyde, C_6H_5CHO, an oily liquid with the odor of bitter almonds, also relaxes smooth muscle and is a rather feeble local anesthetic (Macht, 1919), as it oxidizes rapidly to benzoic acid in watery solutions. Its dose is stated as 0.03 cc., ½ minim.

◆

CANNABIS

The flowering tops of the pistillate hemp plant, Cannabis sativa, contain resinous constituents (cannabinol) which produce a peculiar psychic exaltation. As "hashish," cannabis is employed as an inebriant in the Orient, and as "marihuana" cigarettes in Mexico and Brazil and to an increasing extent in the United States. Therapeutically, it was used as an adjuvant to other drugs in nervous headaches, and as a coloring agent for corn remedies. The drug is of uncertain activity, and has no rational indication.

The **effects on man** are identical for oral administration (about 2 grains of the solid extract) and for smoking. The inebriation sets in rather abruptly, after a latent period of about an hour, in which there may be temporary digestive phenomena, anorexia, dryness or burning thirst. The phenomena differ in kind as well as in degree according to the individual personality and disposition, the surroundings and the mental preparation. *The emotional sphere* develops euphoria, expansiveness and gaity, less commonly anxiety. Waves of exaltation sweep over the consciousness and may alternate precipitously with fear and terror. The subject is likely to be quarrelsome and violent if crossed. In *the subjective sphere,* a feeling of unreality is among the first effects, with a consciousness of double personality. Objects and sensations appear exaggerated in size and in degree, the limbs are lengthened, the head is swollen, the body alternately light and heavy, time enormously lengthened. *Motor excitement* and restlessness vary in different persons; tremors of the tongue and fingers, and muscular rigidity may occur. The *pupils* become widely dilated and barely react to light. The eyes appear glazed, the conjunctiva congested, the lids reddened. The pulse is generally rapid, with marked palpitation. *Mental confusion* may deepen to visual illusions and hallucinations. The imagery is likely to become terrifying in the dark. Aphrodisiac desire, rather than impulse, occurs in some and not in others. The *after-effects* are generally light. The exaltation is succeeded by irritability and somnolence, and after some hours by sleep, from which the subject awakens hungry and thirsty, with a clear recollection of the episodes. *Toxic doses* cause vertigo and collapse, with soft arrhythmic pulse, and blood concentration sometimes to 50 per cent. Serious poisoning is rare, since the margin between the effective and fatal dose is wide; the intravenous fatal dose for dogs is a hundred times the narcotic dose.

Addiction to cannabis is usually casual, since psychopathic individuals tend to drop it for a more potent narcotic. It generally takes the form of an occasional hedonistic indulgence, whose chief harm lies in the introduction to more serious addictions. No relation to criminal offenders, sexual or other, has been established. Physical consequences are no more significant than with tobacco; digestive disturbances and marasmus are not prominent. Conjunctival congestion is common. There is apparently no material tolerance, either in man or in animals, nor are there withdrawal symptoms, except, perhaps, in extreme cases. *Insanity* is a rare sequel, and the cannabis is probably only a provocative agent that unveils the latent psychopathy. Psychopathic patients react to cannabis like normal individuals, but usually become more self absorbed and less communicative, in contrast to their response to cocaine and amytal.

Comprehensive descriptions of the effects of cannabis are given in R. P. Walton's book, "Marihuana," Lippincott, 1938; in the review of W. Bromberg, 1939, and S

Loewe, 1944. The psychiatric complications of continued use are reviewed by H. J. Anslinger, 1943, and in a clinical study by Allentuck and Bowman, 1942. The use of cannabis *in the Orient* presents a rather different picture, depending on national differences of temperament, mentality and culture, which determine different psychic reactions and "dreams." Six to eight pipes daily do not seem to produce serious consequences in hemp smokers of Northern Africa. The most deleterious results are seen in those who use the concentrated resin ("charas"). Dementia is exceptional even in advanced cases; but release of subconscious impulses may lead to violence, aggressive mania, suicide, etc. (R. N. Chopra, 1942). Withdrawal reactions are relatively mild. Cannabis is not truly aphrodisiac even in Oriental users; a few may experience psychic sexual excitations, but not physical. The addicted generally lose libido; "they are content with their pipe and their pot" (J. Bouquet, 1944). The smoking of cannabis under the name of Dagga by the *natives of South Africa* is discussed by Watt and Breyer-Brandwjik, 1936, citing a thesis of Bourhill, 1913. Native boys begin at eight or ten years, much as white boys begin cigarettes. Adolescents smoke for good fellowship rather than for the effects. The habit becomes fixed in adults, who now smoke for effect, with some craving, chiefly restlessness, on withdrawal, never as strong as with morphine or even alcohol addiction. With old age, the addiction has become ingrained.

Electroencephalograms during marihuana smoking show marked increase in the number and amplitude of the fast waves, but these appear to be of muscular, not nervous, origin (Wikler and Lloyd, 1945).

The effects on animals are also narcotic and are used for *bio-assay*. Dogs are most suitable for the general inebriation, which may be induced by oral or intravenous administration; the drug is not sufficiently absorbed from hypodermic injections. The animal becomes quieted at first, then apprehensive, and then develops static *ataxia* on standing, swaying as in the Romberg sign, standing with its legs spread to avoid falling, but it may still be able to perform complicated movements; then it becomes unable to stand alone, and finally to rise. This is succeeded by deep and prolonged sleep, during which the sensation of pain is much diminished, while the reflexes persist. Some animals show acute mania. The response of different dogs varies and must be checked against a known standard (Houghton and Hamilton, 1907, 1908; Walton *et al.*, 1938). The ataxia is the best criterion of potency, if the assay is properly performed on standardized dogs. Their tolerance is neither increased nor diminished by numerous administrations (S. Loewe, 1944; general discussion of bio-assay methods).

The ataxia in dogs is the most specific action of cannabis. It resembles that occurring after excision of the cerebellum. It is best observed in dogs, but occurs also in cats, and less typically in rabbits, monkeys and mice. It is considerably increased by amphetamine; it is not affected by amytal. *Scratching* is also a characteristic symptom in dogs. *Corneal anesthesia* in rabbits (on intravenous injection, not on local application, and not observed in dogs) was proposed as an assay method by Gayer, 1928. Reflexes in other locations are not abolished by cannabis. Psychic alterations have not been established for animals. The *Beam test*, an alkali color reaction, does not parallel the activity and has led to erroneous conclusions (S. Loewe, 1944).

Historical.—The Oriental use of cannabis as an intoxicant antedates recorded history, the tops or resin being made into a confection or smoked with tobacco. The Greek and Latin name cannabis is said to be derived from the Assyrian Kunnapu, and "hemp" is formed from the same root. It is known as Indian Hemp, Hashish, Bhang, Guaza, Gangja, Charas and Momeka. The name "marihuana," given to it in Mexico and Latin America, is said to be derived from maraguango, signifying an inebriant plant. Cannabis was introduced into therapeutics by Aubert-Roche, 1839, O'Shaughnessy, 1843, and Moxeau de Tours, 1843. Its use as an inebriant was rare in the United States before 1918 and did not become extensive until the last decade. Over 195 tons were confiscated by the Treasury Department in 1935. The hemp plant thrives practically in any climate and has long been cultivated in the Central States for its fiber and seed, but its narcotic properties were not generally known to the farmers until its recent notoriety.

The potency of the hemp plants is greatest in the resinous material exuded by secreting glands. It is much more abundant in the flowering tops than in the leaves. According to tradition, the female plants are more active; but in this country there is not much difference. The potency is said to decrease during the ripening of the seed, but this is also questioned. Hempseed contains an insignificant quantity of active substance. Hemp fiber is quite devoid of activity (Loewe). The hemp for fiber is marketed before the flowers are fully developed, and when the potency is low. The activity varies chiefly with the heredity of the plant, but environment has some influence. Plants grown in a dry, hot atmosphere, as that of certain regions of East India, are generally about twice as potent as those grown in America (Houghton and Hamilton, 1907, 1908; Walton *et al.*, 1937; S. Loewe, 1944). Different samples, however, vary considerably, and that used pharmaceutically is assayed on dogs for narcotic ataxia (U.S.P. IX). Experienced smokers in East India assay it subjectively with surprising accuracy (Chose and Bhattarcharji, 1935). The crude drug may lose activity quite rapidly (three-fourths in a year), but the extract and fluidextract are fairly stable (H. C Hamilton, 1913; Walton, 1938).

The active constituents of cannabis resin have been isolated by Roger Adams, 1940 (review, 1942), with identification of their chemical structure, as closely related aromatic derivatives. The most important are the isomeric *tetrahydrocannabinols*, which are solely responsible for the psychic actions in man and the ataxic effects in dogs (S. Loewe and Modell, 1941). They are chemically intermediate between two products that constitute the bulk of the resin-oil: the labile cannabidiol and the stable cannabinol. *Cannabidiol* determines a synergistic hypnotic action in mice. Cannabinol is not materially concerned in any of the characteristic actions. It has a feeble ataxic action on dogs (S. Loewe, 1945). The corneal anesthesia of rabbits is due to an undetermined constituent. Numerous synthetic cannabinol derivatives have been synthesized and examined. Many are active, but not as potent as the natural tetrahydrocannabinols (R. Adams, Loewe *et al.*, 1942; Alles, Haagen-Smit *et al.*, 1942; C. K. Aldrich, 1944). Cannabis also contains a volatile oil (terpenes), paraffin, pitch, etc., which are not concerned in its action. There is no specific alkaloid, but the extracts may give alkaloid reaction from the formation of choline and trimethylamine. These are not connected with the action. The fresh extract has a beautiful green color (if prepared without excessive heat), due to chlorophyl. The active principle is completely extracted by alcohol, but is insoluble in water.

The Extract (dose, 15 mg., ¼ grain) and the Fluidextract (dose, 0.1 cc., 1½ minims) were formerly in the U.S.P. The extract was about twenty-five times as strong as the fluidextract.

◆

PEYOTE (MESCAL)

"Peyote," misnamed "mescal buttons," consists of the tops of a small narcotic cactus, Lophophora williamsii (formerly Anhalonium lewinii), which grows in the Rio Grande region of the United States and Mexico. In Mexico "peyote" refers also to a number of other plants of varying kinds, which has resulted in much confusion (R. E. Schultes, 1937). It is dried and eaten by the Indian tribes of the Southwest in religious ceremonials, for the sense of well-being which it induces and sometimes to promote trances and hallucinations. Since 1885 the cult has spread extensively among the Negroes.

Blair, 1921, claims that the Indians are also using it as a habit drug, but Safford, 1921, states that its usage is still entirely ceremonial. Schultes, 1937, reports that the Indians consider it a panacea for practically all illness "as the White Man uses aspirin."

The cactus contains eight alkaloids structurally related to hordenine and the epinephrine series. They have been synthesized. Their actions differ somewhat (Lewin, 1888). Several are sedative. The most important is *Mescaline* (trimethoxyphenyl methylamine), which produces peculiar psychologic disorientations, with hallucinations of the special senses, particularly flashes and lines of ever-changing brilliant colors. They appear the same in both eyes and are therefore central (Dixon, 1899). A psychologic study of mescaline hallucinations was made by Knauer and Maloney, 1913. Waeber, 1912, failed to find the described visual and auditory effects and double personality, but observed other psychic and physical disturbances. Bresler, 1905, experimented with its actions on mentally deranged patients. E. Guttmann and Maclay, 1936, who administered small doses (0.1 to 0.2 Gm.) of the synthetic alkaloid orally to psychotic patients, classify the effects as depersonization (confusion of personality), derealization (unreality of environment) and hallucinations similar to those in schizophrenia. Mescaline and its related compounds produce a number of *other effects*, including fall of blood pressure (prevented by vagotomy or atropine), motor paralysis by depression of the central nervous system and death by respiratory failure (G. S. Grace, 1934). *Pellotine*, one of the alkaloids, was investigated by Pincussohn, 1907. *Anhaline* seems to be identical with hordenine (Spath, 1919). Mescal is not used therapeutically.

"Cactus."—Preparations from the cactus Cereus grandiflorus have been used as substitutes for digitalis, particularly in functional cardiac neuroses. Proprietary preparations have been widely advertised. Experiments on animals and men have shown them devoid of digitalis and strychnine actions and indeed absolutely inert. The clinical testimony is not conclusive. Careful observers have failed to find any clinical effects; those who describe positive results have perhaps undervalued the element of suggestion in the treatment of functional neuroses (report, Council on Pharmacy and Chemistry, 1910; J.A.M.A., *54:* 888).

The drug was introduced in 1864 by Rubini, a homeopathic physician. Boinet and Teissier, 1891, described a weak digitalis action on the frog's heart, produced by an alkaloid, which they considered derived from Cactus grandiflorus. They were evidently working with some other substance. No serious attempts were made to check on the extreme claims for the cactus preparations, until Hatcher, 1907; Matthews, 1908; Lyon, 1910; and Hatcher and Bailey, 1911, showed that even enormous doses of the best known preparations are practically inert—entirely so when given by mouth—in animals and in man, in health and in disease. Gordon Sharp, 1894, also found the clinical results negative when the genuine drug was used. The favorable clinical literature (summarized by Hatcher and Bailey, 1911) does not bear stringent criticism. Some of the discordant statements are probably due to *confusion with other cacti*. No alkaloid or other definite principle has been demonstrated in the grandiflorus, but alkaloids have been isolated from a number of cacti (Heffter, 1898): mescaline, anhalonidine, pellotine, pectenine, pilocereine, etc. Mogilewa, 1903, investigated their action on the heart and found that they produce slowing, without decrease of pulse volume (in contrast to digitalis).

◆

HARMALINE ALKALOIDS

Harmine is an alkaloid of the seeds of Peganum harmala, a plant growing in the steppes and wild places of the Mediterranean and East Indian belt, used since antiquity for a variety of conditions, especially as anthelmintic (review, J. A. Gunn, 1937). It is identical with *"banisterine,"* isolated from a South American liana, Banisteria *caapi*, which the natives of Guiana make into a mildly narcotic beverage, used in ceremonials and reported to produce visual hallucinations and dreams, at first pleasant, then horrifying (A. L. Chen and Chen, 1939). Several derivatives (harmol, harmalol, harmaline) act similarly. Harmaline constitutes about two-thirds of the alkaloid content of harmala seed. The chemical structure is related to quinine, and these alkaloids are toxic to amebae and protozoa and somewhat antimalarial. Harmaline acts on ascaris similarly to santonin (Flury, 1911).

Harmaline is used to relieve the tremor and rigidity of the postencephalitic *parkinsonian syndrome*, when they are referable to functional cerebral depression (Lewin, 1928; Beringer, 1928). Eichler, 1929, reported a favorable but transitory effect on voluntary motion and on the rigidity of the orbicularis muscle, but no effect on the tremor, salivation, seborrhea or on myotonic tics; nor does it produce euphoria like the hyoscine drugs. The mechanism is not fully explained. The improvement was attributed to cortical stimulation, with better regulation of the impulses and therefore better control of the movements. However, the action of harmine appears to be on subcortical centers, for it produces its typical motor and psychomotor effects (but not the convulsions) in cats whose cerebral hemispheres have been excised by two stage operation (A. G. Beer, 1939). It is ineffective clinically if there is extensive anatomical degeneration. Doses of 20 to 40 mg., hypodermically, are well tolerated (Dohmann, 1929).

The harmaline alkaloids produce a variety of central and peripheral actions, which have been investigated especially by J. A. Gunn and his associates, 1931. In mammals, they cause hallucinations (Lewin, 1928), tremors and clonic convulsions. They also excite the region of the pons which results in the swimming and running movements and stiffness of the extremities (M. Sato, 1935). Central motor paralysis predominates in frogs. Small doses raise the blood pressure and stimulate the respiration. Large doses depress the heart. Fatal doses intravenously kill by cardiac depression; hypodermically, by paralysis of respiration. Strong solutions produce contraction of skeletal muscle. Intestinal muscle is relaxed. The uterus is stimulated if relaxed, and always in intact animals; but high tonus in excised uterus is relaxed. The actions of various alkyl derivatives were studied by Elphick and Gunn, 1932. The relations of the actions of the chemical structure are discussed by Gunn, 1935.

Pukateine.—This alkaloid, prepared from the Pukatea tree of New Zealand, is a phenanthrene derivative. Its chemical structure is related to that of bulbocapnine and apomorphine, but its actions, studied by W. S. Fogg, 1935, are closer to those of morphine, and include analgesia and sleep (10 mg. in man). Large doses produce hyperexcitability toward abrupt stimulation, and death is preceded by convulsions similar to those of strychnine. The respiration stops before the heart.

Peripheral Actions.—Smooth muscle is generally depressed. The *heart* is slowed in mammals and frogs, partly by vagus stimulation, but chiefly by direct depression of the cardiac muscle, prolonging the refractory phase. It renders the ventricles more resistant to fibrillation by faradic stimulation. Perfused *blood vessels*, including the coronary, are dilated. The *blood pressure* falls even with small doses.

Khat.—The Khat habit among Oriental people consists in chewing the leaves of Catha edulis (Celastraceae), grown in Abyssinia, Arabia and Somaliland. They are also used as a tea. The leaves contain three characteristic alkaloids, with somewhat indefinite actions (R. Stockman, 1913).

Piscidia (Jamaica Dogwood) produces ataxia similar to that of cannabis (Pittenger and Ewe, 1919; *bio-assay*), and was introduced as a sedative, hypnotic and analgetic (Ott, 1883; Nagle, 1881). It is practically useless, however (Tyrode and Nelson, 1905). It contains a crystalline nonnitrogenous principle, "piscidin"; but this does not seem to be the bearer of the ataxic action (Pittenger and Ewe). Hauschild, 1936, reports on its toxicity. Death occurred by respiratory paralysis, with convulsions.

Lactucarium.—The dried milk juice of wild lettuce, Lactuca virosa, was introduced by Dr. Coxe of Philadelphia in 1799 as a sedative. The average dose is 1 Gm., 15 grains. Lettuce had some reputation as a hypnotic in ancient times, but it is probably undeserved. Kelterborn took 12 Gm. of Lactucarium without any effects. No active principle has been determined.

Lupulin and hops act as bitters and have some popular but exaggerated reputation as hypnotics. The average dose of hops is 2 Gm., 30 grains; of lupulin, 0.5 Gm., 8 grains. Hops are the dried pistillate flowers of Humulus Lupulus. The active principles are contained in small glands, which can be separated as a powder, and constitute the *Lupulin.* Two acids (*α- and β-lupulinic acids*) are present. They stimulate the respiratory and vagus centers; this is followed by depression. They also depress the cardiac muscle. Lupulin contains a further, unknown constituent which is insoluble in water and is a strong cardiac poison. Power, Tutin and Rogerson, 1913, also found a trace of alkaloid. All these, however, are not active when administered by the stomach and are therefore not concerned in the action of the drug.

Loco Disease.—Horses, cattle and sheep on the Western stock ranches are subject to a peculiar disease which bears some resemblance to drug habits. The symptoms consist in motor incoordination, forced movements, misjudgment of distance, stupidity, apparent hallucinations. In the chronic form there is emaciation. Death is preceded by coma and convulsions. The cause of these conditions is obscure. It is generally attributed to feeding on certain leguminous plants ("loco weeds"—especially Astragalus). C. D. Marsh, 1909, claimed to have reproduced the condition experimentally by long-continued feeding with these plants, but H. T. Marshall, 1914, considered the results inconclusive. Later work shows that the loco weeds thrive in areas with high selenium content in the soil, and raises the question of the share of this element in the symptoms (see Selenium in the Index)

◆

LOCAL ANESTHETICS

Many substances of widely different chemical structure abolish the excitability of nerve fibers on local application, in concentrations which do not cause any permanent injury, and which may not affect other tissues. Sensory nerve fibers are most susceptible, so that these agents produce a selective sensory paralysis, which is utilized especially to suppress the pain of surgical operation. This property was first discovered in cocaine, but because of its toxicity and addiction liability, this has been largely displaced by synthetic chemicals. The oldest of these, procaine (novocain), is still the most widely used. Its relatively low toxicity renders it especially useful for injections, but it is not readily absorbed from intact mucous membranes and is therefore not very effective for them. Many of its chemical derivatives are also used. These and others have a changing vogue. They differ in penetration, toxicity, irritation and local injury as well as in duration of action and potency. Absolute potency is not so important for practical use as is its balance with the other qualities. If cocaine is absorbed in sufficient quantity, it produces complex *systemic actions*, involving stimulation and paralysis of various parts of the central nervous system. These are mainly of toxicologic and scientific interest. Its continued use leads to the formation of a habit, resembling morphinism. This is not so with the other local anesthetics.

Historical.—Cocaine is derived from the leaves of Erythroxylon Coca, a tree indigenous to Peru, Chile and Bolivia. It is now cultivated in other tropical countries. The leaves were chewed by the Incas of ancient Peru, chiefly in religious ceremonials, and prohibited to the common people. Their use spread rapidly after the Spanish conquest. It is now almost universal among the natives of the mountain districts of Peru, Bolivia and northern Argentina, who value their "ration" more than wages. It is popularly believed to be indispensable for strenuous labor at high altitudes, relieving fatigue and hunger. It has extended into the cities, including those of Equador, Chile and Colombia. The number of coca chewers is estimated as eight millions, almost exclusively of Indian race (Gutiérrez-Noriega, 1944; P. J. O. Wolff, 1940). In East India it is combined with the chewing of betel (Chopra, 1931). In Europe, trials with the leaves gave disappointing results. The discoverers of cocaine (Woehler; Niemann and Lossen, 1860) described its benumbing action on the tongue, without realizing its significance. As late as 1880 a British medical commission reported on the drug as merely a poor substitute for caffeine (J. U. Lloyd, 1911, "History of Vegetable Drugs"). In the same year, Anrep subjected cocaine to a more thorough pharmacologic investigation. In 1884 the Vienna oculist K. Koller was engaged in pharmacologic experiments with cocaine, and it occurred to him that the numbing effect on the tongue is anesthesia. Realizing the potential importance of local anesthesia, he tried the cocaine immediately on the eyes of animals, and then in the clinic, and announced the discovery to the German Ophthalmologic Society (Koller, recollections, 1941). Its practical value was at once generally recognized. Einhorn in 1899 (Annalen d. Chemie) demonstrated the production of local anesthesia by esters of aminobenzoic acid, and in 1905 introduced procaine (novocain). The history of local anesthesia in dentistry is described by Tainter, 1940. Prurifacients are used by West African natives to obscure the pain of circumcision and tribal scarification (G. W. Harley, 1941).

Peripheral Nerves.—Direct contact with cocaine, procaine and most of the other local anesthetics paralyzes all forms of nervous tissue, without preceding stimulation. The susceptibility of the various nerve fibers presents marked and characteristic quantitative differences. Sensory fibers are most easily attacked. By using appropriate dilutions, the paralysis is as complete as if the nerve fibers had been severed with a knife. If the drug is washed away, or absorbed, the nerve recovers its functions promptly and completely (but very strong solutions of cocaine may produce neuritis and permanent paralysis). Since these effects are strictly local, the anesthetic agent must be applied in such a way that an effective concentration reaches the nerve supply of the part which it is desired to affect. This may be accomplished by painting a solution on mucous membranes (from which cocaine is very readily absorbed); or by injecting it into or under the skin (infiltration and subcutaneous anesthesia); or around or into the nerve trunk (peri- or intraneural anesthesia); or around the spinal nerve roots (subdural or spinal anesthesia). The intact skin is practically impermeable even to cocaine, although this penetrates slightly if the skin has been macerated (Macht *et al.*, 1916).

Comparison of anesthetic efficiency may be attempted by a number of experimental methods. In transferring the results to clinical problems, the conditions of the clinical use must be borne in mind (Sollmann, 1918).

Intracutaneous injection (the "wheal" or "quaddel" method of H. Braun), observing either the duration or, better, the threshold values of the anesthesia, reproduces practically the conditions of *infiltration and of injection anesthesia.* When combined with epinephrine, it also measures absolute anesthetic efficiency. The ratio by this method is as follows:

Effective Percentage	*Intracutaneous Injections*	*Efficiency Ratio*
$\frac{1}{32}$	Cocaine, procaine, tropacocaine, and alypin hydrochlorides	1
$\frac{1}{16}$	Beta-eucaine and apothesine hydrochlorides	$\frac{1}{2}$
$\frac{1}{8}$	Quinine-urea hydrochloride	$\frac{1}{4}$
$\frac{1}{4}$	Antipyrine, potassium sulfate	$\frac{1}{8}$

The susceptibility of different skin areas varies, even in the same neighborhood, so that discordant results are sometimes obtained. The solutions should be approximately isotonic (3.5 per cent or higher, corresponding to 0.55 to 2.5 per cent NaCl). Stronger and weaker solutions are first irritant, then anesthetic, even when indifferent salts are used (Braun, 1914). A method of hypodermic standardization by dogs is described by Pittinger, 1921. Loewe, 1936, utilizes the *pseudohernia* reaction (depression of postural reflex tonus).

Mucous Membranes.—The skin of the frog's foot is most convenient; but rabbit's cornea (or guinea pig cornea, Chance and Lobstein, 1944) corresponds more closely to clinical conditions. It must be remembered, however, that the absorbability, and therefore the ratios, would differ for various mucosae. The results on the cornea are as follows:

Percentage	*Rabbit's Cornea*	*Efficiency Ratio*
½	Cocaine and phenacaine (holocaine) hydrochlorides	1
1	Beta-eucaine hydrochloride	½
2	Tropacocaine, alypin and quinine-urea hydrochloride	¼
4	Apothesine hydrochloride	⅛
8	Procaine hydrochloride	1/16
10	Antipyrine, KCl	1/20

Modifications of the methods for testing local anesthesia on rabbit's cornea and on the frog's sciatic are described by Rider, 1930.

Sensory nerve fibers of frogs may be tested through reflexes. The results correspond to the conditions of "nerve blocking." (Sixty seconds' immersion seems to give the best comparative results; Munch *et al.*, 1933.)

Percentage	*Sensory Reflex*	*Efficiency Ratio*
¼	Cocaine, procaine and tropacocaine hydrochlorides	1
2	Quinine-urea hydrochloride	⅛
8	Antipyrine	1/32

Paralysis of the motor fibers of the excised nerve trunks of frogs gives concordant results, especially when evaluated by nerve action potentials (Bennett *et al.*, 1942). The absolute values cannot be transferred to sensory paralysis, but the ratio of potency is similar.

Percentage	*Motor Fibers*	*Efficiency Ratio*
⅛	Cocaine, procaine and tropacocaine hydrochlorides	1
¼	KCl	½
1	Quinine-urea hydrochloride and antipyrine	⅛

Spinal anesthesia may be compared on frogs (Bieter and Brown, 1934).

Selective Action on Motor and Sensory Fiber.—When a ½ to 2 per cent solution of cocaine is injected into a mixed nerve or into the subdural canal, the selective action is marked, so that there is complete anesthesia without motor impairment (Alms, 1886). If the contact is prolonged, by stopping the circulation, or if stronger solutions are employed, the motor fibers become paralyzed, so that the difference is merely quantitative. A similar difference in the susceptibility of motor and sensory structures exists also for the alcohol group, aconitine, phenol, hydrocyanic acid and for pressure (Luedvitz); and even for the centrally acting narcotics, ether, etc. It is therefore a characteristic of nervous tissue rather than of cocaine. It is now generally accepted that the selective action in peripheral nerves is due chiefly if not entirely to the ratio of penetration, determined by *differences in the size of the myelinated nerve fibers*, especially the thickness of the myeline sheath for it follows this order closely, the smallest fibers being blocked first, the largest last (Gasser and Erlanger, 1929; Heinbecker *et al.*, 1934; A. J. Clark, 1937).

Peripheral Paralysis of Special Sense Nerves.—Cocaine and other local anesthetics abolish not only the sensation of pain, but other special sensations, if they are suitably applied. Here also there is some selection. *In the skin*, they paralyze first the vasoconstrictor reaction, then progressively the sensation of cold, warmth, touch, tickling, pressure, pain, "joint sense" (Heinbecker *et al.*, 1934). *In the nose*, they abolish the olfactory sense. *On the tongue*, they destroy the taste for bitter substances, but have less effect on sweet and sour taste, and none on salty taste When cocaine is applied to the appropriate nerves, it is found that the centrifugal *vagus fibers* are paralyzed before the centripetal; vasoconstrictor fibers before vasodilator; bronchial constrictors before the dilators, etc (Dixon, 1904).

Site of Action.—Local anesthetics paralyze the nerve fibers anywhere in their course, wherever they are brought into contact with them. When applied to mucous membranes or hypodermically, they select the portions peripheral to the main trunks, the thinner sheath of the terminal fibrils facilitating its penetration. It is unnecessary to assume a selective action on the histological sensory endings.

Nature of Action.—This appears to be functional. No structural changes have been demonstrated in the nerve fibers.

Chronaxia.—Subparalytic concentrations of cocaine raise the rheobase. The chronaxia is first lowered, then remains at a low level, and then rises. These effects occur in motor as well as in sensory fibers, but motor fibers require a ten times higher concentration (Cardot and Regnier, 1927). Different nerves show differences in the relation of rheobase and chronaxia (Fieschi, 1934). If skeletal muscle is immersed in procaine solution, indirect stimulation shows the increase of rheobase and decrease of chronaxia, but direct stimulation gives increased chronaxia and unchanged rheobase (Siems, 1933).

The oxygen consumption of nerve is decreased by cocaine, procaine and urethane, approximately in the ratio of their anesthetic concentrations; but some substances not anesthetic have the same effect (Sherif, 1930). *Carbon dioxide production in nerve* was investigated by Niwa, 1919, on frog's sciatic nerve with the Tashiro method. He found the same effects from cocaine as from the aliphatic narcotics: Subanesthetic concentrations increased the production; with anesthetic concentrations this increase was short or absent, the main phenomenon being decreased production.

Combination of Anesthetics.—The efficiency of mixtures of the local anesthetics corresponds to more or less complete summations, generally without potentiation: If solutions of different anesthetics are diluted until they are "just effective," then a mixture of any two of these solutions will also be "just effective," no more and no less (A. Schmidt, 1933; Sollmann, 1918; Rider, 1930). There would be little or no practical advantage in such mixtures.

Potassium Synergism.—Potassium salts may give considerable potentiation with the other anesthetics (A. Hoffmann and Kochmann, 1914). However, this seems to hold mainly for motor fibers and not for sensory (Sollmann, 1918). One per cent potassium chloride could be used with some advantage in place of sodium chloride for making up isotonic anesthetic solutions (H. Braun, 1913).

Alkalinization.—The addition of sodium bicarbonate increases the potency of most local anesthetics two to four times, for direct application or injection into nerve trunks, and probably for subdural injection and on application to mucous surfaces. This is due to the easier penetration of the free anesthetic bases, as compared with their salts (O. Gros, 1910; Sollmann, 1918; Rider, 1930). It does not apply to nupercaine and pontocaine, since these are precipitated by alkalinization. Acidification diminishes the potency of all (Beutner and Bradlow, 1943).

The usual solutions of the anesthetic salts may be mixed with an equal volume of 0.5 per cent sodium bicarbonate solution, without loss of efficiency, and with a saving of one-half of the anesthetic, and correspondingly smaller danger of accidents. The mixtures, however, do not keep well, and must be made just before use (Sollmann, 1918; Gwinn and Ferber, 1936). Alkalinization or buffering has *no advantage for hypodermic or intradermic injections*, since these do not require much penetration (Tainter *et al.*, 1939). For injection of the mandibular nerve in dentistry, alkalinized solution of procaine has somewhat quicker and shorter action, but the degree of anesthesia averages about the same (R. J. Boothe, 1941). Procaine base dissolved by the aid of carbon dioxide is more potent than the hydrochloride when applied to the cornea, but not for intramuscular injection (Beutner, 1939).

The *effects of temperature on local anesthesia* of frog's nerve differ for various types of anesthetics: cocaine, salicylamide and monacetine are more effective on cooled nerves; alcohol and chloral are more effective on heated nerves. This is probably connected with differences in solubility and the "partition-coefficient" (H. Moral, 1918).

Other Synergisms.—Addition of 0.1 to 2.5 per cent of *urea* to dilute procaine solutions materially increases their potency, to ten times, on direct application to nerve trunks, presumably by favoring penetration. The effect is not due to alkalinization (Guntermann, 1939). The action of local anesthetics is reported to be increased by intravenous injection of *methylene blue;* by the local application of *caffeine* or *theophylline* (Lipschitz and Weingarten, 1928); and by *milk injection fever* (Dannenberg, 1934); by morphine (Arima, 1935) and by the antipyretic analgetics (Stender, 1929). Cocaine anesthesia is said to be ineffective in tissue impregnated with *oxalic acid* (Velkers, 1935). Inflamed tissues are less susceptible to local anesthesia, probably because of their difficult penetration.

Epinephrine-Anesthetic Combinations.—H. Braun, 1903, confirmed that the anesthetic effect of cocaine injections is materially improved by the addition of epinephrine (about 1:50,000). The duration of the anesthesia is prolonged for over an hour. The effective concentration can therefore be considerably lowered, and the danger of poisoning greatly reduced. These results are due to the vasoconstriction, which practically arrests absorption into the circulation. On the other hand, the nervousness induced by epinephrine in hypersensitive individuals may make them more susceptible to cocaine collapse. The greatest field for the epinephrine combination is that of operations involving bleeding. It is useless on the intact cornea (Sollmann, 1918). Epinephrine is similarly efficient with procaine and most other local anesthetics.

Its effect is not as pronounced with stovaine, and is practically absent with tropacocaine, since 0.1 per cent of this destroys the vasoconstriction effect of epinephrine (Smyth, 1911). Beta-eucaine also counteracts epinephrine (Braun, 1914).

Epinephrine is not directly anesthetic either alone or in combination with cocaine; it does not increase the anesthetic effect when the circulation has previously been arrested, nor does it lower the threshold concentration in wheals, although the duration of the anesthesia is greater for a given concentration (Sollmann, 1918).

Local Vascular Action.—Cocaine produces vasoconstriction (blanching), probably by sensitizing to sympathetic stimulation. This action is lacking in the other local anesthetics. Procaine has practically no vascular effect; alypin, eucaine and stovaine cause some dilatation (Impens, 1905; Behr, 1934). Cocaine decreases *capillary hemorrhage;* procaine, apothesine and other synthetic anesthetics tend rather to increase bleeding.

The application of cocaine to mucous membranes, particularly the inflamed conjunctiva, constricts the capillaries and small arterioles, resulting in blanching, astringent sensation and contraction of vascular formations, such as polypi. The action is localized and thus peripheral. It occurs after excision of the adrenal glands and is therefore not due to synergism with circulating epinephrine (W. H. Crosby, 1939).

Vascular perfusion experiments (by the Trendelenburg method) have given contradictory results for cocaine. Abe, 1920, found that this depends on the species of frogs. *Procaine* added to perfusion fluid, 1:10,000 to 2:1000, prevents the vasodilating effect of acetylcholine, or of work on the hind leg of dogs or cats (Fleisch and Weger, 1938).

Antiphlogistic Action.—It was claimed by Bruce, 1913, Januschka and Bardy, 1915, and others that local anesthesia prevents the congestive and inflammatory action of mustard oil on the conjunctiva. Other workers consider the differences within the limits of experimental error (Stevenson and Reid, 1915).

General Toxicity to Protoplasm.—Cocaine is a rather weak protoplasmic poison, paralyzing all sorts of cells, without producing gross chemical changes. It is toxic to the lower forms of animal life (infusoria, etc.), but has little effect on bacteria or ferments.

Precipitation of Proteins and Astringency.—Neither cocaine nor the synthetic local anesthetics precipitate proteins; they are therefore not astringent in the ordinary sense, nor irritant (Sollmann, 1919; alypin, anesthesine, apothesine [slightly], cocaine, cycloform, holocaine, orthoform-new, procaine, propaesine).

Antiseptic Action.—Benzyl alcohol, beta-eucaine and holocaine are antiseptic; cocaine and procaine are not (Macht and Satani, 1920).

Yeast growth is inhibited by small quantities of cocaine, but larger doses accelerate it (Somoggi, 1916).

The *toxicity for earthworm and tadpoles* is not parallel to the toxicity for mammals (Sollmann, 1919).

The **practical application of local anesthetics** involves considerable art which must be learned in the clinic. It falls into two divisions: (1) surface application to the mucous membranes, especially of the eye, nose, throat and urethra; and (2) injections about nerves, in different parts of their course and distribution, from their spinal roots to their ultimate fibrils. The advantages and disadvantages in comparison with general anesthesia, and the selection of the local anesthetic agent also depend on clinical discrimination. Nervous, fearful and excitable patients often suffer severely from apprehension. This also disposes toward accidents. It may be at least somewhat quieted by sedatives (morphine hypodermically) half an hour before the operation, or by barbiturates, which also tend to prevent convulsions.

The *onset of the action* depends on the penetration into the nerve fibers, and the *duration* on the sojourn of the drug. In general, the sensation becomes blunted in a few minutes, but the anesthesia does not reach its maximum for ten to twenty minutes, and lasts ten to thirty minutes after a single application. The duration depends more on the concentration than on the total amount of the agent, so that it is more economical to use small quantities in high concentration, repeating if necessary (Sinka, 1939).

Local Ischemia.—As the anesthetic agent is absorbed and thus removed from the site of application, its local action ceases and its systemic and toxic effects start. Since most of these drugs, especially cocaine, are rapidly destroyed in the body, the systemic toxicity increases with the rapidity of absorption. It is therefore desirable and often necessary to delay the absorption restricting the local circulation by adding epinephrine. More dilute solution may thus be used, and the anesthetic effect is much more prolonged. With intracutaneous infiltration, the pressure and edema also result in ischemia. In suitable situations, the circulation may be slowed by bandages, or arrested by temporarily clamping the arterial blood supply.

Interruption of the circulation was introduced by Corning in 1885. He showed that this makes $\frac{1}{4}$ to $\frac{1}{2}$ per cent cocaine solution more effective than the 2 to 10 per cent solutions then in vogue, and that it greatly diminishes the danger of poisoning (H. Braun, 1914). Persistent ischemia itself, as by ligation of the artery, gradually induces anesthesia, but without drugs requires hours and therefore has no direct share in the ordinary application of local anesthetics.

Surface Anesthesia.—Anesthesia from intact surfaces requires that the drug must be absorbable. This practically excludes the intact skin, although nupercaine and pontocaine in aqueous or oily media are somewhat anesthetic (W. Laubender, 1939). Cocaine, butyn, metycaine and diothane are readily absorbed from mucous membranes, and are therefore efficient, but also correspondingly toxic. Procaine and apothesine are relatively inabsorbable and therefore less applicable. Alypin and beta-eucaine are intermediate, but the order of absorbability varies for different mucosae.

Ophthalmic Anesthesia.—Cocaine, 4 per cent, or butyn, 2 per cent, is applied to the conjunctiva for deep penetration, as in cataract operations; phenacaine (holocaine), 2 per cent, or butyn, 2 per cent, for surface action (foreign bodies), etc. Procaine is too feeble. Toxic manifestations are rare and slight since only small quantities are used. For infiltration, 2 per cent procaine is advised. Several of the anesthetic agents produce some *conjunctival irritation*, smarting and congestion. Cocaine blanches the conjunctiva, but cloudiness and even ulcers of the cornea sometimes follow its application; they are partly explainable by the drying, and the irritation by dust and other foreign matters not perceived on account of the anesthesia, and the abolition of the winking reflex. The protoplasmic toxicity may have a part in their production.

The *relative efficiency* of several local anesthetics for the conjunctiva was shown in the tabulation. Stovaine requires about seven times the concentration of cocaine (Regnier, 1923). The addition of epinephrine does not enhance the local anesthetic action on the conjunctiva (Sollmann, 1918). Experimental data are given by Closson, 1914. It is difficult to estimate degrees of irritation on animals.

Actions of Cocaine on the Eye.—Cocaine, applied to the conjunctiva, produces local anesthesia (which may not extend to the iris); local anemia (which extends to the iris, but not to the retina); and submaximal dilatation of the pupil by peripheral sympathetic stimulation. Mydriasis occurs also on systemic administration. The accommodation is impaired, but the light reflex is preserved; there is some exophthalmos. The intra-ocular pressure is usually lowered, but may be increased. The mydriasis and its associated phenomena are not produced by most of the cocaine substitutes.

A single application of 2 per cent cocaine produces complete anesthesia of the conjunctiva and cornea, starting in two minutes and lasting seven to ten minutes. If 5 per cent cocaine is instilled every three minutes for half an hour, the anesthesia generally extends also to the iris.

The *cocaine mydriasis* differs from atropine mydriasis: with atropine the dilatation is greater; the light reflex is preserved; the intra-ocular tension is always raised; exophthalmos is absent. The pupil does not react readily to pilocarpine or muscarine, while these constrict the cocaine pupil easily. These differences point to a different mode of action: Atropine paralyzes the oculomotor (constrictor) endings, while cocaine stimulates the sympathetic (dilator) mechanism; for when the sympathetic fibers have degenerated (eight days after extirpation of the superior cervical ganglion), ordinary doses of cocaine cease to be effective (Limbourg, 1892). Dilatation may still occur, however, with large doses or under special conditions. Simple (postganglionic) division of the sympathetic does not immediately abolish the cocaine reaction; the stimulation must therefore involve the endings; but since the dilatation is not as strong, it would seem that, ordinarily, the pupillo-dilator center is also concerned (Schultz, 1898). Under ordinary conditions the cocaine pupil continues to respond to oculomotor stimulation, showing that the constrictor mechanism is not paralyzed. Prolonged application of a 5 per cent solution, however, also paralyzes the oculomotor endings. Cocaine also inhibits isolated sphincter muscle (Yonkman, 1930). *Procaine* dilates the pupil, normal and denervated, from the blood stream (MacGregor, 1939). In *birds' eyes* cocaine produces no dilatation; in *frogs* this is marked.

Cycloplegia.—Strong solutions of cocaine act somewhat on the oculomotor endings, and therefore impair accommodation. This begins in five or ten minutes. The maximum is reached in thirty minutes and lasts ten to fifteen minutes; the normal is restored in one and one-quarter to two hours. The accommodation is merely disturbed by a drop of 6 per cent solution; high concentrations paralyze it completely. The mydriasis develops somewhat more slowly and is more lasting (Horovitz, 1912).

Intra-Ocular Pressure.—This may be unchanged, or raised or lowered (Tourriere, 1913). The reduction is probably due to the local vasoconstriction, which would tend to lessen the lymph flow into the chambers. This is partly counteracted by the mydriasis, which leads to obstruction of the lymph channels by the relaxed ciliary muscles (see "Atropine"). This obstruction may predominate and the pressure may thus be increased, especially in glaucoma (Myashita, 1913). Holocaine is said to have provoked acute glaucoma (Gjessing, 1915). Tropacocaine and acoine are probably inactive (Bollet and Curtil, 1911). The *retinal vessels* are strongly constricted by cocaine (Hirschfelder, 1915). This may be responsible for the occasional occurrence of optic atrophy (Harnack, 1912).

Catarrh, Hay Fever and Asthma.—Cocainization of the nasal mucous membrane may temporarily relieve attacks of hay fever and asthma. The astringent action renders it effective in acute coryza. The *danger of addiction* should preclude its use in these conditions; many cases were started by proprietary catarrh "cures." One per cent cocaine ointment has been recommended in *herpes zoster;* it is reported not only to relieve the pain, but to arrest the disease.

Urethra and Bladder.—The urethra is a good absorbing surface and has often given rise to poisoning. This danger is minimized by using dilute solutions. Even procaine is fairly effective. Metacaine, 1 to 4 per cent, is commonly used. With dog's urethra the hydrochlorides of alypin and tropacocaine are absorbed somewhat better than cocaine; apothesine, beta-eucaine and procaine are absorbed somewhat less efficiently; but the differences are not great. The rate of absorption increases with the dose and concentration. The absorption is more rapid during the first ten minutes, but continues quite markedly after this time. Alkalinization does not increase the absorption (Sollmann, 1918).

In *rectal surgery,* the action of local anesthetics can be greatly prolonged by applying them in oily solution (C. H. Morgan, 1935). Cocaine locally relieves *hemorrhoids,* producing contraction and diminishing pain. It has been taken by the stomach to prevent *vomiting* and dyspeptic pain. The addiction danger renders these uses inadvisable.

Dentine.—Dental enamel offers an effective barrier, and even with exposed dentine the anatomical arrangement of the tubules precludes sufficient penetration to produce effective local anesthesia. Apparent results are psychical. This holds also for the mixture devised by L. L. Hartman, 1936: thymol 1.5, alcohol 1 and ether 2 parts (Tainter, 1939).

Insoluble Anesthetics for Open Wounds and Ulcers.—The soluble anesthetics are absorbed too rapidly to be of material use in persistent pain. The limited and slow solubility of the free synthetic bases renders them more adapted to these conditions, but their practical usefulness is not great. They are employed for painful wounds, ulcers, etc., of the skin and accessible mucous membranes; for instance, after dental operations. Ethyl aminobenzoate (benzocaine, anesthesine) may be applied diluted with 5 to 20 parts of talcum or boric acid; or lozenges of 0.01 to 0.02 Gm. A 0.5 per cent emulsion of ethylaminobenzoate base in a synthetic resin-glycerin monostearate and water vehicle is more effective than a saturated solution in oil, and is especially useful for burns (R. Beutner, 1944).

Insoluble anesthetics have been used against the pain of gastric ulcer or cancer and other gastralgias, but their efficiency is doubtful. Anesthesine, cycloform, orthoform-new and propaesin are about equally effective through intact mucous membranes (Sollmann, 1919). They are practically nonirritant and nontoxic.

Conduction and infiltration anesthesia consists in the injection of the local anesthetic into or around the nerve trunk or in the area of its distribution, so as to block sensory impulses from the operative field. Since fatal effects may arise from the absorption of the anesthetic, the smallest amount of the least toxic agent that is effective should be employed, under conditions which minimize absorption. Procaine with the addition of epinephrine (1:100,000) is generally preferred. A well planned technic is important. It is not necessary to flood the entire field of operation, as in the earliest methods; nor even to infiltrate the whole line of incision, as in the "infiltration anesthesia" of Schleich (1892). It is now aimed to confine the anesthetic mainly to the nerves, by placing it where the nerves chiefly run, or injecting it into the nerves themselves (H. Braun).

Infiltration with oil solutions produces Wallerian degeneration of the nerve fibers, and therefore persistent paralysis. This was most marked with nupercaine, least with eucupine, procaine base being intermediate (D. Duncan, 1939).

Intravenous and intra-arterial anesthesia were introduced by Bier, 1908, and have a limited field, but are generally unsatisfactory and dangerous (Bevan, 1915). The action of cocaine is sufficiently selective so that a marked, though incomplete, general analgesia, without disturbance of consciousness or motor functions, can be produced by intravenous (Ritter, 1909; Harrison, 1911) or intra-arterial (Ransohoff, 1909) injection even without ligation.

Spastic Rigidity of Skeletal Muscles.—Local injection of 0.1 to 2 per cent procaine or other anesthetics blocks centripetal proprioceptive impulses and depresses the muscle, relaxing muscular tonus, normal and abnormal, such as spasmodic torticollis. It effects almost instantaneous relief of the pain, stiffness, malposition and incapacity of fibrositis, lumbago, acute sprains and fractures (Moynahan, 1939). The site of greatest tenderness may be infiltrated with 10 to 30 cc. of 1 or 2 per cent procaine hydrochloride (Outland and Hanlon, 1940). Even 1 or 2 cc. may give prompt, complete and often lasting relief in myalgia (M. Good, 1942).

Injected systemically, procaine relaxes traumatic tetanus (E. Meyer and Weiler, 1916 and 1917) and removes decerebrate rigidity, so that spontaneous movements of the limbs and of the respiration return. Its curare action may also be concerned in this effect. It relaxes Parkinsonian, but not myotonic rigidity (Allers and Hockstaedt, 1928; Liljestrand and Magnus, 1929). It has some systemic analgetic action (10 cc. of 2 per cent procaine hydrochloride), about comparable to that of acetylacetic acid, but not as lasting (Bigelow and Harrison, 1944, Wolff's method).—*Serum sickness* and *urticaria* are relieved by *intravenous injection* of procaine hydrochloride, 1 Gm. in 500 cc. of saline in the course of two hours. No untoward reactions were observed with this slow rate, but faster injection produces flushing, dizziness and generalized numbness (State and Wangensteen, 1946).

Spinal anesthesia is really nerve root anesthesia, produced by lumbar or sacral subdural injection of procaine or other local anesthetics, which anesthetizes the sensory nerve roots at their emergence from the spinal cord, and abolishes sensation in their entire peripheral distribution, beginning in two to ten minutes, and lasting half an hour to two hours. There is little if any interference with motor functions. Consciousness is, of course, preserved. The anesthesia extends to the level of the nerve roots reached by the anesthetic, the aim being to confine it to the lower half of the body. If it extends to the fourth ventricle, it paralyzes respiration. Other side actions consist in fall of blood pressure, in severe headache which may sometimes last for days or weeks; and in cord injury. Bronchial pneumonia and atelectasis are fairly common (Apgar, 1939). Spinal anesthesia may cause more psychic shock than does general anesthesia, but usually less somatic disturbance. It is *especially useful* in pulmonary disease, arteriosclerosis, bladder and rectal operations, impending uremia and in diabetic patients. It is more difficult and more dangerous for operations above the costal margin. If the respiration stops, artificial respiration is the most effective treatment (E. F. Hill and MacDonald, 1933). Strychnine and caffeine have little or no value. Epinephrine or ephedrine is injected if the blood pressure falls.

Historical.—Spinal anesthesia was demonstrated by Corning of New York in 1885 and introduced into practice by Bier, 1899, but it was then abandoned, and did not come into vogue until about 1904.

Technic.—The patient generally receives a preliminary sedative, morphine or barbiturate. The injection is performed by lumbar puncture, withdrawing some cerebrospinal fluid and injecting 3 to 5 per cent solution of procaine hydrochloride. The average dose is 1 mg. of drug per pound of body weight, the total not to exceed 200 mg. The slower the injection, the less the spreading. Increase of concentration produces longer anesthesia and greater relaxation, but more risk of damaging the nervous tissue. Ten per cent should not be exceeded. Pontocaine has been recommended for operations lasting longer than half an hour (F. W. Marvin, 1933). Epinephrine may be added; or ephedrine, 50 to 100 mg., may be injected intramuscularly, ten minutes in advance to counteract the fall of blood pressure. The spread of the anesthetic solution may be diminished by increasing its specific gravity by adding 5 per cent of dextrose, or its viscosity by 5 to 15 per cent of acacia (Smith and Porter, 1915). A special technic for spinal anesthesia of the chest was elaborated by Etherington-Wilson (Bourne, 1939).

Phenomena of Spinal Anesthesia.—These occur in the following order: loss of knee jerk; of plantar and cremasteric reflex; ascending analgesia; later, ascending loss of motor power. The upper limit is usually quite abrupt. Minor temporary motor paralysis occurs rather frequently if the dose is fairly large, not otherwise (J. L. Emmett 1934). Subjectively, there is an ascending feeling of warmth, swelling and heaviness. Occasional *toxic effects* are pallor, nausea, vomiting, sweating, feeble pulse, relaxation of sphincters, dyspnea. The most frequent *after-effects* are headache and insomnia. *Order of disappearance of sensation from the skin:* Baglioni and Pilotti, 1910, state this at first, of pain; then, after some time, cold; then, soon, heat. Finally, pressure. Recovery occurs in the reverse order. *To paralyze the anterior roots* would require a concentration about four times as high as suffices for the posterior roots (Sebastian). The *intestines* are firmly contracted and quiescent, probably from the morphine. Spinal anesthesia with procaine promptly abolished *paralytic ileus* produced experimentally in dogs by peritonitis or severe intra-abdominal trauma (Markowitz and Campbell, 1927).

Fall of blood pressure is a common phenomenon of spinal anesthesia (especially in patients with essential hypertension; R. Gregory *et al.*, 1943). Smith and Porter, 1915, found that it is due to paralysis of the splanchnic fibers in the cord, not in the medulla. Epinephrine with tropacocaine or procaine caused an even greater fall. Measures to restore the pressure were only temporarily successful. As the effects of the anesthetic began to wear off, sciatic stimulation produced a fall, instead of the normal rise. *The combined action of stovaine and strychnine* on the cord was investigated by Aron and Rothman, 1909; and Simon, 1915. The two drugs are not antagonistic; and strychnine does not render stovaine any safer.

The *spinal injury* depends on the nature, amount and concentration of the anesthetic agent. It is rather rare clinically when procaine is used in concentrations of less than 8 per cent. The nerves exposed to the greatest concentrations are most affected (M. J. Nicholson and Eversole, 1946). It is more common with some of the other anesthetics, *f. i.*, nupercaine. Higher concentrations of procaine in animals result in aseptic meningeal inflammation and degeneration of the myelin in the cord, with permanent paralysis (L. Davis *et al.*, 1931; Lundy *et al.*, 1933; Brock *et al.*, 1936, reviews the literature).

Injection of local anesthetics in the cisterna magna or local application to the fourth ventricle results in depression (chiefly in amplitude) and paralysis of the respiration, sharp fall of blood pressure and slowing of the heart, abolition of conjunctival and pupillary reflexes. The respiratory and vasomotor centers respond fairly well to stimulation by carbon dioxide; reflex stimulation is less effective. The animals can usually be saved by prompt artificial respiration (Hill and MacDonald, 1933; Nicholson and Sobin, 1936). Injection of ephedrine (2.3 mg. per Kg.) into the cisterna shortens the respiratory paralysis and hastens the return of the reflexes, much more effectively than intravenous injection. This may be useful in emergencies (Isenberger and Rice, 1936).

Caudal sacral anesthesia, injection below the termination of the spinal cord, blocks sensation from the urinary bladder, posterior urethra and uterus. *Continuous caudal analgesia,* by repeated injections of the local anesthetic, is used in obstetrics. It abolishes pain without interfering with the uterine movements. It relaxes the cervix, which is kept contracted by parasympathetic impulses through the second, third and fourth sacral nerves (R. A. Hingson, 1944). Spinal anesthesia heightens the response of the pregnant uterus to mechanical stimulation (P. Malpas, 1944).—*Intravenous injection* has also been tried successfully in obstetrics to dull the pain of the second stage of labor, presumably by central action (F. M. Allen, 1945).

Sympathetic Stimulation.—The phenomena of systemic cocaine poisoning are largely those of sympathetic stimulation, but not so consistently as with epinephrine (D. F. MacGregor, 1939). The sympathetic stimulation is mainly central (midbrain), but partly peripheral. The chief manifestations of sympathetic stimulation are (1) sensitization to epinephrine, but antagonism to ephedrine by peripheral action; (2) mydriasis and slight exophthalmos by central and peripheral action; (3) cardiac acceleration (chiefly central). Other sympathetic symptoms are: constriction of the blood vessels, erection of hair and relaxation of the intestines. High concentrations of cocaine paralyze all smooth muscle. *Procaine* also produces sympathetic stimulation on systemic administration, dilating the pupils, augmenting the heart, inhibiting the intestines, increasing the pressor action of tyramine (D. F. MacGregor, 1939). It inhibits the response to stimulation of sympathetic nerves, but not epinephrine. It combats the actions of *acetylcholine* on the heart, lungs and intestines (R. Hazard, 1946).

K. V. Thimann, 1943, suggested that the local anesthesia is due to *competition with acetylcholine* for the excitable substrate.

The cocaine sensitization to epinephrine is manifested especially in the blood pressure rise, but can be demonstrated also in the bronchial dilatation and in the uterine actions. It is not shared by the synthetic cocaine substitutes, not even by dextro-pseudococaine (Mercier, 1931). The sympathetic effects are produced in rabbits by the hypodermic injection of 35 to 50 mg. of cocaine; or by 10 mg. of cocaine with 1 mg. of epinephrine (Mills, 1919)

Sympathetic Ganglia.—Cocaine and procaine abolish the response to stimulation of their preganglionic fibers, to acetylcholine and to nicotine, and suppress their normal output of acetylcholine during stimulation (D. F. MacGregor, 1939; A. M. Harvey, 1939).

Circulation.—The effects of cocaine on the general circulation are partly central, partly peripheral. They vary according to the dose, and are also influenced by individual susceptibility.

Very small doses diminish the pulse rate, by stimulation of the vagus center (Vulpian, 1884). There is a quick rise of *blood pressure* from stimulation of the vasomotor center; this is followed by a temporary fall due to the slowing. *Moderate doses quicken the pulse,* mainly by central and peripheral depression of the vagus (v. Anrep, 1880) with some stimulation of the accelerator center (Mosso, 1887). *The pressure rises* (v. Anrep) from stimulation of the vasomotor center (Berthold, 1885), aided by the faster heart rate. The vasomotor factor is predominant, for the rise is practically absent if the cord is cut. *Large doses cause severe fall of pressure* and slow and weak pulse (v. Anrep), from the depression of the medullary centers (collapse) and of the cardiac muscle.

Cocäine stimulates the cardio-inhibitory center when *perfused through the medulla* of the turtle (Bush, 1920). In *perfused mammalian heart* low concentrations slow and strengthen the contractions; higher concentrations cause slowing and weakening; fatal concentrations give diastolic arrest (Kochmann and Daels, 1908; and Prus, 1913). Kuroda, 1915, observed no stimulation in excised hearts of mammals or frogs. MacGregor, 1939, reports amplification of the contractions of isolated auricle of cats' hearts by *procaine.*

The Frog Heart.—Dilutions of cocaine 1:500,000 increase the excursions of Straub hearts; 1:300,000 slow and diminish the systole; 1:60,000 arrest the ventricle (Kochmann, 1921). Perfusion produces heart block, which may be prevented by atropine or epinephrine (Kuroda, 1915). Direct application of 6 per cent cocaine to the sinus suppresses the nodal rhythm and therefore arrests the heart, while the same application to the auricles or ventricles does not produce arrest (Maestrini, 1916). *The turtle heart* is also stimulated by low and depressed by somewhat higher concentrations (H. G. Bayer, 1885). *Procaine* depresses similarly to cocaine (Roth, 1917). Local application of procaine to the sinus or auricles of the frog heart renders them irresponsive to electric stimulation, when they still beat spontaneously and set the pace for the ventricle (H. Witz, 1938).

Intrapericardial injection of local anesthetics (2 cc. of 5 per cent procaine in dogs) abolishes completely the inhibitive response of the heart to vagus stimulation. *Direct application to the epicardium* (1 cc. of 10 per cent cocaine, mesycaine, procaine or potassium chloride) raises the minimal strength of stimulus required to provoke extrasystoles, and immediately arrests tachycardia or auricular fibrillation from operative manipulation of the heart (Mautz, 1936; R. F. Baker and Madden, 1944). *Intravenous injection* of procaine (10 to 20 mg. per Kg.) or of pontocaine into dogs also prevents *auricular fibrillation* from faradic stimulation or local application of acetylcholine to the heart (Hirschfelder and Tanuales, 1942). Intravenous injection also prevents *ventricular fibrillation* and the production of heterotopic rhythms by electric stimulation, epinephrine (especially during cyclopropane anesthesia; Burstein and Marangoni, 1940) or barium, although 7.5 mg. per Kg. has no direct effect on conduction time or refractory period (Van Dongen, 1938; Mautz, 1937). This method of arresting ventricular fibrillation is effective in resuscitation as a preliminary to establishing normal rhythm by direct electric stimulation of the heart (C. S. Beck and Mautz, 1938). Para-aminobenzoates also protect somewhat against epinephrine-cyclopropane ventricular fibrillation in dogs, but much less effectively than procaine (Marangoni *et al.,* 1940).

The blood pressure reacts similarly to cocaine and procaine, being raised by small and lowered by large doses (Roth, 1917). Even small concentrations of cocaine potentiate the *epinephrine constriction* (Braun, 1914; Fischel, 1915). Cocaine therefore increases the pressor effect of epinephrine. This may result in a marked rise of blood pressure when cocaine is used clinically in connection with epinephrine; and the excessive vasoconstriction may be the factor in the toxicity (E. L. Ross, 1922). The *carotid sinus blood pressure reflex* is abolished by cocaine (10 mg. per Kg.) and by large doses of procaine; also in spinal anesthesia by procaine or percaine (Heymans *et al.,* 1933). *Traumatic shock* from crushing of muscles is prevented or mitigated by local or spinal anesthesia (G. W. Crile and Lower, 1914; Eversole *et al.,* 1944). The *cerebral circulation* is increased by cocaine and still more by procaine (Frankfurther and Hirschfeld, 1910). The vessels of the retina and pia mater are constricted (Hirschfelder, 1915). The **urine flow** is usually diminished, but sometimes increased, depending mainly on the vasomotor effect.

Smooth muscle is generally first stimulated, then depressed by cocaine, regardless of innervation. The stimulation is therefore not through the sympathetic; nor is it parasympathetic, for it is not prevented by atropine. It must be exerted directly on the muscle. This applies also to the synthetic cocaine substitutes (Waddell, 1917). The reactions of the *uterus* to cocaine appear confusing: G. H. Miller, 1926, reported that a dilution of 1:10,000 acts like epinephrine 1:1,000,000, *i. e.,* augmentor and depressor depending on the animal and state of pregnancy; but Thienes, 1928, found that half the uteri responded inversely to the two agents. *Excised ureter* is stimulated by cocaine and by procaine (Roth, 1917). The *urinary bladder* (excised) is stimulated by cocaine, less by the synthetic substitutes. Mixtures of these give simple summation. So do pituitary and epinephrine, the latter being depressant (Waddell, 1917). Karashima, 1927, confirmed the stimulation by small doses of cocaine. *Excised bronchial muscle* is somewhat dilated (Trendelenburg, 1912). The bronchiolar constriction of morphine is completely abolished by hypertonic injection of cocaine (10 mg. per Kg.); that of histamine only incompletely; that of physostigmine and pilocarpine is not abolished (Swanson) *Excised small intestine* responds to dilute solution of cocaine by either stimulation or depression (Roth, 1917; Thienes, 1928; Karashima, 1927) or by inhibition followed by marked rise of tonus (G. H. Miller, 1926). Concentrations above 1:2000 are usually depressant. The pH of the Locke's solution has marked effects on the response of the cat's intestine (Salant and Parkins, 1932). In *unanesthetized dogs* with Thiry-Vella fistulas, intravenous injection of cocaine also causes variable responses, the tonus being sometimes increased, sometimes lowered

(Gruber, 1936). The *esophagus, stomach* and *colon* are stimulated to increased tonus and contractions by dilute solutions of cocaine; concentrations above 1:20,000 tend to depress (Thienes, 1928).

Striated Muscle.—Cocaine and procaine weaken neuromuscular transmission in mammals and frogs, so that the muscle responds better to direct than to nerve stimulation. They reduce the response toward tetanic stimuli to a single twitch, and weaken acetylcholine and potassium contracture. These effects resemble those of curare, but occur also after degeneration of the nerve (D. F. MacGregor, 1939; A. M. Harvey, 1939). Neostigmine contractions are depressed by procaine and cocaine much more readily than normal contractions, so that the action has been attributed to diminished production of acetylcholine at the neuromuscular junction (Jaco and Wood, 1944). Procaine also depresses and abolishes the response of the muscle to direct stimulation, the effect being nearly as great as that on the nerve (Sollmann). All local anesthetics, even in very dilute solutions, counteract various *spasms*, such as those of nicotine, guanidine and veratrine, also after curarization or after degeneration of the nerve endings. The antagonism is mutual (Frank and Katz, 1921). Procaine (1:500) prevents *caffeine contracture and rigor* and the overproduction of lactic acid, even in concentrations which do not directly depress the response of the muscle to stimulation. The concentration, however, must increase with that of the caffeine. The action is reversible, *i. e.*, when the procaine is washed away, the muscle again becomes susceptible to the caffeine. Established rigor is not removed. Cocaine acts similarly, but requires considerably higher concentrations; anesthesine is quite effective; atropine lacks this action (Schüller, 1925).

Glandular secretions are but little affected by cocaine. The *saliva* flow is not stimulated (Kuroda, 1915). The albumin and shell material in the *oviduct secretions* of birds appear to be somewhat decreased (Riddle and King, 1921).

The **central actions of cocaine** are rather variable and complex, depending largely on the dose.

Cerebral Stimulation.—The first systemic effect of cocaine is psychical stimulation, somewhat resembling that of caffeine. This differs considerably in degree and in kind with individuals, and may be manifested as alertness, loquacity, elation, wakefulness, excitement, sometimes markedly sexual; or anxiety and flutter. The stimulation is greatest in excitable individuals and may interfere seriously with operations. Patients should be forewarned of the anxiety complex.

Oral administration of 1 to 3.5 mg. per Kg. of body weight to nonhabituated subjects results in slight rise of temperature (larger with larger doses); slight increase of spinal reflexes; no important changes in pulse, blood pressure and respiration; slight alterations of mental activity in some cases (V. Z. Ortiz, 1944).

The natives of the Andes chewed coca leaves to *suppress hunger and fatigue*, and cocaine is reported to counteract mountain sickness. The increased resistance to fatigue has been confirmed by "blind" experiments with the ergograph (0.05 to 0.1 Gm. of cocaine by mouth; Thiel and Messig, 1930). O. Boje, 1939, reports that cocaine is the only agent that produces definite improvement of athletic performance; caffeine was not effective. In dogs, 4 mg. of cocaine per Kg. hypodermically increase resistance to swimming fatigue by 70 to 150 per cent; caffeine (10 mg. per Kg.) by 37 to 108 per cent; metrazol (5 mg. per Kg.) did not increase resistance (Gutierrez-Noriega, 1944).

Animals respond to cocaine by great *restlessness*, sometimes by circus movements. The suppression of the continuous motor activity induced by cocaine in mice may serve as a means of assaying the potency of sedatives (Modrakowski and Rusiecki, 1937). Cocaine increases the resistance to general anesthesia. Mosso, 1887, and Airila, 1913, found that 10 to 40 mg. of cocaine, hypodermically, waken dogs or rabbits from deep chloral sleep. Most of the synthetic local anesthetics are *analeptic* to morphinized rabbits, but less so than cocaine, and the effective dosage is near that which convulses (Keil and Gropp, 1934).

Incoordination, Narcosis, Convulsions.—The stage of stimulation may be short or even absent. With somewhat larger doses it is usually succeeded by depression, first of the coordinating functions. The movements lose their purposive type and become choreic. General narcosis follows and then epileptiform convulsions, located chiefly in the midbrain. If the paralysis is rapid, the convulsive stage may not appear.

The site of the convulsant action appears to be complex. After removal of the hemispheres, cats respond to cocaine by a short period of motor excitement, followed by strong tonic contractions of the extensors. The differences from the ordinary epileptiform convulsions are probably indirect (modification of inhibitions, etc.) After section of the posterior roots, cocaine produces extensor spasms, apparently by acting above the cord and below the corpora quadrigemina, perhaps on the pontine nucleus (Allers and Hochstaedt, 1928 and 1930). Feinberg and Blumenthal, 1887, reported that cocaine convulsions do not occur in dogs after ablation of the cerebral cortex, or in newborn animals in which the cortical motor centers are not yet excitable. Rabbits deprived of the hemispheres do not show the clonic convulsions or respiratory effects; but they do exhibit tonic convulsions and "running movements." Their resistance to toxic doses is increased (Morita, 1915). *The action currents of cerebral cortex* show attacks of rapid potential variations, succeeded by temporary unexcitability as with other convulsants, such as caffeine and strychnine (Fischer, 1932). The ganglion cells of the cerebral cortex reveal *histologic changes*, primarily in the basophilic granules of the nuclei (Fukunaga, 1926). *Frogs* show increase of voluntary movements and exaggeration of reflexes, sometimes leading to convulsions. This is followed by paralysis of the whole central nervous system. In frogs from which the brain has been removed, cocaine causes at first an increase of the reflexes, then convulsions, and finally total paralysis.

In intact animals this effect is obscured by the action on the higher centers of the nervous system.

The **respiration** is at first accelerated. During the spasms it is irregular. The volume then diminishes. It may assume the Cheyne-Stokes type. Respiratory paralysis is the usual *cause of death*. This is also the first center to fail when the cocaine is applied locally to the fourth ventricle. Roth, 1917, found that small doses of procaine also increased the respiration, large doses being depressant.

Emesis.—The frequent vomiting in cocaine poisoning is perhaps due to the medullary stimulation, but its mechanism has not been fully investigated.

Temperature.—*Cocaine* produces hyperpyrexia in mammals, due to increased heat production, by the motor excitement and rise of basal metabolic rate, reinforced by the convulsions. It probably acts directly on the midbrain temperature centers. Cocaine lowers the temperature of birds (L. Forchheimer, 1931; the paper also discusses the relative susceptibility of birds to other poisons). *Procaine* lowers the temperature of mammals by increasing heat loss. It is antagonized by thyroxin and by dinitrophenol (Alwell *et al.*, 1937).

Metabolism.—In man, 0.1 Gm. of cocaine hydrochloried by mouth increases the basal metabolic rate by 7 to 22 per cent in twenty-five to thirty minutes, returning to normal in fifty minutes. There is also rise of temperature, respiration rate and blood pressure (R. Herbst and Schellenberg, 1931). In *rabbits*, large doses of cocaine cause rapid loss of weight. The quantity of urine, its specific gravity and particularly the urea, are diminished, while the incompletely oxidized (extractive) nitrogen is increased (Maestro, 1904). The effects of *repeated injection on dogs* have been investigated by Underhill and Black, 1912: doses of 10 mg. (per kilogram) produced no change in fat or nitrogen metabolism; 15 mg. gave a slight impairment of fat utilization, and considerable decrease of body weight; 20 mg. markedly decreased the nitrogen and fat utilization. The nitrogen balance may become negative. Lactic acid excretion was markedly increased in well fed dogs, but not in starvation—the increase being probably due to the muscular activity. The *blood sugar level* is not changed (cats, 15 to 35 mg. per kilogram), except as a result of excitement (Schaer, 1915).

Acute poisoning by local anesthetics is fairly frequent, especially with cocaine, and is likely to be fatal. Reliable statistics of fatalities are not available, but they are more common than is ordinarily supposed (E. Mayer *et al.*, 1920–1924). A large proportion of the accidents (25 per cent in one series) are due to mistakes in the drugs, concentration and dosage. Susceptibility varies greatly, owing to differences of absorption and of destruction, and to varying response to the actions. Fright plays a considerable part.

Safe and Toxic Dosage of Local Anesthetics.—Probably all commonly used local anesthetics have produced fatal accidents. These depend not only upon the absolute dose, but also on the rate of absorption, on idiosyncrasy and on other conditions. The Local Anesthetic Committee of the American Medical Association made recommendations (E. Mayer, 1924), which should minimize the accidents. The following are the most important: Procaine appears the safest of the more widely used local anesthetics and may be employed for subcutaneous and submucosal injections; but the concentration should not exceed 1 per cent. Cocaine and butyn should not be injected under the skin or mucous membranes, but restricted to surface application. The total quantity of cocaine should not exceed 0.06 to 0.1 Gm. (1 to 1½ grains). The patient should be recumbent, if the operation permits. With nervous patients, it is advisable to inject morphine fifteen minutes before the local anesthetic, and to delay the start of the operation till twenty minutes after the injection of the local anesthetic (Mayer *et al.*, 1920). Urethral injections are especially dangerous, and should be avoided if there is trauma or stricture.

Strict attention should be given to prevent the confusion of procaine and cocaine. The solutions should be kept in different kinds of bottles. Cocaine solution may be distinguished by tinting with sodium fluorescein, 1 mg. per Gm. of cocaine. This would also show the concentration of the solution.

The ordinary fatal dose of cocaine is considered to be about 1.2 Gm. (Watson-Williams, 1924), but death has been reported from 20 mg., and serious poisoning from 2 drops of a 4 per cent solution (5 mg.) on the conjunctiva, and with three drops of ½ per cent cocaine (1 mg.) in a tonsil operation (Mayer). In other cases, very large doses produced no effect (bibliography, Roth, 1917). *Dilution* slows the absorption of cocaine and insures its thorough utilization, and thus economizes its use. Solutions above 1 per cent should not be used for hypodermic injection. With solutions of ½ per cent and proper precaution, Reclus considers 0.2 Gm. quite safe. The addition of *epinephrine* to injections reduces the toxicity materially, chiefly by delaying absorption (Zaus and Moody, 1936; Beutner *et al.*, 1936). All local anesthetics are less toxic when injected into an *artery* than by vein (Kuroda, 1927), presumably because they reach the general circulation more gradually.

Safe Operations.—In open wounds, body cavities or other surfaces from which any excess will be moved when the operation is completed, the total quantity of cocaine is practically immaterial if dilute solutions (0.1 to 0.2 per cent) are employed, for only a small fraction will be actually absorbed.

Dangerous Operations.—Cocaine is especially dangerous when 2 to 10 per cent solutions are injected into closed mucous or serous cavities, such as the urethra, bladder, scrotal sac, etc. Very severe poisoning has repeatedly followed after urethral injection of 1 Gm. in 5 to 20 per cent solution, in one case even after 7 cc. of 1 per cent (70 mg.). Indeed, a fairly large number of toxic cases are reported from 10 to 50 mg. in 5 to 20 per cent solution (Weigand; H. Braun, 1914). Tonsil operations, when cocaine is injected, show many more fatalities than do operations on the nose (Mayer). The toxicity is increased by severe hemorrhage, also by chloral narcosis; probably by interference with the activity of the liver (Eggleston and Hatcher). Procaine proved fatal in a tonsil operation with 4 cc. of ¾ per cent, injected with epinephrine (Mayer).

The **toxic symptoms** are similar for cocaine and the synthetic substitutes, procaine, apothesine, butyn, etc. (Mayer, 1924). Fatal cases run a rapid course, with anxiety, sudden fainting, extreme pallor, dyspnea, sometimes brief convulsions, arrest of respiration and death generally in a few minutes. With smaller doses or slower absorption there is confusion, laughter, loquacity, vertigo, motor excitement; quickened pulse and palpitation; irregular respiration. Larger doses cause pallor; chill, with sweat and rise of internal temperature; dilated pupils and exophthalmos; nausea, vomiting and abdominal pain; great anxiety; disturbance of cutaneous sensation (worms under skin; etc.), feeling as if limbs had disappeared; finally delirium, dyspnea and Cheyne-Stokes respiration, extreme pallor of face, widely dilated pupils, strong tremors which progress to clonic convulsions, unconsciousness, rise of temperature and death by collapse and asphyxia. If death has not occurred within a few minutes, the patient will almost always recover. Unconsciousness and Cheyne-Stokes respiration may persist for one or two hours. Recovery may be followed by more lasting apprehension, insomnia, psychic depression and melancholia.

Symptoms in animals are similar to the clinical. *Intravenous injection of fatal doses into cats* produces almost instant extensor spasm, fixation of the respiration and sudden cessation of the heart. *Sublethal intravenous injections* cause immediate stimulation of the respiration and abrupt fall of blood pressure of cardiac origin; the heart rate is inconstant, but generally slowed. The respiration may be temporarily arrested. Within a minute, the heart begins to improve and the blood pressure rises; the respiratory stimulation diminishes; there may be brief but severe clonic convulsions. Within five minutes the animals may be apparently normal. As the doses approach the fatal, the convulsions are more prolonged, and recovery is slower, especially after cocaine (Eggleston and Hatcher, 1919).

The **treatment of poisoning by local anesthetics** should begin with prevention, the selection, dosage and technic of the administration. Previous administration of a sedative, especially of the barbituric series, diminishes the risk, by suppressing the convulsions and their interference with respiration, so that animals survive one and a half to four times the ordinary fatal dose of cocaine or procaine, if administered hypodermically (Tatum and Collins, 1926; Knoefel, Herwick and Loevenhart, 1930). Clinically, 0.2 Gm. of phenobarbital or 0.6 Gm. of sodium barbital may be administered an hour before operation (M. R. Guttmann, 1928; E. Y. Martin, 1928). Barbiturates do not prevent the direct circulatory collapse and depression of respiration which occur on intravenous injection of procaine (Isenberger, 1930), and are useless or harmful either for prophylaxis or treatment if the anesthetic agent is rapidly absorbed; but if the symptoms develop slowly, the suppression of the convulsions is at least helpful (Malone, 1934; Beutner *et al.*, 1936).

Knoefel *et al.*, 1930, reported the order of the antidotal efficiency of hypnotics as: amytal (highest), phenobarbital > barbital > paraldehyde > chloral > urethane and ether. A. M. Hunt, 1938, found evipal effective in controlling procaine convulsions that had lasted half an hour. Intracisternal injection of ephedrine is effective against the procaine respiratory paralysis (Isenberger and Rice, 1936).

If an overdose of the local anesthetic has been taken by mouth, evacuation and chemical antidotes are indicated; if the anesthetic was injected, absorption should be checked by ligation, if possible; for whatever delays death is likely to save the life in view of the rapid destruction of these drugs. If the symptoms have developed, the head should be lowered, the convulsions arrested by intravenous injection of sodium pentobarbital or amytal, and artificial respiration instituted if necessary, with cardiac massage if the circulation fails. The use of epinephrine or morphine is not advised (Emil Mayer, Commission, 1924).

Epinephrine, when 1:50,000 is added to injections of cocaine or procaine, is reported to increase the toxicity for mice materially; below 1:85,000 it had little effect (Gurd and Sachs, 1939). *Ephedrine,* 1:1000, diminished the toxicity and increased it only above 1:200 (J. D. P. Graham and Gurd, 1940). Failing respiration is not improved by metrazol, caffeine, lobeline or amphetamine. Artificial respiration is generally successful in saving dogs from the M.L.D., 14.6 mg. of procaine per Kg. with fast intravenous injection (J. R. Schamp, 1941).

L. Butturini, 1934, reported that *intravenous injection of dextrose* mitigates cocaine convulsions and raises the M.L.D. It had no effect on the toxicity of strychnine, santonin or calcium chloride. *Calcium chloride* injection was reported ineffective by Soma Weiss, 1923, but Beutner and Miley, 1938, claim that it protects against procaine convulsions. Beutner, 1940, attributes this to diminished absorption. Mersalyl, mercuric chloride and lead nitrate when mixed with procaine delay its absorption by precipitation (V. G. Haury, 1941). *Magnesium* injection is harmful (Knoefel, Herwick and Loevenhart, 1930). *Pituitary* solution has been recommended (Nielson and Higgins, 1923).

Fate of Cocaine.—This is partly destroyed in the organism, but mainly excreted unchanged in the urine.

McIntyre, 1936, reported the recovery of 429 mg. of cocaine from the urine of a patient who survived for twelve hours with barbiturate treatment after the peritonsillar injection of 800 mg. of cocaine. Tatum and Seevers, 1929, reported that dogs excrete cocaine by the urine, but that rabbits do not. Langecker and Lewit, 1938, found that rabbits detoxicate cocaine better than do guinea pigs or cats; percaine was poorly detoxicated by all three; atropine equally well by rabbits and guinea pigs. Cocaine is detoxicated in rabbits by rapid demethylation, atropine by ester hydrolysis. Procaine, apothesine and stovaine and probably the other synthetic anesthetics are rapidly destroyed in the liver.

Persistence of Effect and Cumulative Action.—Most synthetic local anesthetics are destroyed so rapidly in the body that the toxicity is much smaller when the drug is introduced slowly. Cocaine and phenocaine (holocaine), however, are not destroyed nearly as promptly (Eggleston and Hatcher, 1919).

Procaine is destroyed (hydrolyzed) by the blood, inside as well as outside the body, in some twenty minutes with physiological doses. This is due to an esterase which is formed in the liver and is therefore absent in hepatic disease (R. Hazard, 1946).

Destruction of Cocaine in Vitro; Sterilization.—Long-continued boiling decomposes cocaine into benzoyl-ecgonine and methyl alcohol. It was therefore believed that solutions could not be sterilized by boiling. In fact, however, the decomposition, on boiling half an hour, is insignificant; longer boiling only decreases the activity, for the decomposition products are merely inactive and not toxic. Any decomposition on boiling is probably due to alkalinity from the glass (Baumeister, 1917).

Watery solutions of basic cocaine deteriorate rapidly, losing their anesthetic power within seven hours, and still more rapidly when heated. Basic procaine and alypin are stable in solution (Gros, 1912). *Solutions of cocaine salts* are much more stable than basic solutions, but liable to mold.

Procaine solutions are said to be difficult to sterilize (Ersner, 1917). They turn brown on keeping, but their efficiency or toxicity is not altered, at least for several months. Solutions that have developed a sediment (generally molds) should not be used (Bonar, 1923).

Resistance to Putrefaction.—Positive tests for cocaine were obtained in cadavers even months after death (Palet, 1919).

Benzoyl ecgonine was found by Stockman, 1886, to resemble caffeine in its central and muscular action. It had no effect on sensory nerves or the pupil.

Cocaine Addiction.—The elation and euphoria which cocaine induces in susceptible individuals tend to render it a "habit drug"; but it is more likely to be used for occasional "jags" by Negroes, prostitutes and criminals, rather than daily, as is morphine. The treatment is therefore easier and more likely to be successful. It may be used continuously, however, as by the South American natives. Addiction occurs most rapidly with intravenous, then with hypodermic, least with oral administration. The M.L.D. is only twice as high as the optimal stimulating dose (Gutierrez-Noriega and Ortiz, 1944). Cocaine inebriation is active and sociable, in contrast to the dreamy state induced by morphine. It may induce a more or less maniacal condition, in which the individual becomes dangerous to others. The *immediate effects* include the phenomena of sympathetic stimulation, resembling hyperthyroidism: tachycardia, polypnea, mydriasis and exophthalmos, fine tremors. Some individuals, especially women, react with marked erotic excitement. The stimulation is succeeded by depression tremors, pallor, sunken and unsteady eyes (Owens, 1912). The *chronic effects* show rapid emaciation and severe psychic disturbances, insomnia, hallucinations, apathy, melancholia, suicidal mania (Vallon and Bessiere, 1914). The pupils are inconstant. Acne is common. It is claimed that considerable *tolerance* is acquired, so that the daily hypodermic consumption may reach 2.5 Gm., or even 10 Gm. (Grode, 1912). Chouppe, 1889, reported that morphinists are relatively tolerant to cocaine. Sudden withdrawal leads to abstinence symptoms similar to those of morphine. *With cocaine snuffing,* where smaller amounts are used in intermittent debauches, the chronic effects, the craving and the abstinence symptoms are proportionately less marked. Such patients develop atrophic rhinitis, with characteristic ulceration of the nasal fossae (Owens; also present in heroin snuffing, Phillips). The *treatment of cocaine habit* coincides with that of morphine addiction. The prescribing of cocaine and tropacocaine comes under the Harrison Antinarcotic Law. This does not apply to the synthetic substitutes.

The effects on habituated subjects (South American Indians) are identical for cocaine (4 mg. per Kg. by mouth) and for chewing the leaves (generally about 100 Gm.). The most frequent phenomena are anesthesia of the mouth, slight mydriasis, moderate tachycardia, rise of blood pressure and of temperature, increased metabolic rate, intensification of reflexes, some modification of mental activity, nervousness, euphoria and insomnia (F. R. Mendizabal, 1944). Beginners may have nausea. The commonest mental symptoms are minor alterations of visual and auditory perceptions, illusions and pseudohallucinations (rarely true hallucinations), thought disorders and delusions, turning from reality to a dream world. *Abstinence symptoms* are light and brief (Gutierrez-Noriega, 1944).

Cocaine Habituation in Animals.—Continued administration to dogs and monkeys induces psychoses similar to the human, and marked desire for the drug (Tatum and Seevers, 1923), but withdrawal does not cause serious reaction or erethismus (Grode, 1913; Tatum and Seevers; Downs and Eddy). Animals do not acquire tolerance; on the contrary, the toxic, convulsant and excitant effects of a uniform dosage increase for several weeks and then remain level (Gutierrez-Noriega and Ortiz, 1944). The M.L.D. for rats falls progressively. Dogs habituated to cocaine are hypersensitive to ephedrine, and tolerant to morphine (Downs and Eddy, 1932; Stanton, 1938). Animals that have recovered from toxic doses show diminished resistance to lethal doses; this is probably due to toxic injury of the tissues, liver and other, that normally destroy the cocaine (Atkinson and Tatum, 1925). The *liver* of mice subjected to increasing doses of cocaine shows vacuolar degeneration and often extensive fatty infiltration, with increase of neutral fat especially of cholesterol, the phospholipids remaining constant (P. L. MacLachlan and Hodge, 1939).

Cocaine on Body Weight and Growth.—No effects were produced in rats by doses corresponding to 2½ grains of cocaine per man per day, administered continuously for eight months. Procaine and other synthetic anesthetics reduced the weight, after a few weeks, with doses corresponding to 5 grains per day (Sollmann, 1924).

Comparison of Cocaine and Its Substitutes.—Cocaine is satisfactory from the standpoint of efficiency, penetration, and practical absence of tissue injury. However, its rather high toxicity has led to the use of substitutes wherever practical. Some of these present advantages in special fields, although they lack the general applicability of cocaine.

The differences between cocaine and its substitutes concern especially the following points:

Toxicity.—It is generally believed that cocaine has the highest toxicity. This conclusion was based primarily on animal experiments, but seems in harmony with clinical experience.

Toxicity Comparisons on Animals.—Extensive series of experiments have been published, for instance by Kochman, 1914. These show that cocaine is perhaps three times more toxic to guinea pigs, on hypodermic injection, than are most of the substitutes. It may be questioned whether this reproduces the absorption and destruction sufficiently to justify transfer to clinical conditions.

Intravenous Toxicity for Cats.—This would be a more definite index of absolute toxicity, but its clinical application would also be limited. Eggleston and Hatcher, 1918 and 1919, found the M.L.D. (mg. per Kg.) as follows: Alypin holocaine, 10; Beta-eucaine, 12.5; Cocaine, 15; Apothesine, 20; Tropacocaine, 20–25; Stovaine, 25–30; Nirvanine, 30–35; Procaine, 40–45.

Combinations of any two of these local anesthetics produce simple summation of the effects, so that they would not offer any advantages from this standpoint. The systemic actions of all are similar, death occurring by combined cardiac and respiratory paralysis. The *hypodermic fatal doses* are therefore more than five times greater than the intravenous, except with the relatively indestructible cocaine and phenacaine.

Irritation and Tissue Injury.—In ordinary concentrations, cocaine, procaine and apothesine are practically nonirritant. Eucaine, alypin, phenacaine (holocaine), and benzyl alcohol produce smarting and some pain, but no permanent injury. Tropacocaine raises wheals on the scarified skin. Stovaine and quinine-urea cause more pain and lead to induration or gangrene if the ordinary concentrations are exceeded.

The irritative phenomena have been compared for the intracutaneous injection by Braun, 1905. Procaine up to 5 per cent produced no pain or hyperemia. Stovaine caused strong local irritation, even with dilute solutions, and gangrene with 5 to 10 per cent. Alypin as dilute as 0.1 per cent gave pain and hyperemia, but less than stovaine; 1 per cent produced persistent irritation; and 5 per cent, gangrene. Cocaine is practically nonirritant. The irritation has also been studied by Le Borcq, 1919, Kochmann, 1914, and Closson, 1914.

Stability of Solutions.—Cocaine solutions should be freshly made, although their deterioration is not so rapid as was formerly supposed. Alypin solutions also should not be kept longer than a week (Impens, 1905). The others keep for a considerable time. Phenacaine (holocaine) solutions must be slightly acid and are therefore irritant. Procaine solutions become discolored. Solutions of the synthetic local anesthetics may be *sterilized* by boiling, and cocaine solutions can safely be boiled for a few minutes. The *solubility of the bases in oil* is, in descending order, alypin (all proportions), eucaine, procaine, cocaine (Gros, 1910).

Addiction has not been reported for the cocaine substitutes.

Structure of Cocaine.—Cocaine is the methyl-benzoyl ester of ecgonine, a base closely related to tropine, the corresponding base of atropine, both being pyrrolidine derivatives. *Ecgonine* itself produces only the least important of the actions of cocaine, *viz.*, the hepatic degeneration. The other actions are developed only by the entrance of *both* radicals. The methyl may be replaced by any other alkyl radical, without changing the actions of cocaine. The benzoyl radical, however, can not be replaced by other aromatic acids (possibly with a few exceptions), nor by fatty acids without great impairment of the local anesthetic action. Indeed, the presence of the benzoyl group gives the anesthetic properties to other alkaloids. It is present in most cocaine substitutes. *Relations of chemical structure and action* have been studied for an extensive series of local anesthetics by Gilman, Goodman *et al.*, 1942.

PREPARATIONS: (In Alphabetic Sequence):—**Allocaine S** is a complex benzol derivative. Kubota, 1919, claims that it is somewhat less toxic and more anesthetic than procaine, but rather more irritant. It does not appear to have any real advantage.

Alypin Hydrochloride, N.N.R. (Amydricaine Hydrochloride), Benzoxy-dimethylamino-methyldimethyl-aminobutane hydrochloride; it is efficient on mucous membranes, and is used especially in the urethra. In structure it resembles stovaine. It is used in about the same concentrations as cocaine, but is more irritant. Several cases of sudden collapse and asphyxia, after its injection, have been reported (Ritter, 1912; Lichtenstein, 1914). The maximal dose of 0.25 Gm. must not be exceeded. Alypin solutions should not be kept longer than a week (Impens, 1905). They are not readily precipitated by alkalis, and the base is very soluble in oils.

Apothesine Hydrochloride, N.N.R., Diethyl-aminopropyl cinnamate hydrochloride, in properties and uses resembles procaine. Dosage, for injection anesthesia, 0.5 to 2 per cent, with epinephrine 1:100,000. On cornea, 2 to 4 per cent. Spinal anesthesia, 2 cc. of 4 per cent. Apothesine is relatively safe; but severe collapse has been reported from the injection of 1 and 2 per cent solutions in throat work (Mayer *et al.*, 1920), and death has occurred from spinal injection (Ireland; Duboff, 1920).

Benzyl Alcohol, N.N.R. (Phenmethylol), $C_6H_5CH_2OH$, was introduced by Macht, 1918. Its toxicity is low, since it is largely converted into benzoic and then into hippuric acid (Diack and Lewis, 1928). Intravenous injection causes vasodilatation. The urine flow may be increased or diminished (Gruber, 1924). The pure substance is irritant and somewhat corrosive, but watery solutions which contain up to 4 per cent are not irritant. Hirschfelder, 1920, claims that injections of benzyl alcohol solutions in man are unsatisfactory; that the anesthesia is uncertain and is often followed by subcutaneous edema and local pain. It is used for injection anesthesia, generally as 1 to 4 per cent solution. This is also anesthetic on mucous membrane, but the action is rather brief (Sollmann, 1919). Benzyl alcohol is fairly effective against the itching of dermatitis; for instance, in the milder grades of "mustard gas" poisoning. It is used as a 10 per cent ointment in lard; or as a mixture of equal volumes of benzyl alcohol, alcohol and water (Hess). Benzyl alcohol is soluble in all proportions in oil.

Benzyl Carbinol (Rose Oil), $C_6H_5C_2H_4OH$. Hjort and Eagan, 1919, find its anesthetic action more powerful than that of benzyl alcohol. Its toxicity is about the same, but it is more stable and sufficiently soluble for therapeutic use. Its isomer, phenyl-methyl-carbinol, is more effective, but also more toxic. It is unstable, and therefore not practical (Hjort and Kaufmann, 1920).

Butacaine Sulfate, U.S.P., *Butyn Sulfate*, a procaine derivative, containing butyl in place of ethyl, and propanol in place of ethanol. Its properties differ practically from those of procaine, for it is absorbable from mucous membranes. It is more toxic even than cocaine, and is therefore not advisable for injections, but it is useful in ophthalmic operations (2 per cent) and in nose and throat work (2 to 5 per cent). It is easily soluble in water· the solutions may be sterilized by boiling. It is somewhat irritant to the conjunctiva.

Butyl Aminobenzoate, U.S.P., *Butesin*. A sparingly soluble and slowly absorbable anesthetic, used as dusting powder; more effective than ethylaminobenzoate.—*Butesin picrate* is used on burns and ulcers as 1 per cent ointment.

Carbinols.—A series of phenyl-carbinols was investigated by Hirschfelder *et al.*, 1920 (see below, Saligenin). All are anesthetic.

***Cocaine Hydrochloride,** U.S.P., occurs as colorless, transparent prisms; or flaky, lustrous leaflets, or white, crystalline powder. Very sol. in water (1:0.5). Solutions may be colored with sodium fluorescein, 1 mg. per Gm. of cocaine. *Incompatible* with alkalis, sodium borate (not boric acid) and silver nitrate. Solutions decompose on keeping (a 15 per cent solution in Dilute Alcohol is said to be permanent; Wintersteiner, 1906). Contrary to older statements, they are not materially decomposed by boiling. Cocaine is obtained from the dried leaves of Erythroxylon species, shrubs indigenous to Peru and Bolivia, and cultivated in tropical countries. Ceylon coca contains mainly cocaine; Java coca contains only other ecgonine derivatives (Jong, 1911). Cocaine may also be prepared synthetically. The free alkaloid, *Cocaina*, U.S.P., is slightly sol. in water (1:600); sol. in organic solvents and oils, and in 80 to 100 parts of liquid petrolatum. It is used especially in ointments or solutions in oil.

Cycloform, isobutyl p-aminobenzoate, is a sparingly soluble local anesthetic. Dose, 0.1 to 0.2 Gm.

Diothane Hydrochloride, N.N.R., Piperidinopropanediol-di-phenyl-urethane hydrochloride, introduced by T. H. Rider, 1933, is claimed to be twice as potent as cocaine on mucous membranes, and three times as potent as procaine on injection (Rider and Cook, 1938). Its action is more prolonged, and is followed by a period of analgesia. It dissolves slowly in water, up to 1 per cent. It is used as 0.5 and 1 per cent solution, but it is so damaging to tissues that its employment appears inadvisable (Beutner and Calesnick, 1942). Its toxicity by hypodermic injection is about that of procaine, but by vein it is three times more toxic (Rider, 1933).

Ethyl Aminobenzoate, U.S.P. (Benzocaine, Anesthesine, $C_6H_4NH_2.COO(C_2H_5)$ 1:4). Small white or colorless crystals, or crystalline powder. Odorless. Very slightly sol. in water (1:2500), freely sol. in alc. (1:5), almond oil (exp.) or olive oil (1:50 at 25°C.). Sol. in dil. acids. Dose, 0.3 to 0.6 Gm., 5 to 10 grains. *Ethyl Aminobenzoate Ointment,* U.S.P., contains 5 per cent in White Ointment.

Eucaine Hydrochloride, U.S.P. (trimethyl-benzoxypiperidine; beta-eucáine hydrochloride). White, crystalline powder; odorless. Sol. in water (1:30) and alc. (1:35). Dosage, locally, one to two times that of cocaine. The anesthetic effect is perhaps slightly slower and weaker, and the irritation considerably greater, than with the same concentration of cocaine. The pupils are not dilated; the tissues are rendered hyperemic. The toxicity is four-tenths that of cocaine. Toxic doses cause convulsions, central vagus stimulation and direct cardiac depression, with fall of blood pressure (Orr, 1916).

Holocaine: see *Phenacaine.*

La′rocaine Hydrochloride, N.N.R., differs from procaine in side chains. It is claimed that it is effective from mucous membranes as well as by injection, and that the action is somewhat more lasting. It is used in the same concentrations as procaine. L. L. Mayer, 1935, recommends it for eye work, as its instillation produces prolonged and lasting anesthesia, without undesirable effects on the conjunctiva, intra-ocular tension, pupils or accommodation.

Met′ycaine Hydrochloride, N.N.R., Benzoyl-gamma-[2-methylpiperidino] propanol hydrochloride. Active from mucous membranes as well as by injection (C. L. Rose *et al.,* 1930). Toxicity, intravenously about three times that of procaine; subcutaneously, it is 20 to 30 per cent more toxic, but the anesthesia lasts about 45 per cent longer (C. C. Pfeiffer and Grant, 1944). Dosage for mucous membranes: eye, 2 per cent; nose and throat, 2 to 10 per cent; urethra, 1 to 4 per cent; dental nerve blocking, 2 per cent; infiltration of small areas, ½ to 1 per cent. A ¾ per cent solution is about the clinical equivalent of 1 per cent procaine, and lasts somewhat longer. Conjunctival anesthesia with 2 per cent procaine lasts eight to ten minutes, with no cycloplegia or corneal injury, nor increase of intra-ocular tension (J. R. Newcomb, 1931). Freely soluble in water. Solutions are stable on boiling and exposure to light and air. Marketed as powder and capsules. It was introduced by S. M. McElvain, 1927.

Mono′caine Hydrochloride is closely related to procaine. It appears to be about a third more potent in anesthetic action and in toxicity. The more soluble *Monocaine Formate* is used for spinal anesthesia.

No′vocaine Hydrochloride: see *Procaine Hydrochloride.*

Nu′percaine Hydrochloride, N.N.R. (introduced as percaine), is a complex amine derivative of quinoline. It was introduced as a local anesthetic in 1929, having been studied especially by Uhlmann, and by Lipschitz and Laubender. A later study of Bond and Bloom, 1931, concerns especially the toxicity. Gessner and Nauheimer, 1930, cover the pharmacology and toxicity. Nupercaine is three to ten times more effective and particularly much more lasting than cocaine, even from mucous membranes, and also about two to five times more toxic. Addiction has not been reported. It may prove an acceptable substitute for cocaine for mucous membranes; for injections, procaine appears preferable, because of its much greater margin of safety. The *local vascular* changes are so slight that the statements are contradictory. There is no immediate *irritation;* for instance, of the sciatic nerve; but local gangrene has occurred. The *clinical fatalities* were reviewed by E. L. Keyes and McLellan, 1930. They were usually due to gross errors of dosage. Death has occurred from the injection of 90 mg. (about 1.5 mg. per Kg.); on the other hand, 750 and 1500 mg. (about 25 mg. per Kg.) have been survived. These doses agree with the *fatal dosage in animals. The symptoms of clinical poisoning* resemble those of other anesthetics (Keyes and McLellan). *Clinical spinal injections* may cause vasomotor collapse, headache, nausea and vomiting (H. Ziegner, 1929). A hypersensitive patient responded with marked chemosis to conjunctival instillation of 1:500 (Perera, 1940). Nupercaine is marketed as the hydrochloride, a white crystalline hygroscopic powder, soluble in water (2:1), freely soluble in alcohol. The solutions may be autoclaved, but even dilute solutions are precipitated by traces of alkali, and therefore by prolonged contact with ordinary glass A few drops of dilute acid may therefore be added (to *p*H 6.2). This is said to enhance the anesthetic action.

Orthocaine, methyl amino oxybenzoate, Orthoform. Dose, 0.1 to 0.2 Gm., 1½ to 3 grains. Sometimes produces inflammatory reaction (McCleave, 1914).

Phenacaine Hydrochloride, U.S.P.; *Holocaine Hydrochloride.* The hydrochloride of ethenyl-p-diethoxydiphenylamidine. Small, colorless crystals, permanent in air; odorless; faintly bitter taste; producing transient numbness on the tongue; sol. in water (1:50), freely sol. in chloroform. Aqueous solutions occasionally become turbid when boiled in glass vessels (alkali of glass causing precipitation). Dosage, for eye, 1 per cent. Its pharmacology and that of its derivatives has been studied by Jeleff *et al.,* 1943. Anesthetic action about as strong as cocaine, but more rapid (anesthesia in half a minute); more toxic. No effect on vessels has been reported (Gjessing, 1915). It is not mydriatic.

Pontocaine Hydrochloride: see *Tetracaine.*

***Procaine Hydrochloride,** U.S.P., Prócaine, *Nóvocaine* (aminobenzoyl-diethyl-aminoethanol hydrochloride). Colorless needles. freely soluble in water (1 Gm. in 1 cc.); sol. in 30 parts of alcohol. The *nitrate* is compatible with silver salts. Dose, by subcutaneous injection, up to 1 Gm.; by intrathecal injection, up to 0.15 Gm. Occasionally, toxic effects occur even with small doses (0.01 to 0.13 Gm.); while in other cases up to 3 Gm. have been used safely. There is no definite ratio between the toxicity of procaine and cocaine, since this depends on the rate with which they enter the circulation, as procaine is rapidly destroyed in the liver. Epinephrine diminishes the toxicity, even by intravenous injection, probably by cardiac stimulation (Hatcher and Eggleston, 1916). By intradural injection the relative depressant effects of procaine and cocaine on blood pressure and respiration were about equal. Renal irritation is not uncommon after local use of 5 to 10 per cent, but disappears in a few days (Morian, 1915). Procaine convulsions in guinea pigs may be prevented by para-aminobenzoic acid, although this does not antagonize local anesthesia (R. K. Richards and Kueter, 1946); nor does it prevent procaine convulsions in rats and mice (Sollmann and Estable). *Procaine dermatitis* is frequent in dentists, from leaky syringes. It is strictly local and usually seems to require repeated contact and hypersensitivity, demonstrable by cutaneous tests (C. J. Lane, 1921; R. C. Morris, 1921). Skin which is allergic to procaine is also allergic to most of its derivatives, such as butyn, larocaine, monocaine, pontocaine and tutocaine; but not to derivatives that lack the aromatic amino group, such as alypine, apothesine, metycaine and stovaine (Orland *et al.*, 1944). J. Rosenbloom, 1922, reports that the use of a 5 per cent ointment against rectal pruritus resulted in marked edema, especially of the face, resembling nephritic edema.

The esterase of the blood hydrolyzes procaine to *para aminobenzoic acid* (Legge and Durie, 1942). This antagonizes the bacteriostatic action of *sulfonamides*, even with clinical applications (O. L. Peterson and Finland, 1944). Derivatives of procaine also have this effect (C. A. Lawrence and Goetchius, 1944). Metycaine does not and is at present the best available substitute (C. C. Pfeiffer and Grant, 1944).

Conversely, sulfonamides, in the concentration ratio of 6:1, antagonize the effects of procaine, such as on excised intestines and the local anesthetic action (R Hazard, 1946).

Procaine Derivatives.—A series of aromatic analogs were studied by J. Braun and Kirschbaum, 1919. The local anesthetic potency of the alkyl para-aminobenzoates correlates strikingly with their surface tension and partition coefficients (R. Adams *et al.*, 1926).

Propáesin (propylaminobenzoate) is difficultly soluble. Dose, 0.25 to 0.5 Gm.

Psicaine (dextro-cocaine) was investigated pharmacologically by Ishibashi, 1926. It potentiates with epinephrine.

Saligen'in (salicyl alcohol, salicain), $C_6H_4.OHCH_2OH$. Hirschfelder *et al.* found this the most effective, and the least toxic and irritant, of the phenyl-carbinols so far studied. Its toxicity is much lower than that of the procaine-apothesine type. In tonsillectomy, 2 per cent saligenin appeared as effective as procaine.

Sto'vaine (benzoyl-ethyldimethyl-aminopropanol hydrochloride). *Amylocaine Hydrochloride,* B.P. Dose (subcutaneous injection), 20 to 50 mg.; (intrathecal injection), 20 to 100 mg. Colorless scales, extremely soluble in water, or in 5 parts of alcohol. Dosage, locally, as for cocaine. Anesthetic action slightly stronger, irritant action (hyperemia) much greater, toxicity two-thirds that of cocaine. No effect on pupil. It has been used especially for spinal anesthesia, in combination with strychnine (T. Jonnescu, 1909). The immediate danger may be somewhat less than with cocaine, although it is not negligible. The local injury is much greater. Spiller and Leopold, 1910, and Consoli, 1913, observed degenerations in the nerve roots and cells after subdural injections of stovaine. The immediate paralysis is more extensive than with cocaine, involving muscular movements (Santesson, 1906) and spinal reflexes (Adler, 1906). On the circulation, it causes in dogs quickened pulse and fall of blood pressure (Kamenzove, 1911). The kidneys are also rather irritated, especially if albuminuria was previously present (Schwartz, 1907; Chiaie, 1913). The liver is not affected (side actions, Seifert, Nebenwirk, 1915, p. 91; lumbar, p. 109). A comparative study of the local anesthetic actions of stovaine and its homologues was made by Symes and Veley, 1911. The literature of accidents is reviewed by M. I. Smith and R. A. Hatcher, 1917. Death occurs by simultaneous and independent paralysis of the heart and respiration. Stovaine disappears rapidly after injection into the blood stream, and but little is excreted It is removed and presumably destroyed by the liver. In over 1000 cases of stovaine spinal anesthesia, about 30 per cent showed more or less by- or after-effects. One patient had respiratory failure; seven patients transient paralysis (Muenchmeyer, 1908).

Tetracaine Hydrochloride, U.S.P. (**Póntocaine Hydrochloride,** Amethocaine Hydrochloride, Pantocaine), is related to procaine. Its local actions are similar. It is effective with lower concentrations, especially from mucous membranes (Runge and Schmidt, 1931). Its toxicity on injection is ten times greater than that of procaine. It is used chiefly for surface anesthesia on the conjunctiva (0.5 per cent) and nose and throat (2 per cent); also in spinal anesthesia (1 to 2 cc. of 1 per cent).

Tro'pacocaine Hydrochloride (benzoyl-pseudo-tropeine) occurs in Javanese coca, but the commerical is synthetic. Colorless needles, readily soluble in water. It destroys the vasoconstrictor action of epinephrine. Dosage, locally, one or two times that of cocaine. Anesthetic action about the same; irritation greater; toxicity one-half that of cocaine; less mydriatic; more stable. It is used especially for spinal anesthesia (Stanley, 1916).

Tútocaine Hydrochloride, N.N.R., is a procaine derivative, effective from mucous membranes, as well as by injection, but toxicity (intravenous) is four times that of procaine, and death has been reported from 8 cc. of 2 per cent urethral injection. Dosage, for mucosae: eye, nose and throat, 2 to 5 per cent; urethra, 0.5 to 1 per cent; hypodermically, 0.2 per cent.

Yohimbine, an alkaloid isolated by Spiegel, 1896, from the bark of Yohimbehe tree (Apocynaceae; West Africa), appears to be identical with quebrachine (Fourneau and Page, 1914; Hamet, 1927). As a local anesthetic it has about the same potency as, but is more lasting tihan cocaine. It is less toxic, but much more irritant. Mydrasis, occurs without loss of accommodation. The vessels are dilated. Intestines, excised or *in situ*, and bladder are stimulated by small, depressed by large, doses (A. Loewy and Rosenberg, 1914). Solutions are unstable. The *systemic effects* vary with the dose and method of administration. Large doses intravenously *reverse epinephrine* and dilate the renal vessels. It does not interfere with the pressor response to electric sympathetic stimulation, or of nicotine or acetylcholine in atropinized animals (Koppanyi, Linegar and Herwick, 1943). It diminishes other epinephrine effects (M. Hutchinson *et al.*, 1942). Slow injection produces slow rise of blood pressure by cardiac stimulation. Intraspinal or suboccipital injection produces anesthesia and lowers the blood pressure (F. Mercier and Delphaut, 1936). The spleen is dilated by large, constricted by small, doses (Bariéty and Kohler, 1939). The autonomic actions were studied by P. Weger, 1929. When it is given by the mouth or hypodermically in moderate doses, it produces general *vasodilatation* in the skin, mucous membranes and particularly in the *sexual organs*. In consequence of the latter, and perhaps by a direct action on the spinal centers, it produces erection. It does not seem to stimulate the production of spermatozoa or sexual desire. It does not increase the rate of reproduction in mice (Rumry, 1918). The effect is not produced by therapeutic doses in man (5 mg. or $\frac{1}{12}$ grain), although it has been promoted as an aphrodisiac. The reports of clinical improvement after several weeks are probably explainable by suggestion. In female rats, small doses, 1 to 2 mg., provoke prolonged estrus; 3 to 4 mg.

produce *pseudopregnancy.* These effects have been attributed to stimulation of the *anterior pituitary* (Fugo and Gross, 1942). A 1:1000 solution ingested by rats as drinking water over three months was nontoxic (F. F. Yonkman, 1944). Yohimbine has been proposed for lowering abnormally high blood pressure; but Lawrence, 1912, found that it may produce a further rise, with dangerous symptoms. Small doses lower the *temperature* of normal rabbits, and also after destruction of the heat centers. Larger doses are antipyretic against cocaine or "tetra" fever (Yamauchi, 1928). Large doses produce psychic excitement, cerebral congestion, vertigo, gastric disturbance; and in rabbits, marked injury of the renal epithelium (Huebner, 1912). Toxic doses produce general stimulation and subsequent paralysis of the nervous centers, particularly in the medulla; and complex effects on the cardiac muscle (F. Mueller, 1907; J. Tait, 1910). The coronary vessels are not affected (Rabe, 1912); or they are dilated (F. Meyer, 1912). Death occurs by respiratory paralysis (literature, Strubell, 1906).

Ethyl yohimbine was studied by A. G. Young and Yonkman, 1929.

◆

DRUGS ACTING PERIPHERALLY ON THE AUTONOMIC SYSTEM

A variety of poisons act peripherally on the several portions of the involuntary or "vegetative" nervous system, in a more or less specific manner. It appears advisable to premise their individual consideration by a more general exposition.

Anatomic and Physiologic Relations.—The "autonomic" system (Langley, 1921) includes all the functions subject to involuntary nervous control—the smooth and cardiac muscles and the glands. They are capable of functioning automatically, when all connections with the cerebrospinal axis are severed, but their functions are normally regulated, augmented or inhibited by central tonic impulses of varying intensity. The distinctive *anatomic* peculiarity of the automatic nerves is that they pass through relay ganglionic cells, situated outside the central nervous axis. The cells of the sympathetic division are mostly collected into the chain of sympathetic ganglia, including the splanchnic ganglia; those of the parasympathetic division are mostly situated on and in the organs. Each nerve fiber has but a single relay, although it may pass through a number of ganglia.

The two divisions of the autonomic nervous system, the *cholinergic* or *parasympathetic* and the *adrenergic* or *orthosympathetic*, generally called the *sympathetic*, differ in their response to drugs; in embryologic derivation in the site of origin in the central nervous system; in the location of the ganglionic cells, and in the fact that both divisions may innervate the same cell, generally in antagonistic directions.

Distribution and Function.—The two divisions are usually antagonistic, a given organ as a rule receiving its innervation from both divisions, one being augmentor, the other inhibitory. The *orthosympathetic division* is generally augmentor to the blood vessels and to the organs derived from the ectoderm; the *parasympathetic system* is augmentor to the organs derived from the endoderm. The inhibiting innervation is generally just the converse. (Circular and longitudinal coats have the same—not reciprocal—innervation; Gaskell). The innervation of the *sweat glands* occupies a peculiar position; anatomically, it is purely sympathetic, but it reacts pharmacologically as if it were purely parasympathetic. The *nictitating membrane* of the cat, with purely sympathetic innervation, also reacts to cholinergic drugs and atropine (review, C. W. Darrow, 1943). The *uterus* is also exceptional: its sympathetic innervation responds to both classes of poisons. It must be remembered, however, that the anatomic evidence of the origin of the autonomic nerves is in some respects inconclusive. The designations "cholinergic" and "adrenergic," introduced by Dale, give a consistent classification (review, O. Loewi, 1945).

The *innervation of glands* is analogous to the muscular innervation; the glands derived from the epidermis (sweat) receive their augmentor supply from the sympathetic; the parasympathetic augments the endodermal glands (pancreas, gastric, mucus, etc.). The salivary glands probably have cells derived and innervated from both systems.

The most important augmentory and inhibitory innervations are:

Vasodermal System.—Augmentory, adrenergic; Inhibitory (so far as they exist), cholinergic.

Genital System.—(Uterus and Ureter.) Augmentory and inhibitory, both adrenergic.

Intestinal Sphincters.—Augmentory, adrenergic; inhibitory, cholinergic.

Intestinal Muscle.—Augmentory, cholinergic; inhibitory, adrenergic.

Esophagus and Cardiac Sphincters.—Augmentory and inhibitory, both cholinergic.

Heart and Vessels.—Augmentory, adrenergic; inhibitory, cholinergic.

Iris Sphincter and Ciliary Muscle.—Augmentory, cholinergic (tectal division); *Iris radial,* augmentory, adrenergic.

Autonomic Ganglia of Both Divisions.—Augmentory, cholinergic.

Pharmacologic Reactions of the Autonomic System.—The orthosympathetic and parasympathetic ganglia react alike toward poisons, for instance, nicotine. Beyond the ganglia the reactions to drugs are often more or less strictly confined to one or the other innervation; *i. e.*, peripheral pharmacologic reactions tend to be either "sympathomimetic" (Barger and Dale, 1910), as epinephrine, cocaine and ergotoxine; or "parasympathomimetic" (Langley), as pilocarpine, muscarine, choline, physostigmine and atropine. It appears that these systems are normally activated by specific neurohormones belonging to these groups, so that Dale, 1934, designated the orthosympathetic system as "*adrenergic*" and the parasympathetic as "*cholinergic*." This suggests a fundamental difference in the physico-chemical characteristics of the receptive mechanism of the two systems, but this is not absolute: A number of poisons act only on certain parts of one or both divisions; and even the most specific of the drugs, such as epinephrine or acetylcholine, may apparently have their actions transferred to the contrary division under certain conditions.

Pharmacology of the Parasympathetic (Craniosacral) Division.—This is stimulated by choline and its esters, pilocarpine, muscarine and indirectly by physostigmine (eserine). It is paralyzed by atropine, which is therefore antagonistic to all the other drugs named. If a sacro-cranial function is exposed simultaneously to the depressant action of atropine and to the stimulant action of one of the other drugs, the end result depends on the nature and quantity of the drug, and upon other conditions. The centers of the parasympathetic system are stimulated by picrotoxin.

The principal results of parasympathetic stimulation consist in: slowing of the heart; constriction of the pupil; bronchial spasm; contraction of intestine and uterus; increase of practically all centrally innervated secretions (sweat, saliva, mucus, gastric, pancreatic, etc.; not urine, bile, milk or the internal secretions). These are the main effects of pilocarpine, muscarine and physostigmine. *Craniosacral depression* (atropine) produces precisely the opposite results.

Discrepancies of Parasympathetic Poisons.—One of the most marked is the response of the retractor penis muscle of the dog: stimulation of the nerves gives inhibition; pilocarpine, contraction. Differences of degree of effect occur, most striking in small intestines.

Pilocarpine stimulates some sympathetic innervations: sweat glands, uterus, contraction or dilatation of arterioles, contraction of spleen. Atropine also paralyzes some sympathetic innervations: submaxillary secretory; sweat glands; skin glands of frog; secretory fibers of the prostate; and antagonizes pilocarpine wherever that acts. Gohara claims that it also abolishes the contractor effect of epinephrine on rabbit's uterus.

Pharmacology of the Orthosympathetic Division.—*Epinephrine*, the alkaloid of the suprarenal gland, produces a pure peripheral stimulation, restricted exclusively to the sympathetic system, but involving the entire distribution of this system (with the exception of the sweat glands). In other words, the effects of typical doses of epinephrine on a given organ correspond precisely to the stimulation of its sympathetic nerve supply (Lewandowsky, 1899; Langley, 1901; Elliott, 1905). The action of epinephrine is therefore augmentory or inhibitory, according to whether the sympathetic impulses are augmentory or inhibitory. The *augmentory reactions* include constriction of most of the arteries and consequent rise of blood pressure; stimulation of the cardiac accelerator; dilation of the pupil; contraction of the plain muscle of the orbit; flow of sympathetic saliva and of tears, not readily abolished by atropine; erection of hair, etc. *Inhibitory reactions* occur only in organs whose function is augmented by parasympathetic stimulation (C. W. Darrow, 1943). They concern the tone and rhythm of the contractions of the stomach, intestine, biliary and urinary bladder (cat), and of the virgin uterus of the cat. *Cocaine* increases the peripheral excitability of the sympathetic system without being directly stimulant.

Divergences of Epinephrine from Sympathetic Stimulation.—The only structures markedly influenced by sympathetic stimulation and not by epinephrine after nerve section are the sweat glands in the cat and some other mammals. There is also an instance of parasympathetic stimulation by epinephrine: the pulmonary arteries of frog and turtle are constricted by epinephrine and by vagus stimulation; antagonized by atropine; and they do not constrict by sympathetic stimulation (Luckhardt and Carlson, 1921).

Quantitative differences are more numerous; in cases where sympathetic stimulation causes both augmentory and inhibitory effects, the predominance with epinephrine may be the reverse of that with nerve stimulation.

Removal of the entire sympathetic system from cats and dogs is compatible with life and with normal functioning and activity (Cannon, 1929), but such animals adjust less perfectly to a number of conditions, such as emotional excitement, heat or cold.

Peculiarities of Species.—Certain of the sympathetic reactions vary with the species of animals, being augmentory in some and inhibitory in others (urinary bladder anal sphincter). The sympathetic reaction of the uterus varies according to its physiological state; in the cat, the virgin uterus is inhibited, while the pregnant uterus is stimulated. All these peculiarities are reproduced exactly in the reaction to epinephrine, thus furnishing the most striking illustrations of its sympathomimetic action.

Other Drugs with Sympathomimetic Action.—Similar actions are possessed by a large number of primary and secondary amines, the simplest being the primary fatty amines (amylamine, etc.). There are quantitative differences between these. The relative effect on the different sympathetic distributions does not go parallel; nor is there any parallelism between augmentory or inhibitory innervations. The intensity and specificity increase as the amines approach the structure of epinephrine (Barger and Dale, 1910). A compilation of the amines and their relation to pharmacology is also given in Guggenheim's book.

Peripheral Sympathetic Paralysis: Ergotoxine.—The active alkaloids of ergot (in large doses) destroy the response of the augmentory sympathetic impulses, and in larger doses also the inhibitory sympathetic impulses (Röthlin, 1929; Dale, 1906). It therefore prevents the vasoconstrictor action of epinephrine, but not ordinarily the inhibitory action on the intestine or uterus. Similar effects result from certain synthetic phenoxyethylamines and dioxane derivatives prepared by Fourneau ("F 833" and "F 933"). The most distinctive "sympatholytic" action appears to be exerted by *dibenzyl-beta-chloroethylamine* and related compounds (M. Nickerson and Goodman, 1946).

The **autonomic ganglia** of both divisions are cholinergic; they are stimulated by the parasympathetic stimulants and depressed by atropine and by epinephrine.

The best evidence is furnished by the action potentials in the postganglionic nerve trunks (for instance, the cervical sympathetic) in response to natural or test stimulation of the preganglionic trunks (Marrazzi, 1939). These action currents are increased by pilocarpine and depressed by atropine, with mutual antagonism in the ratio of A:P::1:10. Pilocarpine in the ordinary doses only increases the ganglionic response and never initiates ganglionic activity. Excessively high concentrations of acetylcholine inhibit the response. Epinephrine, ephedrine and their derivatives in full doses inhibit synaptic transmission through the ganglia (Marrazzi, 1940). Small doses of epinephrine improve it (Bulbring and Burn, 1944). Cannon and Rosenblueth, 1937, concluded that sympathetic ganglia are stimulated and then depressed by acetylcholine, and that prostigmine potentiates electrical stimulation of the preganglionic fibers. It has no direct effect on the postganglionic fibers, but depresses their response to preganglionic stimulation by leading to excessive acetylcholine accumulation in the ganglia. *A difference,* however, appears to exist between the parasympathetic and sympathetic ganglionic synapses, in their reaction to *deficiency of calcium ions;* for intravenous injection of sodium citrate temporarily paralyzes the parasympathetic path to the pupillary sphincter of the cat, at the ganglionic synapsis, but has no effect on the pathway for pupillary dilatation, for vasoconstriction and other sympathetic reactions (G. D. Shafer, 1939).

Nicotine paralyzes all the ganglionic synapses of both the parasympathetic and the orthosympathetic nerves (often after fleeting primary stimulation). The paralysis is so specific that it has proved of great value, especially in the hands of Langley, for locating the site of these synapses. Nicotine, whether it is applied locally or systemically, abolishes the response to stimulation of the preganglionic fibers, while the postganglionic fibers respond normally.

Strychnine, acetylcholine, choline, arecoline, physostigmine and potassium ions, like nicotine, stimulate and then depress all autonomic ganglia. Curare, sparteine, large doses of atropine, methenamine iodomethylate and the Fourneau sympatholytics depress without precedent stimulation. The depression is antagonized by stimulant doses of nicotine. The susceptibility to paralysis is in the following order: *first,* cardio-inhibitory; *second,* chorda-secretory, sweat, pilomotor, pupil dilator and constrictor, probably also bulbar and sacral vasodilators; *third,* nictitating membrane and cutaneous vasodilators; *fourth,* epinephrine secretors and abdominal vasoconstrictors.

Localization of Action.—The possible points of attack in the peripheral distribution of the autonomic system may be grouped as (1) The ganglionic elements; (2) the nerve endings, including the terminal fibrils; (3) the receptive mechanism or excitability of the terminal cell; (4) the responsive mechanism of the cell, *i. e.,* the contractibility or secretory activity.

The *methods of analysis* rest upon the general principle of localizing depression by the application of stimuli, and stimulation by producing depression or paralysis, centrally and peripherally to the suspected site of action. This is simple for the ganglia, when these are situated apart from the other structures; but when they are intermingled, less direct and correspondingly less decisive methods must be employed. The difficulty increases with the more peripheral structures. Stimulation of the nerve fibrils and endings may be excluded by section and degeneration; but the converse does not hold, *i. e.,* disappearance of response after degeneration does not prove that the stimulation was in the nerves; for section of the nerves also causes degeneration of the muscle fibers, and consequently changes in their excitability. The degeneration method could not throw light on the site of a depressant action. This, and still more the distinction between the receptive and the responsive mechanism, rests upon indirect methods. It is tempting to aid the localization by the use of antagonistic drugs; but this is likely to mislead, since the antagonism of drugs is influenced by factors other than their normal site of action (Magnus, 1908). Because of these difficulties, the current views as to the localization of autonomic actions are tentative rather than final; they serve to classify rather than explain the observations. Their general tendency is toward simplification: It appears that the nerve fibrils and endings are not concerned in the specific autonomic reactions; that the ganglia play a minor share, except with the nicotine group; and that therefore the autonomic poisons act almost exclusively directly on the receptive or responsive mechanism of the muscle or gland cell.

The Ganglia.—Localization in these structures is illustrated by the effects of nicotine on the heart. After the injection of the drug stimulation of the vagus trunk fails to slow the heart, but stimulation of the postganglionic fibers, in the sinus, produces the normal slowing. The nicotine must therefore have paralyzed something between these points, *i. e.*, the ganglia.

The ganglia of invertebrates (*f. i.*, Sipunculus, Magnus, 1903; cardiac ganglia of the king-crab, Carlson, 1906) are susceptible to the whole series of autonomic drugs. With vertebrates, however, wherever the ganglia can be separated with sufficient sharpness, they do not seem to be very susceptible to autonomic poisons other than the nicotine group, but they are somewhat cholinergic.

Functions of the Ganglion Cells.—These are evidently the nutrient centers of the nerve fibers. With invertebrates they may also act as reflex centers; but there is no clearly demonstrated instance of this function in vertebrates. As early as 1868 Maurice Schiff (Leçons sur la Physiologie de la Digestion, pp. 394–396) insisted that the conception of sympathetic ganglia as "peripheral reflex centers" was without experimental foundation. On the whole, the facts seem in harmony with Gaskell's view that the ganglion cells of the autonomic system are connector elements, analogous to the pyramidal cells of the motor system, but transposed to the periphery.

The motor end plates of striped muscle are interpreted by Eichler, 1938, as ganglion cells with normally latent rhythmicity, which mav be made active by veratrine.

Nerve Fibrils.—There is no conclusive evidence that any specific autonomic poisons act on the "nerve endings" that degenerate after section of the nerves; and the evidence of excised organs is distinctly against this mechanism. Nerve fibers, where they can be reached directly, are practically unaffected by most of the specific autonomic poisons. It is therefore improbable that the finer terminal fibrils, which seem to be mere continuations of the axis cylinders, should be the site of the specific actions. They differ from the larger fibers in permeability, but this would cause only quantitative differences. Direct evidence against the nerve fibrils is furnished by the persistence of the responses to autonomic drugs, in excised organs after the excitability of the nerve fibers has been lost. The effects of a number of autonomic drugs, notably epinephrine and acetylcholine (Cattell and Wolff, 1935), can still be evoked after complete degeneration of the nerve, following division of the nerve trunk. This localizes their action definitely beyond the terminals that are in nutritive connection with the nerve.

The interpretation of the converse phenomenon, disappearance of the drug response as the result of degeneration, is not so decisive. The effects of pilocarpine, for instance, can be evoked like those of epinephrine, after degeneration, *i. e.*, when stimulation of the nerve trunk is ineffective. After a time, however (six weeks for sweat; Anderson and Langley, 1904), the response becomes less efficient, although the muscle still responds to electric stimulation. This probably means that in the end the muscle cell also deteriorates, "atrophies," when it is not functionally used; and that this deterioration abolishes its excitability by pilocarpine before it abolishes the contractor response to direct electric stimulation. The protoplasm of motor end plates shows morphologic changes after the nerve is severed, and they may disappear in about six months (review, S. S. Tower, 1939).

The Receptive Mechanism.—Since degeneration of the nerve endings does not interfere with the typical effects of epinephrine, this must act on the muscle cells directly. This conclusion encounters the difficulty that epinephrine acts in reverse directions on smooth muscle in different locations, producing contraction in one place and relaxation in another. The smooth muscle in both cases appears to be identical, and reacts in a uniform direction to other stimuli, such as electric shocks, or poisons like barium. They differ only in their innervation, and this difference is reproduced faithfully by epinephrine. Since the degeneration experiments clearly prove that epinephrine does not act upon the nerves themselves, it becomes necessary to assume the existence of some intermediate mechanism, related to the innervation, but not trophically dependent upon it. Presumably all specific autonomic poisons act through the mediation of receptive mechanisms which differ specifically for ortho- and parasympathetic innervations, probably by releasing epinephrine or acetylcholine at the synapse (review, O. Loewi, 1945).

The mediating mechanism may be regarded in several ways: (*a*) as a morphologic structure; (*b*) as a chemical receptive substance or side chain; (*c*) as a physical system. The available facts do not permit a decision between these; indeed, the theories themselves lack so much in detail that a decisive attitude toward them would not be justified. Consequently, there is an advantage in employing a noncommittal term, such as "*receptive mechanism*," for the entire concept; and restricting the more specific terms, "myoneural junction" (Brodie), "receptive substance" (Langley, 1905) and "synapse," to the special theories that they represent. Critical reviews of the older theories may be found in the reviews of Langley, 1921, and Sollmann, 1922.

The Responsive Mechanism.—The sharp separation of this from the receptive mechanism is of doubtful validity: The functions of excitability and contractility or secretion are so closely related that it is impossible to imagine a muscle that is excitable but does not contract; or one that contracts but is not excitable.

The actual presence of nerves is not necessary for the response to cholinergic or adrenergic drugs, for smooth muscles that are devoid of innervation, such as the chick amnion (Baur, 1928) and tissue cultures of embryonic intestine, contract with acetylcholine and relax with atropine and with epinephrine. The ingrowth of nerves may sensitize and in some cases reverse the response (J. Ferguson, 1940; E. Fischer, 1944).

The heart of the chick embryo does not respond to ordinary concentrations of acetylcholine until the vagus fibers have been developed (V. E. Henderson and Roepke, 1937); nor does acetylcholine inhibit cultures of the chick heart (Garrey, 1937), nor the heart of fundulus embryos until shortly after the nerve fibers have reached the auricles. This holds also for pilocarpine. The striped muscle contracture by acetylcholine, however, occurs before as well as after innervation (Armstrong, 1935).

Chemical Mediation of Autonomic Stimulation: "Neurohormones."—The demonstration that autonomic nerves liberate chemical substances in the end organs, which produce para- or orthosympathetic stimulation according to the kind of nerve stimulated, suggests that the mediation between nerve and cell consists in the specific chemical action of these substances (Dale), therefore called neurohormones by L. Fredericq, rather than in the physical transmission of an electric potential from the nerve to the effector cell. From their pharmacologic actions and chemical behavior, the neurohormones appear to be identical with acetylcholine and epinephrine or noradrenalin (arterenol) respectively, or at least to be closely related derivatives of these. They are presumably formed from relatively inactive relatives, choline and oxidized epinephrine, existing in or about the nerve terminals and cells, probably as reversible systems—esterification for choline, oxidation-reduction for epinephrine (review and bibliography, Bacq, 1934). The relatively slow response to autonomic stimulation speaks for an exclusively chemical mediation, but the high concentration of choline esterase in the nerve axons and at the synapses makes even rapid responses appear feasible (Nachmansohn and John, 1945). This does not exclude the possibility that the nerve impulse may produce potential changes directly, but of this there is no conclusive evidence.

Mornier and Bacq, 1935, argue that the mediation is ordinarily chemical, but that the electrical potential enters into play when chemical mediation is blocked, as by "933 F." Nor need it be supposed that autonomic drug stimulation can occur only through these neurohormones. Some drugs have a specific relation to them, which is clear for physostigmine-acetylcholine, still obscure for the cocaine-epinephrine sensitization, the atropine and ergotamine inhibition, and the ephedrine stimulation. Neurohormones are probably not involved in the response to drugs with nonspecific peripheral actions—barium, magnesium, nitrite; perhaps histamine, pituitary and thyroxin.

Parasympathetic Hormone.—The discovery of neurohormones started with the observation by O. Loewi, 1921, of a typical vagus effect by a Ringer perfusate from a frog heart that had been subjected to vagus stimulation. This was confirmed on the hearts of other vertebrates (*f. i.*, Riccitelli and Vita, 1928), and extended to parasympathetic innervation generally (review, Thompson and Collip, 1934). *Atropine*, which prevents motor or secretory response to the parasympathetic stimulation, and so the action of the hormone, does not interfere with the production of the hormone, but with its action (Loewi).

Smaller doses of atropine generally suffice to antagonize cholinergic stimulation by drugs rather than by electric stimulation of the nerve. In explanation Dale, 1934, suggests that "the nerve impulses liberate acetylcholine so close to the reactive structures that atropine cannot intervene, whereas it can prevent its access to them when it is artificially applied from without." Several new anticholinic agents are reported by Abreu *et al.*, 1946.

Identification of the Parasympathetic Hormone with Acetylcholine.—The pharmacologic and chemic reactions of the perfusate are characteristic of acetylcholine, especially the *specific sensitization by physostigmine* and related bases (neostigmine), so that dilutions which have practically no effect when used alone, produce strong parasympathetic stimulation when used together, in excised organs, or with intact circulation. Physostigmine also greatly prolongs the effects of acetylcholine, which are otherwise brief, especially on intravenous injection (*f. i.*, clinically, Ellis and Weiss, 1932). Physostigmine sensitizes by inhibiting the specific choline esterase which is present in all parasympathetic tissues, and which normally effects rapid hydrolysis of acetylcholine to choline, whose parasympathetic potency is $\frac{1}{500}$ or less that of choline (O. Loewi and Navratil, 1926).

The Physostigmine Test for Acetylcholine.—Using this principle, Fuehner, 1916 and 1918, introduced the physostigminized dorsal muscle of the leech as a specific test for acetylcholine, sensitive to 1:20,000,000,000 (Binet and Minz, 1934). The specificity was confirmed by Chang and Gaddum, 1933; it can be made quantitative by observing uniform conditions (Binet and Minz). Very dilute solutions of physostigmine are effective (1:40,000,000 *in vitro;* Engelhart and Loewi, 1930; 0.01 mg. per Kg. *in vivo*, optimal 0.05 mg. per Kg., G. W. Manning *et al.*, 1937). Conversely, 0.01 γ of acetylcholine may be demonstrated by the blood pressure reaction (Gibbs and Szelöczcy, 1932). Other parasympathetic innervations may be used as test objects: the chorda tympani, frog heart, excised intestine, etc.

The degree of physostigmine sensitization to acetylcholine varies with different organs. The sensitivity of leech muscle is increased more than a thousand times; that of frog rectus abdominis only five times (Chang and Gaddum, 1933). In the frog heart the response is not increased but prolonged (Loewi and Navratil, 1926). It has been suggested that the difference is related to the diffusion of acetylcholine; if this is slow there is more opportunity for destruction (A. J. Clark, 1937).

Physostigmine does not sensitize to other autonomic drugs, *f. i.*, pilocarpine, epinephrine, histamine, peptone; nor for choline itself (although it is utilized for the estimation of choline by previous acetylization). It is characteristic for choline esters, but may be considered practically specific for acetylcholine, since none of the other known esters approach this in the ratio of sensitization for different organs (Chang and Gaddum, 1935). Since this reaction applies to the "vagus substance" (Galehr and Plattner, 1927) and all the other parasympathetic perfusates, the identification of "*parasympathin*" or "*vagotonin*" with acetylcholine is considered practically assured, especially as acetylcholine is the only choline ester which has been isolated chemically from animal tissues (review, G. L. Brown, 1937). Physostigmine greatly prolongs the effects of acetylcholine, which are otherwise brief, especially on intravenous injection (*f. i.*, clinically, Ellis and Weiss, 1932). Removal of acetylcholine by *intravenous injection of choline esterase* prevents the transmission of nerve impulses to the pupil sphincter, so that the light reflex is abolished (Mendel and Hawkins, 1943). Physostigmine apparently competes with acetylcholine for the esterase, which combines with either, destroying them (A. Goldstein, 1944). A series of *synthetic bases related to physostigmine*, such as *neostigmine*, also produce this inhibition of acetylcholine esterase. It appears to be connected with the methylurethane side chain (Stedman and Stedman, 1931). Less potent inhibitions are caused by many unrelated substances: ergotamine (Mather, 1930), strychnine (D. Nachmansohn, 1938), or quinine; by local anesthetics (Adriani and Roverstine, 1941); by certain dyes, including gentian violet and methylene blue (Massart and Dufait, 1941); and by epinephrine oxidation products (Waelsch and Rackow, 1942). Epinephrine itself increases the synthesis of acetylcholine. The parasympathetic effects on epinephrine may be explainable by these actions on choline esterase (Torda and Wolff, 1944). *Nicotine* apparently desensitizes to acetylcholine.

Stimulation of cholinergic nerves liberates *thiamine* as well as acetylcholine (B. Minz, 1938). Thiamine and cocarboxylase inhibit choline esterase *in vitro* (Glick and Antropol, 1939), but the required concentrations are higher than exist in the serum and perhaps in the tissues. Biologic concentrations increase the synthesis of acetylcholine by homogenized frog brain (Torda and Wolff. 1944).

The choline esterase level of serum is very constant in a given individual (Milhorat, 1938), and in a variety of diseases. It is decreased in pregnancy and severe hepatic damage (Butt *et al.*, 1942).

Besides the *specific choline esterase*, which hydrolyzes only certain choline esters, there is *nonspecific choline esterase*, which hydrolyzes a variety of other esters, and is not materially concerned in the neurohormone function (Alles and Hawes, 1940; B. Mendel and Rudney, 1943). Both choline esterases are widely distributed. The superior cervical ganglion of cats contains them in about equal concentration. Most of the acetylcholine hydrolysis in sympathetic nerve trunks is accomplished by the specific esterase (C. H. Sawyer and Hollinshead, 1945). Frog brain contains a true choline esterase which is much more resistant to inhibition by physostigmine than is that of mammalian brain (R. D. Hawkins and Mendel, 1946).

Acetylcholine Synthesis.—The specific acetylcholine esterase perhaps accelerates the synthesis as well as the hydrolysis of acetylcholine. This two-sided reaction may constitute the chemical mediation of stimulation. While physostigmine inhibits the hydrolysis, it permits the synthesis of acetylcholine to proceed (F. H. Shaw, 1935).

Concerning the *site of the formation* of acetylcholine, it is suggestive that choline is a component of the lecithin molecule, which is abundant in *nerve fibers*. Binet and Minz, 1934, found that extracts of the vagus trunk give the acetylcholine test, which is materially greater if the nerve has been stimulated. The sciatic nerve gave a much smaller quantity and it was not increased by stimulation. Lissák, 1939, confirmed that acetylcholine or an analogous substance is liberated by stimulation of isolated parasympathetic nerves, of preganglionic nerves and of autonomic ganglia of both divisions, but not by sympathetic nerves. Stimulation of sympathetic nerves liberates a substance with epinephrine actions; stimulation of the sciatic nerve liberates both cholinergic and adrenergic substances. Quastel, Tennenbaum and Wheatley, 1936, found that acetylcholine or a related ester is formed on the addition of physostigmine to the fluid in which *brain sections* are suspended. The presence of glucose is essential for acetylcholine formation by brain sections (M. C. Sanz, 1943). Nachmansohn and Machado, 1943, report formation of acetylcholine by an enzyme extracted from brain and nervous tissue, in the presence of adenosine triphosphate, under anaerobic conditions. Extracts of nerves that have undergone Wallerian degeneration are much less effective (M. Berman and Nachmansohn, 1946). W. Feldberg and Mann, 1946, describe a complex enzyme system for the synthesis of acetylcholine in the central nervous system. This synthesizing ability is especially great for the cholinergic efferent nerves, small for afferent nerves.

The autonomic ganglia, sympathetic as well as parasympathetic, liberate acetylcholine (by the physostigmine test) on stimulation of their preganglionic fibers (W. Feldberg and Gaddum, 1933; V. E. Henderson and Roepke, 1934). With prolonged preganglionic stimulation of perfused superior cervical ganglion of the cat, the acetylcholine output starts at a high level, then falls rapidly for 20 to 60 minims, and then continues almost level (G. L. Brown and Feldberg, 1936). This has been cited as evidence that their stimulation occurs normally by this chemical mediation, since direct addition of acetylcholine stimulates ganglionic response with lower concentrations, although high concentrations are depressant (Cannon and Rosenblueth, 1937; Marrazzi, 1939); and with *oxygen lack* of the perfused stellate ganglion, there is practically parallel failure to respond to preganglionic stimulation to acetylcholine and to discharge spontaneous impulses (Bronk *et al.*, 1938). However, Lorente de Nó, 1938, 1940, found that the acetylcholine is not regularly released by stimulation of blood-supplied ganglia, but only after some departure from normal conditions, and then in extremely variable amounts; indicating that acetylcholine does not play an indispensable role in synaptic transmission (prolonged stimulation of the preganglionic fibers in dogs also decreases the potassium content of the ganglia; direct stimulation of the denervated ganglion does not do so; M. Vogt, 1936).

Choline Esterase Distribution in Nerve Structures.—Nerve trunks have a high choline esterase concentration. It has been shown in the giant nerve fiber of the squid that this is located at the surface of the fiber and practically none in the axoplasm (Nachmansohn and Steinbach, 1942). The concentration at the synaptic region is perhaps even higher, presumably by surface condensation on the arborizations (Marnay and Nachmansohn, 1933). The acetylcholine must be protected against it in some manner which is not clear (Dale and Dudley, 1929). Nachmansohn and Rothenberg, 1944, suggest that the choline ester is formed by nerve stimulation, and then renders the cell membrane permeable to ions, depolarizing it and generating a current which stimulates the adjacent region, and so propagates the ester formation and stimulation. The concentration of the esterase in the neural surface is sufficient to provide the needed speed of action even for the central nervous system (Fulton and Nachmansohn, 1943). Nerve axons have a high choline-acetylating activity, indicating that this is concerned in conduction along the axon as well as in the synapse (Nachmansohn, John and Berman, 1946).

Beutner and Barnes, 1945, find that aqueous acetylcholine solutions in contact with cholesterol establish a negative phase-boundary potential and suggest that this could furnish an explanation of negative variation ih living nerve. Triglyceride oils do not give a potential witn acetylcholine, but do with sympathomimetic drugs and would explain sympathetic stimulation. They can be sensitized to acetylcholine by lower fatty acids (T. C. Barnes and Beutner, 1945).

Di-isopropyl fluorophosphate (DFP) destroys choline esterase (A. Mazur and Bodansky, 1946), and so produces effects equivalent to persistent parasympathetic stimulation; those on the eye are useful in *chronic glaucoma* by instillation of 0.05 to 0.2 per cent in oil (see Index).

Sympathetic Neurohormone.—Stimulation of the postganglionic sympathetic innervation of an organ (*f. i.*, the accelerators of the heart or the splanchnics of the intestine) results in the production of a specific sympathomimetic stimulant, so that the perfusate produces sympathetic responses in other organs. With intact animals, these pass into the blood stream, and can be demonstrated on the denervated heart, the salivary glands, the nictitating membrane of the cat, etc.; also by crossed circulation experiments. The sympathetic synaptic transmission therefore also involves the appearance of a mediating substance, which was termed "sympathin" by Cannon, 1931. The substance has not been isolated, but from its pharmacological reactions and its chemical behavior, it is closely related to epinephrine, and is presumably epinephrine itself. It agrees in its sympathomimetic specificity, its easy destruction by oxidants and its sensitization by antioxidants, by denervation and by cocaine. In analogy with acetylcholine, its action is intracellular; for it acts not only after nerve degeneration, but also on tissues which have never been innervated: the amniotic membrane of the chick, the heart of early chick embryos (after the fifth day; also acetylcholine; Markowitz, 1931), and tissue cultures of embryonic chick heart. Minor differences, which have been described, appear insignificant (Bacq, 1934).

ME and MI Sympathins.—To account for the sympathetic response being excitant in some organs and inhibitory in others, Cannon and Rosenblueth, 1933, suggested that the sympathin (or epinephrine) does not act directly, but constitutes an intermediary substance "M," which then combines in the cells with a postulated excitant precursor "E" or inhibitant precursor "I" to form the assumed compounds "ME" = "sympathin E," or "MI" = "Sympathin I," which would constitute the effective substances that pass into the blood. The arguments for differentiation of sympathin and epinephrine are reviewed by A. Rosenblueth, 1937. It has been suggested (Bacq, 1937; Greer *et al.*, 1938) that "ME" is demethylated epinephrine (*nor-adrenaline;* arterenol). Oxidation of epinephrine by phenolase *in vitro* forms inactive *adrenochrome,* and then *adrenoxine,* which is inhibitory (review, Jeanne Lévy, 1940) and is supposed to constitute "MI." It is further assumed that this oxidation takes place in the cells inhibited by epinephrine, and not in those that are augmented, thus explaining *why some organs are excited, others inhibited* and others diphasic. *Sympatholytic drugs* are supposed to accelerate the oxidation. However, the actual occurrence of these processes in the cells is lacking in convincing experimental support; on the contrary, the perfusate or blood stream from an inhibited organ never produces inhibitory responses in an organ which is normally excited by sympathetic stimulation, or *vice versa,* as the hypothesis seems to demand. On the other hand, the chronaxia is lengthened both in inhibitory and in augmentory responses to sympathetic stimulation and to epinephrine (Florkin, 1929), so that the basis of the action appears identical in both cases, although the mechanical response is different.

Stimulation of the cardiac sympathetic trunk in frogs perfused with saline solution liberates *calcium ions* from the heart (A. Lanczos, 1936).

Epinephrine as an Oxidation-Reduction System.—The rapid oxidation of epinephrine in the blood and tissue results in physiologically inactive end products. It is a natural assumption that these may again be deoxidized to active epinephrine by the sympathetic nerve impulse, thus furnishing a rotating oxidation-reduction system analogous to the hydrolysis-esterification of acetylcholine in the parasympathetic system; but this has not been demonstrated.

It does not follow that the epinephrine acts on the cell through its oxidation-reduction potential, which is the same for both the optical isomers, while the action is much greater for the levo- than for the dextrorotatory epinephrine. *In vitro,* oxidation of epinephrine occurs in the side chain, yielding geno-adrenaline and adrenalone, or in one of the two phenolic hydroxyls, giving a "quinoid." This is devoid of sympathomimetic action, but recovers it by reduction. Adrenalone has only $\frac{1}{200}$ to $\frac{1}{300}$ the activity of epinephrine (Tiffeneau, 1934). Intravenous injection of sodium *permanganate* (10 to 20 mg. per Kg.) persists for a short time in the blood, and by oxidation prevents response to intravenous injection of epinephrine, but not to electric stimulation of the sympathetic nerves, presumably because it reaches the store of epinephrine in the nerve endings (Bacq, 1938).

Sensitization by Denervation.—The sensitiveness of an organ to epinephrine increases materially after degeneration of the postganglionic fibers following excision (Meltzer and Auer, 1904). This is especially marked for the augmentory responses. It can also be demonstrated for parasympathetic reactions (S. C. Shen and Cannon, 1936). The sensitization does not occur immediately after excision, so that it is not due to removal of central inhibition. It develops with the degeneration of the severed nerve fibers and reaches its maximum about the fifth day. Degeneration of the preganglionic fibers does not sensitize, or only to a slight degree (Elliott, 1905; Cannon and Rosenblueth, 1936). Results of H. G. Wolff and Cattell, 1937, indicate that the sensitization is due to the accumulation of effector substance (epinephrine), which is normally used up by the sustained bombardment of the nerve impulses from the ganglion cells.

Lissák, 1938, found that denervated superior cervical ganglia give extracts with epinephrine action, instead of the normal acetylcholine. After degeneration following removal of one superior cervical ganglion, the iris of this side is more sensitive to atropine as well as to epinephrine; pilocarpine and acetylcholine also become mydriatic on this side, the response to ephedrine and cocaine is diminished, and that to amphetamine is unchanged in cats (M. E. Drake *et al.*, 1939). Cutting merely the preganglionic nerve causes this iris to respond less strongly to mydriatic and more strongly to miotic drugs (Lanczos, 1939). Excision of the superior cervical ganglion augments the response of the *submaxillary gland* to pilocarpine and acetylcholine, as well as to epinephrine (Simeone and Maes, 1939). Denervation of *intestines* sensitizes to epinephrine, not to ephedrine or cocaine (Drake *et al.*, 1939). Denervation of the skeletal *rectus muscle* of toads sensitizes them to acetylcholine and to nicotine contracture. This has been attributed to decreased potassium content. Soaking in calcium solution has the opposite effect (L. Y. Lee, 1939).

Cocaine Sensitization to Sympathetic Stimulation.—Froehlich and Loewi, 1910, discovered that intravenous injection of cocaine (which has little effect on the spontaneous autonomic activity even after postganglionic degeneration) materially increases the responses of the blood pressure, iris and urinary bladder to epinephrine. This has been confirmed for the other responses of epinephrine, including the hyperglycemia, but is less marked for inhibitory than for augmentory reactions. The sensitization extends also to electrical stimulation of the sympathetic nerves (Rosenblueth and Rioch, 1933), but the sensitization to epinephrine is even greater after degeneration of the postganglionic fibers, the two sensitizations being additive (Rosenblueth and Cannon, 1932). The denervated nictitating membrane of the cat is thus used by Cannon and his associates as a delicate test for epinephrine or "sympathin." Cocaine probably acts by inhibiting the enzyme that oxidizes epinephrine.

Other local anesthetics (or other ecgonine derivatives) do not produce an equivalent sensitization to epinephrine (and desensitization to ephedrine) (Wirt and Tainter, 1932), although there is some such tendency (Bacq and Lefebvre, 1935). The cocaine sensitization is confined to epinephrine and closely related derivatives (Tainter, 1931). The responses to ephedrine and tyramine are more or less inhibited; those to the nonspecific stimulants (posterior pituitary, strophanthus, barium) are not affected (review, Bacq, 1934).

These statements apply chiefly to the blood pressure and to the nictitating membrane of cats. Other organs may differ. In the *intestines* of unanesthetized dogs (Thiry-Vella loops), epinephrine, tyramine and ephedrine decrease the tonus and amplitude; cocaine, intramuscularly, abolishes the depressive response to tyramine and ephedrine and has little effect on that of epinephrine (C. M. Gruber, 1936). In perfused frog legs, cocaine and most local anesthetics (but not procaine) abolish the vasocontrictor response to barium, while the response to epinephrine remains active (Rentz, 1930).

The destruction of epinephrine by perfusion through the leg of cats is decreased by the addition of cocaine, ephedrine or tyramine (W. S. Lawrence, Morton and Tainter, 1942). *In vitro*, cocaine inhibits the accelerating effect of acetaldehyde on the oxidation of epinephrine by potato *tyrosinase*, while this is accelerated by ergotamine, F 933 and F 833, the substances which desensitize to epinephrine (G. Bayer and Wense, 1938). This suggests a tempting explanation of sensitization and desensitization.

Sympatholytic Action.—Responses to stimulation of the sympathetic nerves or to epinephrine are prevented (paralyzed) by the ergot alkaloids ergotamine and ergotoxine (but not by ergonovine; Cannon and Bacq, 1931), by dibenzyl-beta-chloroethylamine (M. Nickerson and Goodman, 1946), and by yohimbine (Langecker, 1926; Hamet, 1927), synthetic phenoxyethylamine and dioxane derivatives synthesized under Fourneau, J. Lévy and Ditz, 1933, and somewhat by the methyl xanthines (N. Fredericq and Descamps, 1921). The ergot alkaloids have been especially investigated, although they produce a variety of other actions which make the interpretation difficult; and they act chiefly on the augmentory reactions. It has been shown (Navratil, 1927) that the interference is with the motor response, not with the formation of "sympathin" (analogous to the atropine parasympathetic paralysis). Bacq suggests that the ergot desensitization is a result of increased muscular tone, which is known to decrease the response to epinephrine. C. W. Darrow, 1943, also denies true sympatholytic action to the ergot alkaloids and attributes the effects chiefly to parasympathetic or physostigmine-like actions.

Fourneau "F 883," diethylamino-methyl-3-benzodioxane, is both adrenolytic and sympatholytic. "F 933," piperidine-methyl-3-benzodioxane, is adrenolytic, but not sympatholytic. These compounds are not used clinically because of side actions. The Nickerson and Goodman compound, *dibenzamine hydrochloride*, is clinically effective by all routes of administration.

Tokieda, 1927, reported that *ergotoxine* annuls the inhibitory as well as the augmentory effects of epinephrine on the uterus, intestines, blood vessels and excised eyes. It had no effect on the uterine actions of pilocarpine, quinine, hydrastinine and pituitary; it had only slight effects on the cocaine action on the eye and uterus. Tainter, 1932, also found that doses of ergotamine which reverse epinephrine do not alter the pressor response to barium and pitressin, and do increase the response to strophanthin. *Quinine* (0.003 to 0.02 per cent) reverses the augmentory effects of epinephrine on excised organs of rabbits (pregnant uterus, bladder trigone) and has no effect on inhibitory responses to epinephrine, nor on the barium and pilocarpine stimulation (Fujita, 1927). All sympatholytic agents diminish the chronaxia of smooth muscle materially, without affecting that of striped muscle (Lapicque, 1934). Low concentrations of ergotoxine, yohimbine and F 933 sensitize rabbits' ear to epinephrine, but not the frog heart or blood pressure. Higher concentrations antagonize epinephrine and sympathetic stimulation; but with cats' nictitating membrane they abolish only the epinephrine response, not that to stimulation of the sympathetic nerve, which may be increased (C. S. Jang, 1941). *Yohimbine* diminishes or reverses the epinephrine blood pressure rise, but not that of electric sympathetic stimulation or of nicotine or acetylcholine in atropinized animals (Koppanyi, Linegar and Herwick, 1943). Yohimbine does not diminish other epinephrine effects (Hutchinson, Shaw and Wragge, 1942). Benzylimidazoline hydrochloride (*Priscol*) stimulates the ileum, apparently by a cholinergic action, for it is inhibited by atropine or trasentine (Yonkman, Hays *et al.*, 1946). *Ascorbic acid* probably inactivates sympathomimetic amines by deamination. Its administration diminishes the excretion of amphetamine as such (K. H. Beyer, 1941).

Ephedrine, whose chemical structure and pharmacological actions appear, superficially, closely related to those of epinephrine, differs fundamentally in its manner of action; for the effectiveness of ephedrine is not increased, but definitely diminished both by nerve degeneration and by cocaine (Burn and Tainter, 1931). The difference is conditioned on the absence of the phenolic hydroxyl groups (Hamet, 1931), which is also responsible for its resistance to oxidation. The significance of the difference, however, is not clear, especially in view of the striking (but not universal) agreement in their sympathetic stimulation, and the fact that both act after nerve degeneration. *Tyramine* resembles ephedrine.

Dibenzyl-beta-chloroethyl amine and related compounds block and reverse augmentory adrenergic responses. After its administration, epinephrine and other sympathomimetic amines do not raise the blood pressure even with large doses, but instead produce a moderate fall. Inhibitory responses to epinephrine, such as the relaxation of nonpregnant uterus, are not altered. The blocking effect of a single dose may last some four days, although the substance is rapidly destroyed at the *p*H of the body, suggesting destruction of a reacting substance which is but slowly replaced. Eventual recovery is complete. Large doses produce chronic convulsions. Moderate doses protect dogs against cardiac irregularities of epinephrine-cyclopropane. The substance is effective by mouth; hypodermic injection produces local necrosis. It is promptly destroyed by sodium thiosulfate (M. Nickerson and Goodman, 1946).

Limitations of Specificity.—The preceding presentation is schematic and includes chiefly the typical effects, as they are currently conceived. When the doses and other conditions are varied, many of these drugs depart more or less from the schema. There are a number of drugs (for instance, histamine and pituitary extract) which do not fit anywhere in the schema, but whose actions involve isolated functions of one or both divisions.

With some autonomic drugs the response is reversed by altering the dosage; for instance, in the action of pilocarpine on the vagus. In such cases the critical concentration generally varies for different organs, so that a certain dosage may stimulate the innervation of one organ and depress that of another. Modifications in the excitability of an organ, for instance by the presence of other drugs, may alter its response. It is also suggestive that perverted drug specificity is most prominent in organs in which the innervation is itself unusual or confused. It is especially common when the tissue receives only one innervation, or when one innervation predominates largely over the other, or where both systems produce the same response; for instance, in the sweat glands, the genito-urinary system, the frog's lungs, the blood vessels

Optical Isomers.—Most if not all autonomic poisons are optically active (or racemic); and the chemic reactions which determine their specificity depend largely on their stereochemic configuration.

Our knowledge of these phenomena dates from the classic discovery of Pasteur that racemic tartaric acid is separated into its optical constituents by mold fungi. Since then, numerous instances have been worked out on higher animals; such as atropine and hyoscyamine; atroscine and scopolamine; the epinephrines, muscarines, nicotines, cocaines, cinchona alkaloids, camphors, etc. Cells and ferments distinguish sharply between these stereoisomers, so that they differ, at least quantitatively, in their pharmacologic effects, the racemic being intermediate between the active forms. In higher animals, the l-alkaloids usually have more powerful peripheral effects. It is probable that the cells can either attack or destroy the one isomer more readily than the other (Poulsson, 1910). With nicotine, both isomers are equally toxic for protozoa and arthropods, but for annelids, chaetognatha and vertebrates the levo is more potent than the dextro. It may therefore be assumed that the receptive substance is optically active in these, and not in the lower forms; and this is probably connected with the appearance of acetylcholine in the nerve transmission (Gause and Smaragdova, 1939). The asymmetric nitrogen atom also modifies the pharmacologic actions, as shown by Hildebrandt, 1905, for conines, and Laidlaw, 1913, for canadines. The curare action of the ammonium bases (Brown and Fraser, 1869) depends upon the peculiar orientation of the pentavalent atom of nitrogen or similar elements "The Biological Relations of Optically Isomeric Substances" forms the subject of a monograph by A. R Cushny, 1926 (Williams and Wilkins Co.).

Synergistic Phenomena.—When autonomic tissues are exposed simultaneously to several autonomic drugs that act in the same direction, the resultant effect is more or less additive, constituting *synergism*. The degree of summation is less complete if the drugs act on the same system (because of the Weber-Fechner law of diminishing returns) than when they act on different systems or structures. The latter constitutes *supplementary synergism;* the former, *complementary*. This principle is helpful in locating the site of action. *Potentiated synergism* exists if the resultant response is materially greater than the addition product of the two separate actions, especially if one of the agents has little or no action effect when used alone. Instances are the *sensitization* of physostigmine for acetylcholine, due to diminished destruction; and the sensitization of cocaine for epinephrine, probably due to a similar cause; but other mechanisms may be involved, as in the sensitization of the uterus in the course of pregnancy.

Antagonism exists if the two agents act in opposite directions. It tends to result in mutual neutralization, or in algebraic summation, which is generally more or less skewed. The most peripheral actions would tend to predominate over those exerted more centrally; accordingly the ganglionic effects are obscured by the actions on the responsive cells. If two drugs are mutually antagonistic, they must both act at the same level. Drugs with opposite actions on the same receptive mechanism (for instance, the parasympathetic) are generally mutual antagonists; but there may also be mutual antagonism between sympathetic and parasympathetic drugs, and between these and the drugs that act on the responsive mechanism. Mutual antagonism is rarely a simple summation; the presence of one autonomic poison modifies the effects of the others, in degree and sometimes in direction. If concentrations of two drugs that produced equivalent effects in opposite directions are mixed, the effect of one usually predominates decidedly over that of the other; for instance, a small dosage of atropine suffices to remove a strong pilocarpine stimulation (Magnus). Again, if a combination has been worked out that is essentially neutral, multiples of this combination are generally not neutral; although in some cases they may be so, within limits (Cushny, 1915). In the pilocarpine-atropine antagonism, pilocarpine action increases with the concentration, atropine with the absolute quantity (Van Lidth de Jeude, 1918). It may also happen that increased excitability produced by one drug renders effective actions of the second drug that are too weak to influence cells of normal excitability, and in this manner the site of action of the second drug may appear to be altered and reversed.

Altered Susceptibility.—Many conditions modify the response of smooth muscle to autonomic drugs, generally quantitatively, but sometimes qualitatively. The more important modifying agents are those with high surface affinity, precipitants, certain lipoids, colloids, changes in Ca, K and H ion ratio (Thienes, 1926).

Clinical Vagotonia and Sympathotonia.—Eppinger and Hess, 1909 and 1910, classified patients into these two groups according to their response to test doses of epinephrine, ergotamine, atropine and physostigmine. Further experience showed that abnormal sensitivity generally involves both autonomic divisions. The various criteria are listed by M. A. Wenger, 1941.

The ion ratio of Ca, K and H ions alters many autonomic functions, quantitatively and sometimes qualitatively. The effects vary for different organs and drugs. Zondek, 1927 ("Die Elektrolyte," Springer, Berlin), generalized from observations on excised heart, stomach, bladder and uterus, that increase of the ratio $\frac{Ca}{K}$ acts like orthosympathetic, and increase of $\frac{K}{Ca}$ like parasympathetic stimulation. Such generalizations are convenient, but the subject is more complicated and there are many exceptions (Bacq, 1934). With excised intestines, for instance, both increase and withdrawal of K augment the tonus and contractions (A. J. Clark, 1921). Lowering of the *Ca level* of the blood or perfusion fluid (in dogs, rabbits or frogs) lowers the excitability of both the sympathetic and parasympathetic division (Bouckaert, 1929). Lowering the $\frac{Ca}{N}$ ratio by increase of Na as well as by decrease of Ca lowers various sympathetic responses (Gley, 1928). The vasoconstrictor response of the perfused ear of rabbits by *epinephrine* requires the presence of Ca, not K, while constriction by ephedrine requires K and not Ca (Pinter-Kovats, 1928). K has directly opposite effects on the epinephrine response in many tissues (Knoefel and Alles, 1938, contradicting Camps and Higgins).

Flocculating agents, including colloids and metallic salts, alter drug responses materially; for instance, Thienes, 1926, found the augmentory response of epinephrine on excised uterus of rabbits increased by soap, camphor, saponin, acacia, tannic acid, paraphenylendiamine; it was reversed by procaine. The barium contracture was increased by saponin, acacia, copper sulfate, paraphenylendiamine and salicylic acid. Van Leeuwen and Györgyi, 1922, reported quantitative changes produced by cephalin and lecithin on the response of excised intestines to pilocarpine and histamine.

Penetration.—The presence of one drug may so alter the penetration or the distribution of the second drug as to modify its effects, without exerting antagonistic actions in the ordinary sense. This was demonstrated by Ehrlich for certain dyes; and similar conditions have been shown by Straub to prevail for muscarine and atropine; and for morphine and chloroform by Fuenher. Asher and Gannus, 1911, found that the gland cells of the nictitating membrane of frogs take up much more of vital stains when they are stimulated by pilocarpine than when depressed by atropine.

The method of administration may modify the distribution of a drug so as to affect the nature of the response, as with intra-arterial injection of choline esters, epinephrine and benzedrine in man (Myerson *et al.*, 1928).

Concentration Gradient.—Drug effects generally diminish when the poisoned solution is washed out, but in some cases the washing at first increases the effect. This has been reported for the action of muscarine on the frog heart (W. Straub, 1907); muscarine, pilocarpine and arecoline on bronchial muscle (Trendelenburg, 1912); intestines and uterus (Kuyer and Wijsenbeek, 1913). Straub assumed that in these instances the effect is due to the *passage* of the agent through the cell membrane either into or out of the cell. It may be questioned, however, whether the phenomena attributed to "*potential gradient*" may not have some clearer explanation (O. Loewi, 1912). For instance, Jendrasik and Moser, 1924, invoked the gradient to explain the observation that the inhibitory action of epinephrine on excised intestines of rabbits passes off during the immersion, long before the significant quantity of the drug has been destroyed; but Gautrelet and Bargy, 1927, showed that the intestine fails to respond also to increase of epinephrine.

Polyphasic Reactions.—Many drugs appear to have several successive and contradictory actions on a given structure, such as the successive stimulation and depression of ganglia by nicotine. This is often due to gradual rise of the concentration as the drug penetrates, or to several really distinct actions that develop with different speed; for instance, the active shortening of a muscle, which must be brief, and the maintenance of tonus, which may be prolonged (Winton, 1930; Clark, 1926; Nanda, 1931). Jendrasik attempted to explain practically all polyphasic reaction by the Straub concentration gradient; but Rentz, 1929, pointed out that this does not apply.

Central Autonomic Control.—The autonomic functions can be carried on independently of the central nervous system, and are not greatly disturbed by denervation. Cats remain in good health and with almost normal functions after complete removal of their sympathetic ganglion chains (Cannon, Newton *et al.*, 1929). Normally, however, the autonomic activities are guided to varying degrees by the nerve centers with which they are connected, from the hemispheres to the cord, but chiefly in the medulla and diencephalon, the centers being "regions" rather than circumscribed locations (review, A. Kantz, 1936). The *medulla* controls especially the vasomotor reactions. The injection of cholinergic drugs and of pituitrin in the lateral ventricles of the brain produces marked parasympathetic stimulation, by excitation of the *hypothalamic centers* in front of the optic chiasm. Stimulation somewhat posterior to this excites sympathetic responses. The motor area of the cerebral cortex also responds to acetylcholine and physostigmine.

Parasympathetic Stimulation from the Lateral Ventricles.—Harvey Cushing, 1931, observed that the introduction of *pituitrin* into the lateral ventricles produces marked vasodilatation, sweating, lacrimation, salivation, vomiting and fall of temperature. *Pilocarpine* produces similar effects in doses which would be ineffective hypodermically. The effect is arrested by atropine, injected either into the ventricles, or hypodermically. The parasympathetic stimulation does not occur in avertin narcosis, presumably because the centers are depressed. In dogs, however, Aird and Montgomery, 1936, found that the salivation response to the ventricular injection of pilocarpine occurred peripherally, after absorption from the ventricles, for it was not affected by extirpation of the parasympathetic nerve supply of the gland. It is conceivable that the centers were too much depressed in their experiments.

The injection of *acetylcholine* and of *physostigmine* into human cerebral ventricles results in characteristic and prolonged reactions by direct action on the centers (W. R. Henderson and Wilson). Intraventricular injection of 0.1 to 0.5 γ of acetylcholine produces prolonged sleep, disturbed respiration and cardiac irregularities similar to vagus stimulation, but no fall of blood pressure. These effects differ materially from the peripheral effects of acetylcholine and are not prevented by atropine. Similar effects are produced by intraventricular injection of nicotine or caffeine, or by clamping both carotid arteries (Dikshit, 1934). *Electric stimulation of the preoptic region* in cats causes contraction of the urinary bladder, slowing of the heart, fall of blood pressure and stimulation of respiration. Faradic stimulation *behind the optic chiasm* results in sympathetic reactions, viz., mydriasis, rise of blood pressure, increased rate and depth of respiration (Ranson, Kabat and Magoun, 1934). H. B. Carlson *et al.*, 1940, describe sympathetic stimulation and parasympathetic inhibition by electric stimulation of the hypothalamus. ("Psychosomatic Medicine" of January, 1939, contains reviews of the hypothalamus, with extensive bibliographies.)

Removal of the cerebral hemispheres in the higher vertebrates is followed by increased activity of certain viscera with autonomic control, such as the heart and intestines. Administration of mecholyl to patients with *frontal lobe lesions* produced sympathetic stimulation contralateral to the lesion (S. M. Fisher and Stavraky, 1944). In monkeys, *stimulation of the premotor area* causes vigorous intestinal peristalsis (Fulton, Kennard and Watts, 1934). Gastric movements in the monkeys were not augmented by faradic stimulation of the cortex, but inhibitory effects were obtained by stimulation of the frontal and premotor areas (D. Sheehan, 1934). Chatfield and Dempsey, 1942, describe characteristic changes in the somesthetic, motor and auditory areas rather than spontaneous activity.

The cerebral motor cortex of cats also responds with specifically localized *somatic movements* to the local application of physostigmine; *i. e.*, contralateral tremor, rigidity and clonus of the same muscles that respond to the electric stimulation area (F. R. Miller, 1937). *Electroencephalograms* show increased activity on application of *physostigmine* or *acetylcholine* to the motor cortex with potentiation of the two drugs. Cerebral application of *atropine* modifies these effects (Miller *et al.*, 1938). The acetylcholine discharges are preceded by depression of the electrical activity (F. M. Foster *et al.*, 1946). Epinephrine has no effect when applied alone, but the response to acetylcholine is materially augmented by low concentrations and depressed by high (review, J. H. Burn, 1945).

Local application of acetylcholine to *the floor of the fourth ventricle* produces hyperactivity of the respiratory center, with potentiation by physostigmine (Gesell, Hansen and Worzniak, 1943). In man, intrathecal *spinal injection* of acetylcholine has little effect. Physostigmine produces transient depression of the spinal reflexes, followed rapidly by increased excitability. Prostigmine depresses the muscular tonus and reflexes, without change of sensation (M. Kremer, 1942).

The exclusive role of acetylcholine synaptic transmission in the central nervous system is neither proved nor disproved. It appears inherently improbable, especially because of the rapid sequence of reversals in tetanus. These difficulties are perhaps removed by the high concentration of choline acetylase in the reacting surface, and by the reversibility of its action. W. Feldberg, 1945, considers the evidence good for some central synapses, but not for others.

AUTONOMIC REACTIONS OF THE GASTRO-INTESTINAL TRACT

Innervation.—The entire gastro-intestinal canal is innervated from both autonomic systems. The orthosympathetic supply comes through the splanchnic and mesenteric ganglia. The parasympathetic supply from the esophagus to the ileum is furnished by the vagus; the erigens and pelvic innervate from the colon to the anus. The functions of the two systems are reciprocally antagonistic. Parasympathetic stimulation generally augments the contractions or tone of both coats of the muscular tube; orthosympathetic stimulation augments the sphincter tone and inhibits the muscular tube. This reversed arrangement of the orthosympathetic innervation of the sphincters and the muscular tube simplifies their functional cooperation. The intrinsic functions of the intestinal musculature, especially its tonus, play an important part in their behavior, and may profoundly modify their reactions to nerve stimulation and to drugs. Consequently there are conspicuous exceptions to the simplified schema in some situations, which vary, not only with different species, but even in the individual animal, at different times. The small intestines of mammals, however, respond generally by augmentation to parasympathetic stimulation and by inhibition to orthosympathetic stimulation.

Innervation of the Sphincters.—According to Gaskell, the orthosympathetic appears to augment the tonus of most if not all sphincters; in the urinary as well as in the digestive tract. Parasympathetic stimulation inhibits the urinary sphincters and the internal sphincter ani; but the response on other sphincters has not been definitely established. The cardial sphincter may respond by either augmentation or inhibition, to either vagus or sympathetic stimulation (Carlson, Boyd and Pearce, 1922).

Visceral pain arises if the excitation is extreme, and from moderate stimulation of certain kinds, especially by stretching; but it is not clear whether this acts directly or by causing ischemia, for vascular spasm or occlusion also gives rise to severe pain. The pain-excitability may be increased by rise of temperature or by chemicals, especially by toxins.

The Significance of the Intestinal Nerve Plexuses.—There is no good reason to assume that the ganglionic nerve plexuses of Auerbach and Meissner differ in function from the analogous ganglionic plexuses in most autonomic organs, for instance the heart, or to doubt that they are the neuron cells of the efferent link of the parasympathetic nerves (Gaskell).

They have, however, also been interpreted as peculiar peripheral nerve centers, the "*enteric system*" of Langley (1900, 1913) for the local coordination of peristaltic reflexes. According to this view they might be excited and inhibited by afferent impulses directly from the intestinal mucous membrane and muscle, as well as by efferent impulses from the central nervous system. This explanation was suggested by the impressive appearance of the nerve plexus and the apparent complexity of intestinal coordination; it seemed to be supported by the observation of Magnus (1904), that the removal of the nerve plexus suppresses the rhythm of intestinal strips. It was subsequently shown, however, that the plexus-free strips remain rhythmic if proper precaution is taken to prevent injury of the muscles, and that coordinated peristaltic movements can be evoked in muscle that has been kept on ice five days, when nervous structures would presumably have died (Gunn and Underhill, 1914, 1916; Alvarez and Mahoney, 1922). The myenteric plexus has a high resistance to anoxia; this may be connected with its high acetylcholine content (J. H. Welsh and Hyde, 1944). This leaves no direct evidence for the local coordinating centers.

The progression and coordination of peristalsis can be adequately explained by the inherent properties of smooth muscle, especially the gradient of tonus and the stimulant effects of distention. The electric potential changes accompanying intestinal movements indicate that these are syncytial, with conduction impulses within the muscle (E. Bozler, 1939). It may be recalled that the uterus executes equally complex movements without needing an enteric system.

The Intestinal Movements.—The intestines, like the uterus and ureter, exhibit two fundamental types of movement: (*a*) pendulum rhythm; (*b*) localized contraction rings, stationary or progressive, *i. e.*, peristaltic. Both types are modified by the prevailing state of tonus and excitability, local and general, of the intestinal muscle. For the whole small intestines, there is a strong general gradient of tonus, decreasing from the pylorus to the cecum, which determines the descending direction of the peristalsis. In the large intestine, the gradient varies from time to time, and this determines peristalsis and antiperistalsis.

Pendulum movements consist of continuous rhythmic contractions of the longitudinal muscle of the "resting" intestines, at the rate of about ten per minute. They are conspicuous through their regularity and from the fact that they are well maintained by the excised intestines immersed in oxygenated Ringer's solution (Magnus, 1904) and are therefore easily studied. They have no material effect, however, on the intestinal lumen, and do not have any apparent function; they are perhaps a mere by-play of the healthy excitability of the intestinal muscle. They are diminished or arrested if the general excitability of the intestine is low and when the contraction of the strong circular muscles interferes with the movements of the weaker longitudinal coat. Pendulum movements of the circular muscles, on the other hand, if they exist, are so much more feeble than those of the longitudinal muscle that they are not ordinarily observable.

Differences of Rhythm at Various Levels.—In intact animals, the rhythm is faster toward the ends of the intestine than toward the middle. In excised intestine, the rate decreases with the distance from the pylorus; the rate of the duodenum in rabbits is about 50 per cent faster than in the lower ileum. The oral end is more irritable and therefore acts as pacemaker. It is also less subject to epinephrine relaxation and its tone is higher. The slower rate of the aboral end is accompanied by greater excursions (Alvarez, 1914, 1915). The different rates are perhaps based on intrinsic differences in the intensity of metabolism. Cyanide, or shutting off the oxygen supply, interferes more with segments from the higher portions of the intestine. Alvarez and Starkweather, 1918, believe that this gradient of excitability is mainly concerned in regulating the physiologic rate of propulsion of the food through the various levels of the intestinal tract.

Drugs on Intestinal Rhythm.—The effects have been studied by Alvarez, 1918. The changes in rhythm are not necessarily parallel to those of the tonus and amplitude of the contractions. This has also been found by Pilcher for the uterus.

The peristaltic movements consist of more powerful contractions of the circular coat, which are normally initiated by distention of the intestines, in excised intestines as well as in the living animal (Trendelenburg, 1917). Such distention results first in gradual increase of tonus. When this reaches a critical point, which varies with conditions, the circular coat suddenly contracts, stretches the longitudinal coat, constricts the lumen and expels the contents. The peristaltic contraction occurs only when the intestine is in good condition and tonus, and begins at the region of highest tonus at the oral end of the segment. The contents are propelled in the direction of the lower tonus, *i. e.*, to the adjacent lower segment, which is thereby stretched, distended and thrown into a peristaltic contraction. This accounts for the Bayliss-Starling (1899) "Law of the Intestines" (Alvarez and Starkweather, 1918). The peristaltic wave may travel in this manner, by a purely muscular mechanism, until so much of the contents has been lost on the way that the intestine is not sufficiently distended, or until a region of low irritability is reached. When a segment has contracted, it gradually relaxes, so that it again becomes filled with fluid from above, and the process is repeated, at the rate of two to four contractions per·minute. When normal intestines become empty, peristalsis ceases and a period of rest ensues. If the propulsion of the contents is prevented by an obstruction, functional or mechanical, the contractions increase in violence; but they are rather rapidly fatigued by the excessive pressure. The occurrence and extent of the peristaltic contractions depend on the irritability. When this is high, they may occur even in the empty intestines. The height of irritability is also the chief factor in the extent of spread of the peristaltic wave; exceptionally, a single wave may thus travel rapidly through long disdistances, the so-called "rolling movement" or "peristaltic rush" (*cf.* Meltzer and Auer, 1907). In the large intestine, the gradient of irritability and tonus changes from time to time, so that peristalsis travels in both directions, at different periods.

Stationary Tonus Rings and Intestinal Spasm.—Contractions of the circular coat may also occur without spreading. The specialized kneading "segmentation movements" of the small intestine of the cat are rhythmic contractions of alternating segments. More common are strictly localized contraction rings which persist for long periods sometimes quite stationary, sometimes traveling slowly, and sometimes rapidly. The latter constitute a gradual transition to ordinary peristalsis. These rings may be narrow or wide bands, or extend over a considerable distance, in which case they merge into intestinal spasm. While they persist, they occlude the lumen and form a strong functional sphincter. They constitute the normal type of contraction in the large intestine (Lenz, 1924; Cannon, 1911). In the small intestine they occur only when the irritability is abnormally heightened, especially by the parasympathetic and "muscular" stimulants. They give rise to temporary obstruction, and provoke the phenomena of "colic."

Paresis of the Intestine.—The tonus and excitability of the intestines are sensitive to nervous and chemical conditions, and are easily depressed below the level necessary for the contractions, especially of the circular coat. Temporary inhibitions are perhaps a normal provision for resting the intestines; both temporary and more lasting inhibitions occur clinically, in psychic states, in laparotomies, in intestinal obstruction, etc. *Increased excitability of the muscle* is probably an important factor in the action of many cathartics, especially those that act on the large intestines.

Drug reactions of small intestines are relatively simple: Ordinarily, epinephrine is inhibitory; the parasymptahetic stimulants augmentory; and the nonspecialized drugs produce their usual effects. The longitudinal and circular muscles act in the same direction; but when the circular coat is active, its contraction stretches the weaker longitudinal muscle (Inoue, 1923). Antagonism appears to occur generally between augmentors and relaxors, no matter on which system they act.

Parasympathetic Drugs. — Physostigmine, pilocarpine, choline and muscarine increase the tonus, the pendulum movement and the peristalsis in mammalian intestine. Excessive concentrations produce tonus bands and intestinal spasm. The effects are removed by atropine. This is especially effective against pilocarpine, which is neutralized by doses of atropine much smaller ($\frac{1}{500}$) than those that affect the unpoisoned intestines or block stimulation through the vagus nerve, or by physostigmine (Magnus, 1904).

Pilocarpine.—Neukirch, 1912, found that the action of pilocarpine on the excised intestine is purely stimulant, even with 5000 times the effective dose. The action can be removed by washing, but during the passage of the pilocarpine out of the cells there seems to be a supplementary stimulation.

Pilocarpine-Atropine Ratio.—The antagonism of these drugs on the excised intestine is not in simple ratio to their concentration; for while the pilocarpine, physostigmine and muscarine stimulations depend on the concentration of the drug in the fluid, the atropine inhibition depends on the absolute dosage. The antagonism is not materially influenced by temperature or H ion concentration (van Lidth de Jeude, 1918).

Atropine and Choline.—The effect of atropine on the unpoisoned intestine is variable and inconstant, especially in the excised intestine. This has been attributed to variations in the content of choline that is normally present in the intestinal wall and acts as a peristaltic stimulus: the greater this stimulation, the more pronounced is the sedative action of atropine; when the parasympathetic stimulation of choline is absent, atropine becomes ineffective except in abnormal concentrations (Le Heux, 1918).

Propulsion of charcoal in small intestine in unanesthetized dogs is increased by intramuscular administration of prostigmine (averaging 38 per cent) and ergotamine (27 per cent); it is decreased by atropine (36 per cent) and ephedrine (35 per cent). Cocaine has no appreciable effect (Van Liere *et al.*, 1944).

Epinephrine inhibits the normal intestinal movements, and antagonizes the stimulant effects of pilocarpine, nicotine and strophanthin (Magnus), and also those of barium (Roth).

Nicotine paralyzes the ganglia and therefore renders stimulation of the vagus and of the splanchnic ineffective. At the same time, it produces violent peristalsis and intestinal spasm (Nasse). This stimulation is the most conspicuous effect in excised intestine. It may be preceded by brief inhibition, and with large doses it is followed by paralysis (Trendelenburg, 1917; Magnus, 1904). This paralysis (which is also produced by coniine, curare and gelseminine) is mutually antagonistic with physostigmine stimulation (Ikeda, 1916).

Muscular stimulants include barium, veratrine, colchicine, strophanthin, pituitary histamine, peptone and anaphylaxis. They produce violent stimulation, increase of tonus and intestinal spasm. Their antagonisms follow the usual pattern: They are effectively relaxed by the muscular depressants, including the nitrites and magnesium. They are also relaxed by sympathetic stimulation through epinephrine; but parasympathetic paralysis, by atropine, has little effect (Magnus, 1904; Roth, 1923; Sollmann and Rademaekers, 1925). *Morphine* produces a peculiar increase of tonus which does not proceed to spasm, but prevents peristalsis.

Histamine, peptone and pituitary extract act less definitely on the intestines than on the uterus. In general, they produce more or less stimulation, which tends to be followed by relaxation. Pituitrin generally gives initial stimulation followed by inhibition (Krishnan, 1934). The details vary in different animals (Olivcrona, 1921), and appear to be somewhat influenced by diet (Degener, 1922). Various *amino acids* have practically no effect (Hirschfelder and Cantwell, 1918). *Anaphylaxis* produces marked stimulation; normal *serum* also tends to stimulate, but the response is uncertain (Schlecht and Weiland, 1921). *Colloids* often enhance the reaction to other stimulants. Van Leeuwen and Szent Györgyi, 1922, studied the influence of cephalin and lecithin on the response to pilocarpine and histamine.

Muscular Depressants.—The intestines are relaxed and inhibited by magnesium, nitrites, chelidonine, papaverine (not narcotine), the benzyl esters (Trendelenburg, 1917). *Insulin* stimulates the intestinal movements indirectly by lowering the blood sugar level (Krishnan, 1934). Its direct action on excised intestines is depressant (Farah, 1938).

"Female Remedies" on Excised Intestines.—Delzell, Burman and Pilcher, 1916, found the effects on rabbit's intestine practically the same as on the guinea pig uterus. Caulophyllum, however, leaves the tonus almost unchanged, while the amplitude is lowered. Valerian (oil) depresses the contractions. The viburnums are inactive.

Hydrogen Peroxide.—Very weak concentrations (sometimes 1:1,000,000) increase the tonus of excised intestine temporarily; this soon returns to normal and further peroxide is then ineffective. Larger doses inhibit the movements (H. J. Hamburger and Brouwer).

The Oddi sphincter is reported to be spasmodically contracted in man by the presence of dilute hydrochloric acid in the duodenum and by administration of morphine. Atropine relieves the spasm induced by acid, but not that of morphine. Duodenal instillation of magnesium sulfate solution relaxes the sphincter, papaverine produces brief relaxation, and epinephrine has little effect (Doubilet and Colp, 1937). W. Walter *et* al., 1937, observed little change with parasympathetic stimulants, atropine, ergotamine, alcohol, histamine, adenosine phosphate and papaverine.

Reactions of the Large Intestine.—The normal movements are generally more sluggish than those of the small intestines (Alvarez and Starkweather, 1918), and persistent tonus bands are especially important (Cannon, 1911). Their reactions to the autonomic drugs agree generally with those of the small intestines (Lenz). They respond more readily to the emodin irritants (senna, rhubarb, etc.).

The ileocolic sphincter is closed by stimulation of the splanchnic nerve; it does not appear to have an inhibitory innervation. It is contracted by epinephrine (Elliott, 1904). Kuroda, 1916, and H. Schroeder, 1933, reported that it is also contracted by pilocarpine and that this is antagonized by atropine. Morphine caused prolonged contraction; papaverine, relaxation.

The **muscularis mucosa** of the small and large intestines has both cholinergic and adrenergic augmentory innervation. Inhibitory nerves have not been demonstrated. The rhythmic movements are myogenic, but may be augmented by nerve stimulation (C. E. King and Robinson, 1945). The movements of the intestinal villi are increased by vagus stimulation and inhibited by atropine (V. Ludany and Jourdan, 1936).

The **gastric musculature** is generally stimulated by parasympathetic and relaxed by orthosympathetic stimulation. The responses of the fundus and sphincters differ in detail, and are modified by the functional condition of the muscle: Low tonus favors stimulation; high tonus, relaxation. *Parasympathetic stimulation* through the vagus nerve, pilocarpine, cholines, or physostigmine augments the contractions of the fundus if the tonus is low; but the same doses may inhibit the contractions if the tonus is high (M'Crae and MacDonald). Pilocarpine increases the tonus of the pyloric sphincter and hastens its contraction (J. E. Thomas, 1929; H. Schroeder, 1933). In most human subjects, the emptying of the stomach begins earlier, but is completed later (Herrion, 1936). The intragastric pressure is raised. *Atropine* inhibits all the effects of parasympathetic stimulation on the fundus and sphincter. In normal human subjects and dogs it delays both the initial and the final emptying time (Herrion). *Epinephrine or stimulation of the orthosympathetic nerve* generally arrests the rhythmic movements and lowers the tonus of the cardial and pyloric sphincters as well as of the fundus; but if the tonus is already low, they may give slight augmentation. In rabbits it generally stimulates. *Ergotamine* relaxes epinephrine contraction. *Ephedrine* acts similarly to epinephrine. Its gastric effects do not last as long as the blood pressure rise (M'Crae and MacDonald). *Nicotine* depresses and often arrests the movements and lowers the tonus of the excised stomach; but in intact animals it causes violent emesis by central action. *Gastro-intestinal hemorrhages and acute ulcers* may result from the violent contractions induced by large doses of the parasympathetic or muscular stimulants, acetylcholine, pilocarpine, physostigmine, histamine, pitressin (Necheles and Masur, 1939).

The emptying time of the stomach in normal human subjects, measured by intubation, is not materially altered by clinical doses of mecholyl, prostigmine, atropine, ergotamine, amphetamine, trinitrin or sodium bicarbonate. It is delayed by morphine (Folley and Abbott, 1942).

Esophagus.—In dogs and rabbits this consists of striped muscle and reacts as such: Although it is innervated by the vagus, it is inhibited by curare and not by atropine. In man and cat, the lower third consists of smooth muscle, which is inhibited by atropine and not by curare (V. Koenig, 1928).

Pigeon's Crop.—The responses of the pigeon's crop to autonomic drugs were described by Hanzlik and Butt, 1928.

Gastro-Intestinal Reactions of Cold-Blooded Animals.—These do not show pendulum movements, but their tonus waves and rings are similar to those of mammals, though slower. Epinephrine is inhibitory, as in mammals, but parasympathetic stimulants also tend to produce inhibition. This is especially marked in the *small intestine of the frog*, which is relaxed by epinephrine, pilocarpine, physostigmine and nitrites; and each of these is antagonistic to the contractor effect of barium. This is perhaps the most definite instance of inhibitory sympathetic stimulation by the parasympathetic stimulants. It has the further unique peculiarity that it is not antagonized by atropine. The direction of these reactions is not influenced by the ion ratio or H ion concentration of the bath (G. B. Roth, 1923).

Small Intestine of Turtle.—Epinephrine is inhibitory and pilocarpine and barium augmentory, as in mammals; but physostigmine tends to inhibit, and tyramine to stimulate. Atropine relaxes and antagonizes barium as well as pilocarpine, although it is less effective against barium (Roth, 1923).

Rectum of Frog.—The innervation is parasympathetic augmentor and orthosympathetic inhibitory. The excised organ is inhibited by epinephrine and stimulated by the parasympathetic stimulants; the latter are antagonized by atropine. Muscarine, the methyl ammoniums and arecoline stimulate strongly, but pilocarpine only slightly, and physostigmine still less; and pilocarpine actually removes the arecoline stimulation (Schueller, 1921). Similar phenomena have been described for the frog stomach.

The frog's stomach has been an important object for the study of the general properties of smooth muscle. Goltz used it in 1872 to demonstrate the reflex tone and inhibition of the alimentary tract. Bercovitz and Rogers, 1921, investigated the response to nerve stimulation; also in the turtle. The reactions to drugs are described by Fuehner, 1918.

The esophagus of frog is generally inhibited by epinephrine and stimulated by pilocarpine, but it behaves abnormally to the muscle poisons. Barium is said to have no effect, and histamine and pituitary inhibit (Bercovitz, 1922).

The esophagus of turtle appears to show a marked difference in response according to the duration of the application. At first, epinephrine is stimulant, pilocarpine depressant; after a time epinephrine becomes depressant and pilocarpine stimulant. Histamine produces stimulation (Bercovitz, 1922).

The intestine of fly consists of striped muscle, but performs peristaltic movements similar to those of higher animals. Its behavior toward drugs resembles that of smooth rather than striped muscle (T. B. Robertson, 1920).

AUTONOMIC REACTIONS OF THE MUSCULATURE OF THE GENITO-URINARY ORGANS

Uterus.—The innervation of the uterus is essentially orthosympathetic, through the hypogastric nerve. There is also a parasympathetic supply from the pelvic nerve, which appears to act in the same direction (Cushny, 1906, 1910), but so feebly and uncertainly that it is generally considered negligible. The uterus, however, reacts readily to parasympathetic as well as to sympathetic drugs, and most actively to direct muscular stimulants, especially pituitrin, the ergot alkaloids and histamine (review, Gruber, 1933).

Natural Movements of the Uterus.—The excised uterus when placed in oxygenated Ringer's solution executes pendulum and peristaltic movements (Kehrer, 1908; Cushny 1910) which vary in intensity and type with the sexual cycle; the predominance of progesterone renders the uterus less contractile in the course of pregnancy, while increase of estrogenic hormones renders it more contractile and precipitates parturition. Analogous movements occur normally in living animals and may be watched by inserting a permanent celluloid window in the abdominal wall (Ludwig and Lenz, 1923; Tscherepachin, 1928). They may be recorded clinically by a piston resting on the abdominal wall over the parturient uterus (Dodek, 1932; Barlow and Jones), or by a rubber bag inserted into the uterine cavity post partum (Moire). The reactions of the excised uterus are quite similar to those *in situ*, except for drugs that increase the output of epinephrine in living animals (Dale and Laidlaw, 1912). In nongravid animals the peristaltic movements are relatively slight and alternate with pauses, much as in the intestines. Parturition is accomplished by powerful peristaltic waves, producing the labor pains, which are aided by the contraction of the abdominal muscles and diaphragm. The nongravid contractions may be intensified or allayed by central impulses; but normal labor may occur after complete severance of the uterus from the central nervous system (Elkin, 1922).

Clinical Drug Responses of the Parturient Uterus.—The records obtained by Dodek, 1932, with an external hysterograph on women in the successive stages of labor show that the uterine contractions are increased by clinical doses of pituitrin (even small doses produce marked stimulation and incomplete relaxation) and ergonovine, which is very active even by mouth. Ergotoxine intramuscularly was rather unreliable. Epinephrine caused brief arrest of the contractions. Quinine, morphine and scopolamine did not produce any significant effects. *Various anesthesias* react as follows: *Ether* depresses the contractions in proportion to the degree of anesthesia. Ether analgesia, inhalation or rectal, renders them somewhat more shallow, so as to interfere materially with labor. Complete surgical anesthesia with ether abolishes them completely. This would also hold for *chloroform*. *Avertin* (with amylene hydrate), 60 mg. per Kg., depresses more than colonic ether analgesia. *Amytal* sodium sleep (6 to 12 grains) produces practically no depression. *Nitrous oxide with oxygen* does not weaken the contractions, even in deep anesthesia. *Procaine spinal anesthesia* does not alter them significantly.

Effects of pharmacologic reagents on *uterine action potentials* are reported by Bozler, 1931; R. S. Morison, 1940; Balassa and Gurd, 1941.

Sympathetic Stimulation (Epinephrine).—The response varies, in the same direction for *epinephrine* and for hypogastric nerve stimulation, according to the species and the functional state of the uterus. *Human uterus* has two layers of muscle of different embryologic origin and function. The exterior is concerned with expulsion in parturition, and is stimulated by epinephrine; the inner layer is especially strong at the cervix, and its contraction represses expulsion. It is inhibited by epinephrine so that both actions of epinephrine assist parturition (J. Daels, 1941). Epinephrine tends to increase uterine tonus and movements in most species (monkey, dog, rabbit, hedgehog). This stimulation is more marked in pregnancy; but strong or spastic contractions, as in actual labor or by ergot, pituitary or histamine, are generally relaxed by epinephrine. The pregnant cat uterus is also contracted by epinephrine, but the nonpregnant uterus is generally relaxed by it. The change of response is related to the concentration of progesterone (J. H. Kennard, 1937). In the final stage of pregnancy the cat uterus is again inhibited by epinephrine (E. C. Del Pozo, 1946). Guinea pigs, rats and mice usually show relaxation, both when pregnant and nonpregnant (Gunn and Gunn, 1914; Athias, 1921). Guinea pig and rabbit uterus reacts alike (almost quantitatively) toward other drugs (pituitary, ergot, pilocarpine, atropine, quinine, potassium, calcium).

Parasympathetic Drugs.—In animals in which sympathetic stimulation produces contraction, the parasympathetic stimulants also produce contraction (Cushny, 1910). When the sympathetic response is inhibitory, the effects of parasympathetic stimulants are inconstant. Atropine depresses the normal uterus *in situ* (Ludwig and Lenz, 1923) and antagonizes the pilocarpine contraction (not that of hypogastric stimulation).

In nonpregnant cats, in which hypogastric stimulation or epinephrine usually relaxes or inhibits the contractions, Cushny also noted inhibitory phenomena after pilocarpine injection; but they were much less characteristic than with epinephrine. Dale and Laidlaw did not observe relaxation when the excised nonpregnant uterus was subjected to pilocarpine, although it occured sometimes during life. This they attributed partly to increased suprarenal output, partly to action on the sympathetic ganglia, and not to a peripheral autonomic effect. Gunn and Gunn (1914), however, did occasionally observe inhibitory effects on the excised uterus of rats and guinea pigs. *The uterine cervix* in rats is inhibited by epinephrine, unaffected by pitocin (S. Genell, 1940).

Direct Stimulants.—Powerful contractions are produced in nonpregnant as well as pregnant uterus of all animals by *ergot* and its alkaloids, by posterior pituitary extract (Frankl-Hochwart and Froehlich, 1909), by *histamine* (Barger and Dale, 1910); and by related amines, peptones, and *anaphylactoid poisons* (Hanzlik, 1920). *Quinine* and the other cinchona alkaloids may cause strong contractions (Kurdinowski-Kehrer, 1906; Hale, 1915), but are uncertain (Rucker 1921; Frank and Katz, 1922). *Hypotonic solutions* produce contraction (Barbour and Rapoport, 1922).

Demerol increases the contractions of intact human uterus; *syntropan* relaxes (Solomons and Widdess, 1943).

Other drugs which tend to stimulate contractions include *tyramine*; *congo red*; *hydrastine*, *hydrastinine* and *cotarnine*: many *organ extracts* (Fawcett *et al.*, 1915), especially prostate (Macht, 1920), ovary (Itagaki; Athias, 1921) and placenta (Ludwig, 1920). The miscellaneous plants used in proprietary "*female remedies*" have little if any action on the uterus (Delzell *et al.*, 1916; Pilcher, 1917).

The *ratio of potassium and calcium* in the Ringer solution modifies the reactions of the excised uterus (Fate and Clark, 1921; Rosemann, 1923). Excess of potassium weakens and excess of calcium increases the responses to stimulating drugs. Decrease of potassium increases the contractile responses. Absence of calcium prevents stimulation by pituitary, quinine and ergot, but does not prevent stimulation by epinephrine, cocaine or pilocarpine (Inami, 1928).

Reflex Increase of Uterine Movements.—Drastic cathartics and irritant volatile oils produce reflex stimulation of the uterus (Kehrer, 1910). These should therefore be avoided in pregnancy. They are reputed abortifacient, but are highly dangerous. For the excised uterus, moderate concentrations of the *emmenagogue oils* are indifferent, and higher concentrations inhibit (Gunn, 1921).

Antagonists to the Contractor Effects.—Ergotoxine is more effective against epinephrine than against the parasympathetic stimulants; atropine is more effective against these than against epinephrine; however, both depressants are sometimes antagonistic against both stimulants (Cushny, 1910; Dale and Laidlaw, 1912; Gohara, 1920). The relaxing action of epinephrine in the guinea pig and mouse may overcome the barium, histamine and choline stimulation (Sugimoto, 1913; Adler, 1918).

Pregnancy on the Drug Responses of the Uterus.—The change in the response of the pregnant cat uterus to sympathetic stimulation and epinephrine (Cushny, 1921) appears within a few days after conception (Athias) and disappears again within two days after birth (N. B. Dreyer and Moreash, 1933). It must therefore be due to functional sensitization, and not to the development of new muscle fibers, as was suggested by Quagliarielli, 1918. The susceptibility to stimulation by extracts of the *posterior pituitary* also goes through a striking cycle of changes in all animals, decreasing early in pregnancy, then increasing toward term and especially near parturition, and then decreasing promptly thereafter. In normal primiparous women it decreases parallel with the spontaneous contractions, disappearing about the tenth day. It may then be partly restored by administering estrin (W. Bickers, 1942). This pregnancy cycle has been demonstrated on excised human uteri; also in regard to *ergotoxine*, but the response to *histamine* is not altered (M. M. Robson, 1933). It holds for *cocaine* and *quinine*, but it does not appear to apply to *pilocarpine* (Inami, 1928). The dependence of the pregnancy changes on *sex hormones* was established by Van Dyke and Gustavson, 1929, when they showed that treatment with corpus luteum confers the pregnancy responses on the uteri of kittens. It is now recognized that they depend on the changes in the relative preponderance of estrogens, which increase uterine excitability, and progesterone, which allays it.

Vaginal muscle is innervated by the sympathetic. Epinephrine or electric stimulation may cause contraction or relaxation, regardless of the direction of the uterine response; they relax after ergotoxine. Physostigmine and pilocarpine contract, and are antagonized by atropine (review, Gruber, 1933).

Fallopian tubes are usually contracted by epinephrine, but a small dose may inhibit. Atropine relaxes the epinephrine contraction.

Round ligament is relaxed by epinephrine in cats, contracted in rabbits. **Prostate gland** is contracted by both epinephrine and pilocarpine. Epinephrine relaxes after ergotoxine (Waddell, 1916). Extracts of prostate stimulate all genital muscles, and especially the uterus (Macht, 1922).

Seminal vesicles, vas deferens and "uterus masculinus" react like the prostate muscle (Waddell, 1916, and Macht, 1917).

Erectile Tissue of the Penis.—Stimulation of the *parasympathetic* "erigens" branch of the pelvic nerve produces dilatation of the penile arteries and erection. Nikolsky, 1879, claimed that these effects also follow pilocarpine and are antagonized by atropine, but others have reported no effects from parasympathetic stimulants. It is conceivable that they may be negatived by the effects on the general circulation, malaise, etc. Stimulation of the *sympathetic* pudic nerve, or epinephrine, produces constriction of the vessels of the penis and flaccidity (Elliott).

The retractor penis muscle of dog furnishes a striking anomaly. The smooth muscle has a double innervation, the sympathetic being augmentor and the parasympathetic inhibitory (Langley and Anderson). Epinephrine produces contraction and this is antagonized by ergotoxine, as would be expected. The parasympathetic stimulants, however, also produce contraction, that is, they act on the sympathetic and not on the parasympathetic. Similarly, atropine, although it antagonizes the parasympathetic stimulants, does not abolish the response to electric stimulation of the parasympathetic (sacral) nerve. It appears therefore that the action of the parasympathetic poisons has been transposed to the sympathetic division. However, ergotoxine does not antagonize the parasympathetic stimulants. Nicotine stimulates, although there are apparently no ganglion cells (Edmunds, 1920; Zilva, 1901; Bottazzi, 1916; M. J. Oppenheimer, 1938).

The ureter contracts rhythmically when distended with urine; and as its excitability is normally highest at the renal pelvis and lowest at the bladder end, the contractions progress as peristaltic waves which help to propel the urine to the bladder. (The gradient may be reversed, and with it the direction of the peristalsis, by depressing the pelvic end with drugs, etc. C. M. Gruber, 1928.) The ureter peristalsis is increased by stimulation of either the sympathetic (splanchnic and inferior hypogastric) or the parasympathetic (pelvic) nerves, but sympathetic stimulation may also be inhibitory. The sympathetic innervation is more active in the upper portion, the parasympathetic in the lower (Satani, 1919).

Epinephrine increases the rate, tonus and sometimes the amplitude of the ureteral peristalsis. Pilocarpine and other *parasympathetic stimulants* also do so, but generally more feebly. Ergotoxine is more effective against epinephrine, and atropine against parasympathetic stimulants. *Nicotine* first stimulates and then arrests the movements of the excised ureter (Satani). The reactions to the *nonspecialized drugs* are of the usual type: augmentation also results from barium, veratrine (Rossi, 1918), morphine, cocaine, procaine and increased alkalinity. Depression is produced by chloroform (Lucas, 1906), by papaverine and the other isoquinoline alkaloids, by chelidonine, benzyl benzoate, hydrastine and emetine (Macht, 1916, 1916–1918; Roth, 1917). The effects of obstruction on ureteral peristalsis are described by Wislochi and O'Conor, 1921. Sano, 1927, reports that the ureter of gravid rabbits is inhibited by epinephrine and pituitary, stimulated by pilocarpine and barium.

Urinary Bladder and Urethra.—The urinary bladder is an instance of smooth muscle subject to central control, and voluntary in normal micturition. This is affected by contraction of the smooth muscle of the *body of the bladder*, whose motor innervation is chiefly parasympathetic by the pelvic erigentes nerves, with ganglion cells in the bladder wall. Its sympathetic innervation, through the hypogastric nerve with relay cells in the inferior mesenteric ganglion, is less potent and chiefly relaxant. The *trigone of the bladder* (including Bell's muscle; Gruber, 1935) and the muscular fibers of the *urethra*, which function as the *sphincter* to the bladder, have different and reciprocating autonomic reactions. They are strongly contracted by epinephrine stimulation, and rather feebly relaxed by parasympathetic stimulation (Elliott). *Evacuation of the bladder* is effected chiefly by the parasympathetic stimulation of the body of the bladder, probably with some inhibition of the sympathetic tonus of the trigone and urethra. The *autonomic drugs* act in close accordance with the innervation, both in excised bladder and in living animals.

Pilocarpine contracts the body of the bladder, and increases the intravesicular pressure (Graf and Froberg, dogs, 1933). The trigonal region is generally not affected, but may be contracted. Choline and its esters (Winters, 1940) and physostigmine and prostigmine act similarly, and the latter is used clinically against postanesthetic paresis of the bladder. (The cholinergic mechanism shows certain peculiarities; V. E. Henderson and Roepke, 1935.) *Atropine* relaxes the parasympathetic contraction. Considerably larger doses are required against electric stimulation of the nerve than against pilocarpine. It tends to lower the normal intravesicular pressure in children and is often useful against enuresis (Amberg and Gros, 1931). It is not effective against the violent contractions of urethral obstruction, nor is hyoscyamine. These can only be allayed by deep ether or chloroform anesthesia. I. C. Winters, 1940, reports increased bladder tonus and decreased capacity, similar to morphine, in unanesthetized dogs. *Epinephrine* gives somewhat different reactions according to the kind of animal (Elliott, 1905), dose and other conditions. In general, moderate doses tend to relax the body of the bladder, especially if the tonus was high (Griffiths). It therefore antagonizes parasympathetic stimulation and ergotoxine. With other doses, the epinephrine relaxation may be followed by contraction. The trigone region is generally contracted (Edmunds and Roth). It also provokes contraction of the posterior urethra (Elliott; Flagge; Young) and thus increases the resistance to bladder outflow. The intravesical pressure is briefly increased (Graf and Froberg). *Ephedrine* does not act on the bladder like epinephrine (MacDonald and M'Crea, 1930). In unanesthetized dogs, it relaxes the tonus and increases the capacity (Winters, 1940). *Ergotoxine and ergotamine* reverse contractor responses to epinephrine, but not the inhibitory effect (MacDonald and M'Crea, 1930). Excess of calcium also diminishes contractor and favors relaxor response of excised bladder (Streuli; Chiari and Frohlich).

Urethral resistance to micturition, in unanesthetized dogs, is diminished by acetylcholine, mecholyl, scopolamine, atropine and morphine; increased by pilocarpine, physostigmine, neosynephrine, amphetamine, and ephedrine; epinephrine has no effect. *The irritability of the bladder* is increased by scopolamine, atropine, morphine, physostigmine, and neosynephrine; lowered by amphetamine and ephedrine (I. C. Winter, 1941).

Miscellaneous Drugs.—These generally act alike on all regions of the bladder. *Ether anesthesia* produces relaxation. *Morphine* and *ephedrine* may cause spastic retention, the former, at least, probably by central stimulation of the urethral muscles. *Pituitrin* and barium contract (histamine does not; Abelin, 1919). The barium and pituitary constriction can be overcome by epinephrine, and barium by atropine; at least in frogs (Adler, 1918), whose bladder shows less differentiation and contracts both to sympathetic and parasympathetic stimulants (Langley). The *literature* to 1933 is reviewed by Gruber.

AUTONOMIC REACTIONS OF THE EYE

The iris is controlled by two reciprocating sets of muscle fibers, the circular sphincter with oculomotor innervation of parasympathetic type; and the radial dilators, innervated from the superior cervical ganglion. The dilator-sympathetic set is concerned mainly in the pupillary changes of emotion (Ingalls, 1923) and in asphyxia. The changes of the pupil for vision are effected mainly by the oculomotor-sphincter set, which also controls the ciliary muscle. The sphincter receives continuous tonic constrictor impulses from the pupillary center, the tone of which is being continuously inhibited, but to a varying degree, by afferent and emotional impulses. The diameter of the pupil is the resultant of these opposing forces. Peripheral autonomic reactions are produced through stimulation and paralysis of (*a*) the ganglia of both systems by nicotine; (*b*) stimulation of the sympathetic receptive mechanism by epinephrine and cocaine (mydriasis); and (*c*) paralysis of the oculomotor receptive mechanism by atropine (mydriasis); and its stimulation by pilocarpine, choline, physostigmine and the related drugs (miosis).

The localization of the oculomotor reactions offers interesting problems: *Atropine* dilates the pupil. Stimulation of the short ciliary nerve, *i. e.*, of the postganglionic fibers of the oculomotor, fails to constrict the pupil. Atropine must therefore have paralyzed the sphincter mechanism peripherally to the ganglia. Direct electric stimulation of the sphincter muscle still produces contraction; so that the contractility of the muscle is not injured. The atropine must therefore act on the nerve endings, or on the receptive mechanism. As we are dealing with a paralysis, degeneration of the nerve could not be employed to distinguish between these. Recourse must be had to the indirect method of matching atropine against pilocarpine.

If the short ciliary nerve is divided and allowed to degenerate until it becomes irresponsive to electric stimulation, *pilocarpine* still produces miosis (Anderson). It must therefore stimulate peripherally to the degenerable oculomotor endings. Atropine, however, removes the miosis; from this it follows that the pilocarpine does not directly act on the contractility of the muscle, for this is not affected by atropine, as was shown above. The pilocarpine must therefore stimulate the receptive mechanism. The experiment also shows that the atropine action can not reside in the nerve endings, for in that case it could not antagonize the effects of pilocarpine peripheral to these endings. This therefore also localizes the atropine action in the receptive mechanism. Although *physostigmine* is more potent than pilocarpine against atropine mydriasis, it is not miotic after nerve degeneration, because it does not act directly, but prevents the decomposition of acetylcholine, which is apparently present only when the nervous mechanism is intact.

The response of the iris to physostigmine disappears within a few days after section of the nerve; that of the fibrillary contractions of striped muscle only between the eighteenth and twenty-seventh days (Magnus, 1908). The response of the iris returns after about ten weeks, probably by regeneration of the postganglionic fibers (I. H. Leopold and Comroe, 1945).

The *iris of guinea pigs* reacts typically to atropine, muscarine, physostigmine and arecoline, but *pilocarpine* is mydriatic and antagonistic to the parasympathetic stimulants. If the iris is denervated, it becomes constrictor (Koppanyi, 1929). *Rats* react similarly (Koppanyi and Sun, 1926). R. D. Barnard, 1943, attributes the paradoxic mydriasis of rat eyes to cholinergic drugs, especially cyanamide, to pressure of the engorged harderian glands on the optic nerve, cutting off the reflex pupillodilator tonus.

Conflict of Sympathetic and Parasympathetic Actions.—Langley and Dickinson, 1890, showed that the effects of *nicotine* on the pupil and nictitating membrane are the result of simultaneous stimulation of the sympathetic and cranial innervation. In cats, the sympathetic usually predominates (dilatation of pupil and retraction of membrane). Pilocarpine, on the other hand, causes constriction (oculomotor stimulation), which is also unaffected by complete denervation (Anderson). It acts also on the sympathetic, however, for the nictitating membrane retracts. Both drugs therefore act on both systems.

Both drugs act after degeneration of the nerves, in the body; but with the excised iris, only the augmentor (oculomotor) response persists. To explain this contradiction, Dale and Laidlaw, 1912, assume that the sympathetic stimulation in denervated animals is brought about by increased secretion of epinephrine, to which the denervated sympathetic endings are especially susceptible.

Excised Iris.—In dogs, beef and cats the central region consists exclusively of circular (sphincter) fibers, the outer predominantly of radial (dilator fibers). The two regions react qualitatively alike to the autonomic drugs; *i. e.*, both are constricted by the cholinergic and dilated by the adrenergic stimulants (Leyko, 1927). The dilator effect of the sympathetic stimulants on the inner region must be by inhibition of the tonus of the circular fibers; in the outer region the radial fibers are also stimulated.

The reactions of the radial-free *iris sphincter* are as follows: *Epinephrine* dilates, even in dilution of 1:400,000,000, effective also after physostigmine; epinine, cobefrin and arterenol act like epinephrine. *Ephedrine*, amphetamine and neosynephrine dilate occasionally; *cocaine* may dilate, also after atropine. *Pilocarpine*, *choline* and its esters and *physostigmine* constrict; physostigmine sensitizes to acetylcholine and mecholyl, not to pilocarpine. They are antagonized by *atropine*, and feebly by the sympathetic stimulants. *Barium* and *ergotoxine* constrict, and are but slightly antagonized by atropine. *Histamine* constricts in dilutions of 1:1,000,000,000 (Yonkman, 1931; Gunter and Mulinos, 1939).

Excised Iris of Frog and Eels.—These show rather peculiar reactions: in the excised bulbus, atropine (2 per cent) or cocaine (2.5 per cent) dilate; but no contraction is produced by pilocarpine, physostigmine, nicotine or muscarine, 0.1 to 2 per cent (Magnus, 1899).

Iris of Striated Muscle.—The iris of birds consists of striated muscle, and responds to drugs like other striped muscle; *f. i.*, it is paralyzed by curare. The iris of the *alligator* also consists of striated muscle, but is innervated like the constrictor iris of mammals, and responds to the autonomic drugs, as does also the iris of the *turtle* (Iske, 1929).

Clinical Susceptibility of Iris.—K. K. Chen and Path, 1929, found that the susceptibility to the sympathetic mydriatics (cocaine, enophthalmine and ephedrine) is greater in Caucasians than in Chinese, and least in Negroes. Gnad, 1930, reported that blue iris is much more responsive than brown to all kinds of pupillomotor drugs.

The ciliary muscle has exclusively parasympathetic innervation. Physostigmine and pilocarpine produce spastic contraction, and fix accommodation for near vision. Atropine relaxes the static tonus, more than any other agent, and fixes accommodation for distant vision. Sympathetic stimulants (epinephrine and cocaine) do not affect the static tonus, but they reduce the range of accommodation (Hartgraves and Kronfeld, 1931). The range of accommodation is greatest at birth and decreases steadily as *age* progresses (J. S. Friedenwald).

Intra-ocular pressure is markedly affected by the parasympathetic drugs, especially in glaucoma when the margin of safety for the drainage of the intra-ocular fluids is small. The drainage canals in the ciliary margin are mechanically compressed by the attachments of the ligament of the lens when the ciliary muscle is relaxed by atropine, and are opened by physostigmine or pilocarpine. Sympathetic mydriatics have little effect on the drainage, but epinephrine may raise the intra-ocular pressure by the rise of blood pressure. Nitrites may raise it by dilating the ocular vessels.

The *filtration of organic dyes* from the blood into the aqueous humor of rabbits was reported increased by physostigmine and pilocarpine, and decreased by atropine and epinephrine (Sawada and Mizuta, 1927). Wesselkin, 1929, found it increased by all agencies that cause congestion or increase intra-ocular pressure, including intravenous injection of epinephrine. The penetration of intravenously injected arsphenamine and tryparsamide into the aqueous humor is also increased by conjunctival application of pilocarpine or physostigmine (A. C. Krause *et al.*, 1930).

The extrinsic muscles of the eye are the only mammalian striated muscles which respond like the muscles of the lower vertebrates and like denervated or innervated fetal muscle to choline and nicotine, *i. e.*, by tonic contracture (Duke-Elder, 1930). **The nictitating membrane** of cats is contracted by parasympathetic stimulants, augmented by cocaine, inhibited by atropine (Rosenblueth, 1932). *After ergotoxine*, it responds to epinephrine and noradrenaline by relaxation; to nerve stimulation or acetylcholine by contraction, followed by relaxation (Acheson, 1940).

AUTONOMIC REACTIONS OF BRONCHIAL MUSCLE

The smooth muscle of the air passages in mammals, extending from the trachea to the beginning of the infundibula, is innervated solely by the vagi, which carry mainly constrictor, but also dilator fibers—the latter sympathetic—from the stellate ganglia. It responds both to parasympathetic and to sympathetic drugs. The parasympathetic stimulants produce constriction; atropine, relaxation. Epinephrine results in relaxation, especially if the muscle was contracted; ergotoxine causes constriction. The bronchial muscles contract violently to the nonspecialized muscular stimulants, barium, etc.; and especially to histamine, peptone and other anaphylactoid poisons, and to true anaphylaxis. Hypersusceptibilities of this type constitute one group of bronchial asthmas. Bronchial spasm may also be produced reflexly, as by irritant vapors. Direct muscular depressants, such as nitrites, relax the bronchioles. Constricting and dilating agents are mutually antagonistic, regardless of their mechanism of action.

Methods.—Bronchial reactions were studied in intact animals by Dixon and Brodie, 1903, and by Sanoz, 1914, by recording the excursions of the lungs under uniform artificial respiration. These, however, can be altered also by cardiac dilatation, pulmonary congestion or edema, and by changes of the blood volume and blood pressure. D. E. Jackson, 1913, introduced a compensator to keep the blood pressure constant, but the other possibilities are not easily eliminated in intact animals. The results should therefore be checked on excised bronchi. Rings of bronchial muscle suspended in a saline bath were used by Trendelenburg, 1912; Macht and Ting, 1921; and others. They are restricted to relatively large bronchi. Sollmann and von Oettingen utilized the resistance of the bronchial tree of excised lung to the flow of saline solution infused through a tracheal cannula. The most direct method is the microscopic observation of the bronchioles of all sizes in free hand sections of lungs, suspended in warm oxygenated saline, as described by Sollmann and Gilbert, 1937. The results of the various methods are in general agreement: for instance, Jackson, 1914; Wornant, 1929; Swanson, 1929; Swanson and Webster, 1930 (including perfusion); Miyake, 1929 (excised); Sollmann and Gilbert, 1937 (microscopic). There are some peculiar differences in the reactions of various kinds of animals: for instance, the bronchioles of rats do not react to histamine; those of rabbits but feebly to epinephrine. Human bronchial muscle is highly susceptible (Sollmann and Gilbert).

Bronchial Movements.—Direct microscopic observations show that normal bronchioles may execute spontaneous rhythmic pendular and peristaltic contractions, or undergo more lasting changes of tonus. They react in the traditional manner to drugs and anaphylaxis, constricting to actual occlusion. The alveoli and infundibula do not react to any of the drugs. The spontaneous rhythmic movements have not been recorded in the intact lung (T. Gordonoff and Scheinfinkel, 1936), because of mechanical difficulties. There can be little doubt that they occur normally, for the vigor and tension are more favorable to them *in situ* than in sections. Their *function* is problematical, but they would tend to offset the dead space of the lungs by alternately shifting the resistance and thus securing more effective air currents. They also tend to diminish firm adherence of the mucus; but they could not effectively propel and expel the mucus, except for short distances. The tonus of the entire bronchial tree could vary the total dead space of the pulmonary air way. It is tempting to assume that it may adapt this to the rate and depth of breathing. It runs riot in the spasm of allergic asthma. The dilatation of the bronchi in inspiration and contraction in expiration, as observed with the bronchoscope (M. Ellis, 1930), are purely passive adjustments to the intrathoracic pressure (H. C. Nicholson and Trimby, 1940).

Bronchial constriction is produced by parasympathetic stimulants (mecholyl, pilocarpine, physostigmine); by histamine (not effective in rats) and less powerfully by anaphylaxis, barium, nicotine, cyanide, benzedrine. Chloroform and ether produce slight constriction, sometimes followed by dilatation (microscopic observation, Sollmann and Gilbert). Other methods have shown that the following also produce bronchial constriction: Choline, arecoline, muscarine; morphine, thebaine, dionin; ergotamine (slight), potassium, calcium (D. E. Jackson, 1914; Swanson, 1929). In intact animals, nicotine, lobelia and curare and small doses of pilocarpine produce an initial constriction, followed by dilatation. Jackson attributes this secondary dilatation to stimulation of the suprarenals. This dilatation is also produced by acetylcholine if it is preceded by atropine and ergotamine, but does not occur if the adrenal glands have been removed (Melville, 1938).

Bronchial constriction from higher centers, directly or reflexly, is produced by cerebral anemia, nasal insufflation of ammonia, nicotine, cyanide and barium (Houssay and Cruciani, 1929).

The anaphylactic response may be observed microscopically on sections of the lungs of rabbits sensitized by injection of egg albumen. Such bronchioles are constricted by the addition of egg albumen, which has no effect on unsensitized bronchioles. The spasm passes off spontaneously in a few minutes, and can not be repeated by further addition of albumen. The sensitized or desensitized bronchioles respond to drugs in the normal manner (Sollmann and Gilbert).

Anaphylaxis in intact animals includes congestion and edema of the bronchial mucosa. In clinical asthma this is further complicated by chronic inflammatory changes.

Bronchial dilatation may be observed microscopically with atropine and epinephrine (epinephrine acts feebly in rabbits). These dilate normal bronchioles, and both antagonize equally parasympathetic and muscular constrictors. Papaverine, dilute acid, ephedrine, magnesium and nitrite dilate more weakly. Other methods confirm these dilatations and show that hordenine, lobeline, caffeine and metrazol also dilate. Cocaine intensifies the dilator action of epinephrine and antagonizes ephedrine and especially pseudoephedrine. Sympathetic denervation by excision of the stellate ganglia also intensifies epinephrine dilatation (Co Tui *et al.*, 1936). Iodides have no effect in living animals. They dilate excised bronchial muscle (Macht and Ting, 1921), but only with concentrations much higher than could be maintained in the blood.

Antagonisms.—Bronchial constriction by parasympathetic stimulants, histamine or anaphylaxis, and dilatation by atropine, epinephrine or papaverine neutralize each other without reference to the mechanism or site of their action, according to the observations of Sollmann and Gilbert. This agrees generally with the lung plethysmograph method, except that Swanson, 1929, reports atropine ineffective against histamine and morphine constriction. Epinephrine may dilate after ergotamine, but not after F 933 (Melville, 1938).

Pseudospasm of Bronchi.—*Agar solutions* perfused through the pulmonary artery of guinea pigs produce marked distention of the lung and arrest of perfusion flow. The effect is not antagonized by papaverine or atropine, and is due to agar emboli in the pulmonary vessels. These arrest the circulation and shut off the bronchi by mechanical compression (Hanzlik and Karsner, 1920).

Lower Vertebrates.—In snakes and turtles, the innervation and the response to drugs are as in mammals: contractor to parasympathetics; relaxor to epinephrine, except that the relaxor effect of epinephrine is weak (Carlson and Luckhardt, 1920; Luckhardt and Carlson, 1921). Nicotine, pituitary, lobeline and veratrine produce strong contraction of the turtle lungs, which is not observed in dogs. Codeine and pilocarpine act as in mammals (D. E. Jackson and Pelz, 1918).

In *frogs* and *salamanders,* the musculature of the lung sacs corresponds to the bronchial muscle of mammals, but has a different physiology and innervation (frog, Carlson and Luckhardt, 1920; salamanders, Luckhardt and Carlson, 1910). The muscle possesses a strong and continuous inherent tonus, which is relaxed by parasympathetic (vagus) stimulation, and is highly augmented by sympathetic stimulation. The response to epinephrine is transposed; *i. e.,* it produces relaxation. Atropine presents another anomaly, for it does not prevent the inhibiting response to vagus stimulation. Pilocarpine, which was tried only on salamanders, acts normally, *i. e.,* relaxes. Contraction of frog lung by acetylcholine is a more sensitive assay method even than leech muscle (M. Corstein, 1940).

D. Potick, 1943, also reports that the smooth muscle of frog and toad lung is contracted by cholinergic and relaxed by adrenergic drugs. Histamine has little effect; pituitrin has none.

The **ciliated epithelium of the respiratory** passages extends from the turbinates through the trachea nearly to the terminal bronchioles. In mammals it is not supplied with nerves (Plattner and Hou), and is not affected by most of the autonomic drugs, except as they may affect the mucous covering and thereby the mechanical resistance to the beating of the cilia. A thin film of fluid mucus is moved outward fairly rapidly (twelve to twenty-three seconds per millimeter in the trachea of living guinea pigs) as on a rolling sidewalk (Henschen), and with it any dust and carbon on their surface; but the force is weak. Thick, viscous mucus is moved slowly. The cilia are markedly affected by temperature; 36° to 38° C. is optimal for mammalian bronchi (Gordonoff, 1938); human nasal cilia are most active between 65° and 85° F. These are arrested between 45° and 55° F., but are restored by warming (Proetz, 1934). They are depressed by impairment of circulation (Lommel, 1908).

With *human mucosa* extirpated from the nose, chlorbutanol inhibits ciliary motion; sulfonamides and penicillin have no effect (Lierle and Evers, 1944). On the intact *mucosa* of the turbinates of guinea pigs, *epinephrine* 1:1000 depresses (probably by its chloretone). *Ephedrine* hydrochloride, 3 per cent, and *cocaine* hydrochloride, 5 per cent, are not detrimental; 10 to 20 per cent cocaine slows, but with good recovery. *Menthol, thymol* and *eucalyptol*, 0.5 to 1 per cent, are mildly depressing. *Mild silver protein*, 5 to 20 per cent, has little effect. *Mercurochrome*, 2 per cent, and *zinc sulfate*, 2 per cent, depress. *Silver nitrate*, 0.5 per cent, kills the cilia immediately, without recovery (Lierle and Moore, 1934).

Tracheal and bronchiolar cilia are depressed in *living animals* by large doses of *alcohol* (Herrmann, 1933) and by general anesthetics, chloroform, ether, ethyl chloride, avertin and evipal (A. M. Ernst, 1938), perhaps by depression of the circulation. In *excised bronchioles* (thin sections) most autonomic drugs have no visible effect. *Nicotine* arrests, but this requires rather high concentration (1:2500). *Chloroform, ether* and *cyanide* also arrest (Sollmann and Gilbert, 1937). The *tracheal cilia of the turtle* behave similarly to the mammalian (Lucas and Douglas, 1935).

The reactions of the cilia of frog's pharynx differ materially from those of mammals and turtles. They have a *parasympathetic* innervation (Lucas, 1935), and their beat is accelerated by parasympathetic stimulants (pilocarpine, choline and its esters, arecoline). *Atropine* antagonizes these, but has no effect alone. *Epinephrine* has no effect; nor has morphine, potassium chloride, or 5 per cent alcohol. *Camphor* accelerates. *Nicotine, chloral, ether, quinine, caffeine* and *calcium* depress (S. Ishikawa and Ohzono, 1931; Plattner and Hou, 1931).

The ciliary action of paramecium is reversed by monovalent cations (Mast). The order of potency decreases in the direction $K > Li > Na > NH_4$. It is independent of the anion (Oliphant, 1938). It responds to drugs that act directly on smooth muscle, but not to those that act on the nervous mechanism (J. F. Oliphant, 1943.)

AUTONOMIC REACTIONS OF THE HEART

The parasympathetic innervation of the heart is inhibitory. It comes by the vagus, and its ganglia are intracardiac. The sympathetic is augmentory, with its ganglia in the annulus of Vieussens. *Nicotine* at first stimulates and then paralyzes the ganglia of both divisions; the vagus effect predominates ordinarily. Nicotine therefore renders the heart irresponsive to stimulation of the vagus trunk; but stimulation of the postganglionic fibers, in the sinus region, still arrests the heart.

Parasympathetic Drugs. — Atropine destroys the response to postganglionic as well as to preganglionic vagus stimulation. The muscle is not paralyzed, since the heart continues to beat with undiminished vigor; the action of atropine must therefore be between the ganglia and the contractile mechanism, in the receptive mechanism. *Parasympathetic stimulants*, acetylcholine, muscarine, physostigmine and pilocarpine, weaken and slow the heart and produce diastolic arrest, and are mutually antagonistic with atropine. The pilocarpine effect, however, is liable to change to vagus paralysis.

Orthosympathetic Drugs.—Epinephrine increases the rate and amplitude of the contractions; this is prevented by *ergotoxine*, but only slightly modified by F 933 (W. T. Hill and Myers, 1939).

Ion Ratio.—Increase of the $\frac{Ca}{K}$ ratio stimulates sympathetic stimulation, and renders the sympathetic more sensitive and the parasympathetic less sensitive to stimuli (Burridge, 1912). Conversely, increase of the $\frac{K}{Ca}$ ratio favors parasympathetic stimulation. Radio-activity acts like potassium (Zwaardemaker, 1918).

Nonspecific Drugs.—Barium, the digitaloid drugs and caffeine stimulate the force of the heart, and quinidine depresses. Their relation to the autonomic system is obscure, but they appear to act more directly on the contractile substance.

Composite Effects.—When the heart is subjected simultaneously to poisons belonging to different groups, they may add their actions in a simple manner; for instance, the acetylcholine inhibition may be removed either by paralyzing the inhibitory mechanism with atropine, or by stimulating the augmentory mechanism with epinephrine (Barlow and Sollmann, 1926). However, discordant effects from such combinations have been reported, especially by Kolm and Pick, 1920, and Amsler, 1920, which these investigators interpret as transfer of the action from one system to the other. They conceive that these drugs are really "amphotropic," *i. e.*, that epinephrine may stimulate the parasympathetic as well as the sympathetic; but that the normal sympathetic effect so greatly overshadows the parasympathetic that the latter is only observed when the parasympathetic system is especially sensitive, or when the sympathetic system is especially insensitive.

Central Effects.—The heart rate is normally regulated by tonic and reflex stimulation from the higher parasympathetic and sympathetic centers, especially in the hypothalamus. The *clinical reactions* to therapeutic doses of epinephrine, atropine, ergotamine, pilocarpine and physostigmine may therefore differ from what would be expected from their peripheral actions (H. Freeman and Carmichael, 1936).

The effects of *direct application to the hypothalamic centers* are described by Dikshit, 1934.

After complete removal of the sympathetic chain, the cardiac rhythm of dogs is slower, and emotional excitement produces less acceleration than in normal animals. Cardiac acceleration in dogs, therefore, normally involves stimulation of the sympathetic as well as decreased tonus of the cardiac inhibitory centers (Brouha *et al.*, 1936).

The *distribution of the parasympathetic innervation* varies in different animals. In mammals, the chronotropic fibers of the vagus go chiefly to the sino-auricular node, and thereby set the rate of the whole heart. In isolated rabbit's or cat's heart, acetylcholine, arecoline and pilocarpine act most potently on the Keith-Flack node, then the Aschoff-Tawara node, and much less on the lower ventricular node. With epinephrine, the difference is much less, but in the same direction (Anitschkov, 1934). *Auriculoventricular conductivity* is depressed by vagus and enhanced by sympathetic stimulation. Choline esters depress the conductivity and are potentiated by physostigmine, prevented by atropine; epinephrine enhances the conductivity and is mutually antagonistic with parasympathetic stimulants. Asphyxia first increases then depresses the conductivity (Carlen and Katz, 1939). The inotropic vagus action is distinct from the chronotropic action in dogs, and is believed to be exerted directly on the muscle fibers of the atrium. None of the vagus fibers go to the ventricle in dogs. Stimulation of the left vagus depresses the conductivity and increases the refractory period of the auriculoventricular node, so that the ventricles are slowed more than the auricles, and strong stimulation produces complete heart block. In turtles also, physostigmine slows or stops the rhythm of sino-auricular and auricular, but not of the ventricular segments (Greene, 1932). Pilocarpine and acetylcholine do not inhibit ventricular segments, indicating that the turtle ventricle does not have a parasympathetic receptive mechanism. Its sympathetic innervation is also weak, responding but slightly to epinephrine (Hiatt and Garrey, 1943).

Seasonal Variations in Vagus Response.—During the summer, frogs show a markedly diminished response to vagus stimulation, electrical or by drugs (Cori, 1921; Langecker, 1924). Cori showed that this is not due to altered K and Ca content, and attributes it to thyroid changes

Effect of Epinephrine on Vagus and Accelerator Response.—Vagus stimulation is unable to slow the heart against the maximal stimulation of epinephrine (Kuroda and Kuno, 1916), but smaller doses lower the threshold of vagus stimulation for frogs. Stimulation of the accelerator nerve does not add materially to the augmentation produced by epinephrine, so that the response to accelerator stimulation appears diminished or abolished (Barlow and Sollmann, 1926).

Sensitization by Other Conditions.—In thyroid intoxication the intact heart responds much more than normally to both mecholyl and epinephrine (B. Wise and Hoff, 1938). The presence of *nonelectrolytes* (urea, sugar) renders the heart more resistant to calcium deficiency; which Loewi (1921) interprets as sensitization to the smaller quantities of calcium that remain. The nonelectrolytes also sensitize to strophanthin; they may therefore be classed with the sensitizers of sympathetic action. Treatment of the heart with *lecithin* and *soap* renders it more resistant to choline and pilocarpine, *i. e.*, diminishes parasympathetic stimulation (and by heat). Ergotomine blocks the vagus augmentation. Curare, erythrine, *serum* antagonize parasympathetic stimulation (muscarine), and increase the parasympathetic depression of atropine. This is due partly to its calcium, partly to the ether-soluble extractives (Kirste, 1921). Increase of *alkalinity,* within physiological limits (to pH 7.8) increases the tonus (Andrus, 1919); *i. e.*, acts in the sympathetic direction. The response to vagus stimulation in frogs is diminished by increase of intra-auricular pressure, and by caffeine (Barry, 1929).

Crustaceans react distinctively. The *crawfish* heart is quickened by acetylcholine; atropine is antagonistic. *Crab* (cancer) heart responds to this by increase of tonus without change of rate. Pilocarpine stimulates, atropine antagonizes, epinephrine also stimulates, ephedrine does not (Bain, 1929). *Daphnia* resembles the vertebrate heart reactions rather than that of the higher crustaceans. Acetylcholine depresses the rate and force; atropine and physostigmine produce irreversible toxic inhibitions; epinephrine accelerates, potassium slows (E. R. Baylor, 1942). Acetylcholine accelerates the heart of the higher *arthropods,* some annelids and some tunicates, and slows the rate in most molluscs (C. L. Prosser, 1942; Davenport *et al.*, 1940).

The lymph hearts of frogs and toads contain striped muscle and therefore react differently. These are arrested by sympathetic and quickened by parasympathetic nerve stimulation (and by heat). Ergotamine blocks the vagus augmentation. Curare, erythrine, acetylcholine, nicotine and digitalis arrest; physostigmine, veratrine and ouabain decrease the amplitude; pilocarpine, atropine and pituitrin have no effect (Hotovy, 1939; Braun-Menendez and Foglia, 1940). If all four lymph hearts of the toad are destroyed, death occurs in two to four days, with progressive increase of body weight and concentration of the blood, due to accumulation of water in the lymph sacs. One of the lymph hearts, beating efficiently, suffices for survival (Foglia, 1939).

AUTONOMIC REACTIONS OF THE BLOOD VESSELS

Most blood vessels are innervated only by the orthosympathetic. This has generally augmentory functions which are under continuous tonic control by the vasomotor center. The caliber of the vessels is adjusted chiefly by increase or decrease of these central tonic impulses. In a few situations there is a special vasodilator innervation, generally if not always parasympathetic; for instance, the chorda tympani and the nervus erigens. However, the vessels with purely orthosympathetic innervation respond more or less to the parasympathetic drugs, the stimulants generally being dilator. It may be assumed that they possess the parasympathetic receptive mechanism, but that this has not made connection with the central nervous system.

Dilute epinephrine also often produces dilatation. The arteries and veins show similar phenomena. The capillaries exhibit some special features.

Unusual Innervations.—Reversal of the ordinary innervation is seen in *lung vessels of frogs and turtles.* This is entirely parasympathetic, constrictor in the frog, constrictor and dilator in the turtle. It reacts, however, to epinephrine, which is antidoted by atropine (Luckhardt and Carlson, 1921). The *placental vessels* do not receive any nerves, but react in the usual direction to epinephrine (in the human), barium, histamine and adenosine (von Euler, 1938). The *yolk sac vessels* of chick embryos give opportunity for studying the reactions of vessels before they connect with nerves (Nakatano, 1935).

Dilator Action of Epinephrine.—Under certain conditions, the sympathomimetic constrictor action of epinephrine gives place to nonsympathetic dilator reactions. This is the predominant effect in some vessels (Rothlin, 1921); in others it is seen only with dilute solutions. It may also be evoked by lowering the sensitivity of the sympathetic innervation.

Parasympathetic Drugs. — *Acetylcholine* produces marked vasodilatation, which is antagonized by *atropine* (Hunt, 1918). The effects of *pilocarpine* are also dilator in most cases; but a few contractor reactions have been described (Langley, 1921). Brodie and Dixon found that atropine removes the pilocarpine constriction without impairing the response of electric stimulation of the vasoconstrictor nerves. Hildebrandt (1920) reports that *atropine* antidotes epinephrine and sympathetic nerve stimulation in frog's vessels. It is not antagonistic to barium, but removes veratrine constriction (Kondo, 1919).

Responses of Different Vascular Areas.—The orthosympathetic nerves to dogs' muscles contain cholinergic *vasodilator fibers*; those to the skin do not; those to the intestines contain some. The muscles of rabbits and monkeys are not supplied with sympathetic vasodilators; cats have a small supply; dogs and hares have many (J. H. Burn, 1938). The *human hand* has highly selective arterial reflexes distinct from those of the skin (A. B. Hertzman, 1941). Data for various drugs have been collected on animals by Amsler and Pick (1919) (frog perfusion experiments, splanchnic areas and legs), Adler (1912) (ditto, lung and skin vessels), and Rothlin (1921) (rings of mammalian artery). The vessels of the toes are much less susceptible to vasodilating drugs (papaverine, mecholyl, histamine) than are those of the fingers (E. V. Allen and Crisler, 1937).

The *reactions of systemic arteries* are illustrated by the *excised carotid artery:* In rabbits (also in dogs and cats), *epinephrine* produces marked constriction. This is completely antagonized by *nitrite. Histamine* and *barium* cause marked constriction; *mecholyl;* dilatation. *Anaphylaxis* (egg albumen in sensitized rabbits) had no effect (Sollmann and Gilbert, 1938).

Veins react similarly to arteries, but more feebly (review, K. J. Franklin, 1928). Excised *human veins* were *contracted* by epinephrine, physostigmine, histamine, strophanthin, barium, nicotine and often by caffeine. They are dilated by nitrite (Maloff, 1931). With perfused colic and superior mesenteric vein of cats, Fleisch, 1931, found epinephrine always constrictor with the threshold of 1:10^8. Acetylcholine dilated in 1:10^{11}, higher concentrations constricted; histamine dilated in 1:10^{12} to 10^9 and constricted in 1:10^6.

Vasomotor ganglia are first stimulated, then paralyzed by nicotine. They are also paralyzed by curare and large doses of strychnine and brucine (Langley, 1918).

Ion Ratios.—Calcium excess acts as parasympathetic stimulant to the vessels and as sympathetic stimulant in the heart. The vessels are dilated, and the constrictor response to sympathetic nerve stimulation and to epinephrine is diminished; they may even respond by dilatation. *Calcium deficiency* acts as a sympathetic stimulant on the vessels and as a parasympathetic stimulant on the heart. The vessels are constricted and the constrictor response to epinephrine is enhanced. *Potassium excess* acts as sympathetic stimulant to the vessels; as a parasympathetic stimulant on the heart. The vessels are constricted. However, the effect on epinephrine is abnormal; the constrictor effect is diminished or may even be replaced by dilatation. *Potassium deficiency* also acts as a sympathetic stimulant to the vessels, as well as to the heart. The vessels are constricted and react more effectively to the constrictor action of epinephrine. *Akalinity increase:* Moderate increase acts in the direction of sympathetic stimulation for the vessels, as for the heart; *i. e.*, perfused vessels constrict. This is not antagonized by ergotoxine (Heymann, 1921). Moderate alkalinity also promotes the contractions and tone of excised arteries (Opitz, 1920). Large excess of alkalinity relaxes (Heymann). *Diminished alkalinity* constricts the perfused vessels (Pearce, 1913). The mechanism is not clear; the constriction is prevented by ergotoxine, so that it might be considered as sympathetic; but the constrictor response to epinephrine and to nerve stimulation is abolished or replaced by a dilator response (Heymann; Schmidt). Larger *excess of acid* dilates the vessels; the dilator concentration coinciding with the H ion concentration that stimulates the respiratory center (Adler, 1921). Increase of either acidity or alkalinity favors the production of edema in the perfused frog leg or rabbit ear (Heymann, 1921). *Spleen extract* sensitizes to the pressor (sympathetic) responses of epinephrine; and antagonizes the depressor response (Collip, 1920).

The pulmonary arterioles have given conflicting results. They respond feebly if at all to epinephrine and amphetamine. They are constricted by parasympathetic stimulants (mecholyl, acetylcholine; but pilocarpine dilates) and muscular stimulants (barium, histamine and temporarily by anaphylaxis). Atropine hinders all these agents (A. J. Gilbert, 1938, microscopic section). Foggie, 1937, claims that small doses of epinephrine dilate and large doses constrict. Daly and von Euler, 1932, found epinephrine generally constricting in dogs; acetylcholine sometimes dilated (review of pulmonary and bronchial circulation, Daly, 1933).

Coronary Vessels.—The parasympathetic innervation appears to be generally constrictor; the sympathetic, dilator (Anrep and Segall, 1926); but their susceptibility varies in different animals. Generally, they are *constricted* by choline and its esters, but more powerfully by pitressin. Barium and digitalis are also constrictors. *Dilating* are epinephrine (but varying with species); atropine (against parasympathetic stimulation); nitrite; carbon dioxide, lactic acid, anoxia and cyanide by local action; caffeine and other methylxanthines, adenine and adenylic acid. Histamine dilates in man, dog and cat; it constricts in rabbit. Potassium and strophanthin give indecisive results (Orzechowski, 1933; F. M. Smith *et al.*, 1926). In *dogs*, the vagi carry only cholinergic dilator fibers, which are tonically active. The stellate ganglion sends adrenergic dilator and constrictor fibers, both tonically active, but with constrictor tonus dominant (L. N. Katz and Jochim, 1939). The isolated fibrillating heart of dogs gives *coronary dilatation* on perfusion with epinephrine (sometimes preceded by slight constriction); acetylcholine and physostigmine (antagonized by atropine); $CaCl_2$, NaCl, KCl below $1\frac{2}{3}$ of blood concentration; nitrite and glyceryl trinitrate; histamine; caffeine, aminophylline and other xanthines. *Coronary constriction* results from pitressin, atropine, ergotamine, piperodimethylbenzodioxane, KCl above $1\frac{2}{3}$ of blood concentration (Katz and Lindner, 1939). The coronary flow, however, is complicated by the effect on the cardiac contractions, cardiac output and aortic pressure, and the transfer to the intact circulation is not always clear (Wiggers).

Cerebral vessels respond feebly to autonomic drugs. The cerebral blood flow is therefore determined chiefly by the arterial pressure. In cats and rabbits it is *increased* by vasodilators, carbon dioxide (local concentration), nitrite, mecholyl, caffeine and ether, as well as by vasoconstrictors, epinephrine, pitressin and ephedrine. Histamine *decreases* the flow; ergotamine generally does so (J. P. Hendrix and Schmidt, 1938).

Portal vessels have strong constrictor reactions, the portal blood flow being decreased (in dogs) by epinephrine, choline esters, histamine and digitalis. It was increased by amyl nitrite (L. N. Katz and Rodbart, 1937).

Spleen.—The spongy blood spaces, which may hold a tenth of the entire blood, are largely outside of the active circulation. For instance, the concentration of carbon monoxide and methemoglobin, in poisoning, is less in the splenic than in the circulating blood. Much of the splenic blood can be versed into the general circulation by contraction of the trabecular muscles (Barcroft and Stephens, 1927); a single contraction may increase the total blood volume by 2.6 to 5.6 per cent (Cruikshank). Splenic contraction is stimulated by epinephrine (Suzuki, 1927), and also by ephedrine, the choline esters, physostigmine, pilocarpine, pituitrin, chloroform inhalation, and by nicotine, the latter partly by increasing the output of epinephrine. Intravenous sodium amytal produces relaxation (J. E. Davis, 1937; McCrae, 1930). Contraction of the spleen increases the blood volume and the erythrocyte count, and causes complex changes in the leukocyte picture (Menkin, 1929). The spleen acts as a mechanical elastic reservoir of blood volume. It also has complex and obscure relations to *blood destruction and regeneration of blood corpuscles*. It can be removed with but little disturbance, so that its functions can evidently be carried vicariously by other mechanisms; injection or feeding of extracts ordinarily produces no striking or even very definite effects.

The capillaries tend to follow passively the changes in the arterioles, and are therefore generally constricted by sympathetic, and dilated by parasympathetic, stimulants; and similarly by other arteriolar constrictors (barium, pitressin) and dilators (nitrites). Histamine, peptone, anaphylaxis and inflammatory irritants generally dilate the capillaries directly and increase their permeability. Precipitant agents (astringents) contract and decrease permeability.

P. Rous *et al.*, 1930, believe that the permeability increases toward the venous side of the capillaries. Landis, 1927, found the permeability of dilated capillaries no greater than of the contracted (review, N. L. Hoerr, 1944). Krogh, 1922, believed that the capillary flow is controlled by scattered smooth muscle cells (the Rouget cells), with sympathetic innervation, responding to epinephrine only for a short distance beyond the arterioles, but controlled especially by pitressin, which he considered a special hormone for the capillaries. Other workers claim that the Rouget cells are not muscular but connective tissue (Michels, 1936). Others again assert that mechanical and electrical and sympathetic nerve stimulation causes the endothelial nuclei to bulge into the lumen of the capillaries, so as to occlude them completely (M. E. Field, 1935; Sanders, Ebert and Florey, 1940). *A priori* it seems probable that the endothelial cells themselves may contract, somewhat analogous to the chromatophores; evidence for this was brought by J. B. Rogers, 1935, and E. R. Clark and Clark, 1935. Fulton and Lutz, 1940, conclude that there is neither endothelial contraction, nor nuclear swelling, nor endothelial valves, but that the regulation is performed by the smooth muscle cells at the end of the capillary. Capillary permeability may be tested in rats by intravenous injection of 1 cc. of 1 per cent trypan blue in 6 per cent dextrose and killing the animal in two hours (Spagnol, 1928).

Carotid Sinus and Aortic Reflexes.—Increase of intracarotid pressure lowers the general blood pressure, slowing the heart by increasing the normal tone of the cardio-inhibitory center and by depressing the tone of the vasoconstrictor center. It also depresses the respiratory center and produces reflex depressions and inhibitions, resulting in miosis, diminished discharge of epinephrine, decrease of metabolism and of muscular activity. These effects are in the general direction of parasympathetic stimulation. Lowering of the intracarotid pressure produces the reverse effects, resembling orthosympathetic stimulation. They arise reflexly by the mechanical stretching or relaxing of receptive endings scattered about in the arterial wall of the carotid sinus, the ampulla located at the junction of the external and internal carotid artery. Denervation or cocainization of the sinus produces the hypotensive reactions, tachycardia, rise of pressure, hyperpnea, etc. These reflexes are called into play by pharmacologic agents which raise or lower the general blood pressure; and the autonomic responses may be blocked by drugs which paralyze the autonomic ganglia, or the parasympathetic and sympathetic endings (nicotine, atropine, ergotamine). The intercarotid glomus and the aortic body contain another receptive organ, also rich in nerves, which mediates similar reflexes in response to a variety of chemical agents: Increase of respiration and the orthoparasympathetic group of reactions are produced in this way by hypercapnia, anoxia, acidosis, cyanide, sulfide, nicotine, lobeline, etc., and the vasomotor and respiratory stimulation by these drugs is largely due to this reflex (Heymans *et al.*, 1933; A. Verdonk, 1941; Bouchaert and Pannier, 1942; review, C. F. Schmidt and Comroe, 1940).

Clinically, the carotid sinus reflex is elicited by digital compression of the carotid ampulla (originally described as "vagus-compression reflex" by Tschermak, 1868), resulting in cardiac inhibition, etc. The reverse effects are produced by digital compression of the common carotid artery. *The effects of drugs on the cardio-inhibitory reflex are described* by Nathanson, 1933: Atropine abolishes the response. Epinephrine also prevents cardiac arrest by inducing idioventricular rhythm. Digitalization prolonged the duration of the arrest. Calcium gluconate and therapeutic doses of caffeine had no effect. The *course* of the nerves from the intercarotid glomus and ampulla is through the pericarotid plexus and the nerve of Hering or Castro to the glossopharyngeal nerve trunk. The vasoconstrictor response is general, *i. e.*, it extends to all vessels with vasoconstrictor innervation. *Hyperventilation* decreases the respiratory stimulation of the carotid body by nicotine and cyanide (Larson *et al.*, 1944).

Cardio-Aortic Depressor Nerve.—Receptive endings with functions closely analogous to those of the carotid ampulla are located in the walls of the aortic arch, the subclavian and brachiocephalic arteries and probably in the heart. They help to maintain the normal cardioinhibitory tonus and to moderate the blood pressure. Their stimulation (as also that of the depressor nerve through which they run to the glossopharyngeal nerve) results in fall of blood pressure by inhibition of the vasoconstrictor and reciprocal stimulation of the vasodilator tone; and in slowing of the heart rate, chiefly by stimulation of the vagus, and to a less degree by reciprocal inhibition of the accelerator center. It also decreases the output of epinephrine. Division of the depressor nerve has the opposite effects.

The function of the carotid sinus and cardio-aortic reflexes is to stabilize the circulation of the brain and heart automatically against changes of the general blood pressure or asphyxia. Through the carotid sinus reflex, fall of the general blood pressure results in cardiac acceleration and increased cardiac output, and in vasoconstriction, which diverts a greater proportion of the blood supply to the weakly innervated cerebral and coronary arteries. The aortic and carotid sinus reflexes protect the brain against excessive blood pressure and the heart against excessive resistance; the stimulation of the chemical receptors of the carotid glomus by asphyxia automatically augments the pulmonary ventilation by which asphyxia is ordinarily prevented. The carotid sinus responses are most marked with pressures near to normal. They tend to disappear when the blood pressure rises to 200 or falls to 50 mm. Hg. Below 50 mm., the reactions are reversed.

Reflexes from Other Blood Vessels.—Reflex pressure changes have been described as following the localized injection of irritants, especially acids, into the vessels of various areas (Tournade and Malmejac, 1931): but Heymans *et al.*, 1933, found that the femoral artery responds only to high concentrations which produce intense local contracture of the vessel wall, which would give rise to ordinary pain reflexes.

Melanophore cells of the scales of fish and skin of frogs are typically subject to autonomic drugs, contracting and relaxing much like smooth muscle. Some are controlled by nerves, others by circulating neurohormones (G. H. Parker, 1944). In *fish* this varies with species. In dogfish they are dilated through pituitary hormone, contracted through nerves; in fundulus the control is entirely through antagonistic ortho- and parasympathetic innervation (Parker, 1935). They are contracted by *epinephrine*, and this is reversed by *ergotoxine*. They are relaxed by *atropine* and apparently also by pilocarpine and physostigmine (Barbour and Spaeth, 1917). *Barium chloride* and *guanidine* provoke *rhythmic contractions*, at the regular rate of about once a minute, synchronous for all the melanophores of the scale. This coordination indicates an extracellular action, presumably on the nerve fibers, analogous to the nerve-muscle rhythm which these drugs induce in striped muscle (Veil, Comandon and Fonbrune, 1932). *Frog melanophores* are contracted both by sympathetic (epinephrine, tyramine) and parasympathetic (pilocarpine, acetylcholine) stimulants (Kobayashi, 1928). Pituitary extracts dilate, the active agent being located in the pars intermedia (Geiling). Teague and Noojin, 1938, reported on reactions to an extensive list of drugs. A. O. M. Stoppani, 1942, reports that the color of frogs and toads is not changed by acetylcholine, and believes that their responses are exclusively adrenergic. They are *lightened* by epinephrine, ephedrine, cocaine and calcium chloride; *darkened* by atropine, barium, chloride, caffeine, chloretone, F 933, nicotine, physostigmine, potassium chloride and veratrine. *Denervation* had little effect on the responses. Some of the reactions, such as those to caffeine and nicotine, are mediated through the hypophysis or adrenals.

AUTONOMIC POISONS AND SKELETAL MUSCLE

Skeletal muscles are not "autonomic"; they are entirely passive and do not even have tonus except on direct order of the central nervous system. They respond, however, to cholinergic drugs, and their stimulation is probably mediated by acetylcholine. Their relation to epinephrine is more obscure.

Acetylcholine Formation in Skeletal Muscle.—Dale, Feldberg and Vogt, 1936, reported the presence of acetylcholine in saline solution perfused through voluntary muscle when its motor nerve is stimulated, or on direct stimulation of the muscle, and also after curare, but not after complete fatigue or after degeneration of the divided nerve. From this it appears that acetylcholine is formed in the myoneural junction as chemical mediator of the nerve impulse. It was questioned whether the rapidity of contraction and relaxation of skeletal muscle would leave time for the chemical mediation of synaptic transmission (Bremer, 1934), but this doubt appears resolved by the demonstration that the concentration of choline acetylase in the synaptic region is "many thousand times as high as in the muscle tissue" (Marnay and Nachmansohn, 1938). However, the nerve-free part of the frog sartorius contains as much acetylcholine precursor as the neural region (N. O. Abdon, 1945).

Injection of acetylcholine solution into the artery of exsanguinated skeletal muscle (so that it may reach all the fibers suddenly and at once) produces a strong muscular twitch, similar to that of nerve stimulation. This is prevented by curare, as is the response to nerve stimulation; and by nicotine, as are ganglionar responses. The single twitch requires prompt destruction of the acetylcholine by acetylase; if the muscle was treated with physostigmine, the acetylcholine produces a tetanus (Dale, Feldberg, and Vogt, 1936).

If the whole muscle is immersed in the solution so that the acetylcholine reaches the fibers gradually, the effects are somewhat modified, and are essentially identical with those of physostigmine, nicotine, guanidine and barium, with quantitative differences that tend to disappear by varying the dosage: (*a*) the lowest effective concentrations produce fibrillary twitchings; with increasing doses these pass to clonic contractions, tonus contractures, and finally into curare-like depression. (*b*) With all, the action is strongest at the site of the end plate (Langley). This might mean that the receptive mechanism is concentrated at this place, or merely that the permeability of the cell wall at this place is more favorable to the penetration of the drugs or ions. The "hypolemma" membrane is indeed thinnest in the neural region. After degeneration has been completed, this preferential action of nicotine becomes less marked, and at that time the sarcolemma has grown over the denervated end plate. (*c*) All continue effective for some time after the division of the nerve endings; indeed, the sensitivity is increased for a time, as in other nerve degenerations. Most and probably all become less and less effective when the nerve has completely degenerated, presumably because the receptive mechanism, and eventually the muscle fibers as a whole, deteriorate when they are no longer used. (*d*) All are antagonized, though to a varying degree, by curare, atropine and especially l-scopolamine, and the local anesthetic group. Atropine is more effective against drugs than against nerve stimulation; a difference it frequently exhibits in strictly parasympathetic reactions, which is again merely quantitative, for sufficiently large doses of atropine block the response of striped muscle to nerve stimulation (Haffner, 1918).

Choline and its esters produce a brief twitch in some muscles, a prolonged but reversible contracture in others. In *mammals*, all fetal muscles respond by the prolonged contracture until voluntary control develops. In adult mammals only the diaphragm gives the prolonged contracture, but this reappears in the other muscles if their motor nerve is divided and degenerates; *i. e.*, the long-contracture response disappears when the muscle becomes voluntary and reappears when it is rendered involuntary (review, H. Freund, 1932).

Nicotine produces either fibrillary contraction or tonus and with large doses a curare action. *Guanidine and barium* cause coordinated rhythmical twitching of muscle. The action does not occur after degeneration of the nerves (Veil *et al.*, 1932).

Rhythmic Twitching of Mammalian Skeletal Muscle.—The spontaneous twitching under physostigmine results from repetitive discharges of the motor nerve endings (Feng and Li, 1941). Single nerve volleys evoke a regular series of contraction spikes which undergo a logarithmic decrement (G. L. Brown and Harvey, 1941). *Denervation* renders muscle much more susceptible to fibrillation by acetylcholine, and somewhat more to potassium; both are inhibited by quinidine (Magladery and Solandt, 1942). Transmission fatigue and contraction fatigue are independent phenomena (S. E. Steiman, 1943). Denervation also tends to produce spontaneous fibrillation. Electric potential changes show that these contractions originate solely in the end plate zone, and are arrested if this is excised (Hayes and Woolsey, 1942). S. W. Kuffler, 1943, confirmed on single nerve-muscle fibers of frog's sartorius that acetylcholine, nicotine and caffeine depolarize the muscle membrane where the end plates are located, but not at other regions. Curare opposes the depolarization; nerve degeneration increases it.

Ameboid movements of the end plates are described by E. J. Carey, 1942. The hypolemmal branches expand when the muscle fiber contracts and retract when the fiber relaxes. Physostigmine and acetylcholine expand, curare and quinine retract. Carey, 1944, conceives that neuromuscular transmission is blocked through this ameboid retraction and the formation of a circumscribed precipitation membrane composed on Kühne's granules. Injection of dilute lactic acid into rats causes sudden destruction of most of the motor end plates (Carey and Massopust, 1944).

Epinephrine is reported to diminish the onset of fatigue, even in perfused muscle, where it diminishes the blood flow. The improvement is not seen on direct stimulation of fully curarized muscle, so that it must be due to improved synaptic transmission of nerve impulses. Similar augmentation is produced by ephedrine, tyramine, synephrine and cocaine and also by ergotoxine and posterior pituitary (Bulbring and Burn, 1940). *Ephedrine* is used clinically in muscular dystrophies, but always with other measures, and it is not established that it has any effect.

Sympathetic Innervation of Striped Muscle.—Sympathetic fibers have been traced to the striped muscle fibers, especially by the degeneration method (Dusser de Barenne and co-workers, 1919). Their functional significance is still obscure. Dusser de Barenne (1916) and S. Cobb (1918) showed that division of the sympathetic supply has essentially no effect on the tonus. The sympathetic innervation was then credited with the regulation of the metabolism of the muscle, but Langley pointed out the difficulty of distinguishing a sympathetic innervation of the muscles from a sympathetic innervation of the blood vessels in the muscles. This also vitiates the observation that sympathetic stimulation tends to increase the amplitude of muscular contraction, especially when the muscle is fatigued. Epinephrine does not affect the contraction or tonus in excised muscle (Takayasa, 1916). On the other hand, epinephrine increases the carbon dioxide production, even in excised muscle (Martin and Armitstead, 1922), and also creatine formation (Riesser, 1916). This indicates that the sympathetic innervation may be concerned with functions of muscle in general metabolism; perhaps in heat regulation.

Reactions of Invertebrate Muscle.—The response of the striated muscle resembles closely that of the vertebrates; even the smooth muscle of invertebrates reacts to drugs much like striated vertebrate muscle (O. Riener, 1933). The *central reactions of insects* to autonomic poisons rather resemble those of vertebrate ganglia: When injected into the heart of mantids or roaches, strychnine produces pure depression; pilocarpine and physostigmine, great excitement which is prevented by atropine; acetylcholine has no detectable effect. The electric activity of the isolated ventral nerve cord of cockroaches shows similar changes (K. D. Roeder and Roeder, 1939). The response of various organs in *Daphnia* differs in many respects from those of vertebrates (Sollmann and Webb, 1941).

The nervous system of the invertebrates is reviewed by C. L. Prosser, 1946; that of the arthropods by J. H. Welsh and Schallek, 1946. Cholinergic systems are widespread above coelenterates.

Protozoa.—Papaverine produces marked swelling; histamine, shrinkage. The effects begin at the vacuoles and extend to the protoplasm. This has been proposed as a model of the effects on muscle (H. S. Hopkins, 1922), but the analogy is yet to be established.

Autonomic Poisons on White Cells.—The proportion of these cells is changed, the significance being obscure. Pilocarpine and choline increase, atropine diminishes the eosinophils and lymphocytes. Epinephrine increases the lymphocytes but diminishes the eosinophils. Histamine also diminishes the eosinophils (Port and Brunow, 1914).

Yeast formation is affected by some of the autonomic drugs. It is accelerated by low and inhibited by higher concentrations of atropine, quinine, and basic dyes (methylene blue). Pilocarpine and cocaine inhibit in low and accelerate in higher concentrations (Somoggi, 1916).

THE RESPONSE OF SECRETIONS TO AUTONOMIC POISONS

Pilocarpine stimulates and atropine arrests the secretions controlled by a central parasympathetic innervation: saliva, buccal and bronchial mucus, gastric and pancreatic juice. The sweat glands respond to cholinergic drugs, although their innervation is chiefly if not solely orthosympathetic (review, C. W. Darrow, 1943). Other parasympathetic stimulants are much less effective than pilocarpine. The salivary and sweat glands can also be caused to secrete by stimulating their sympathetic nerves; but epinephrine does not evoke secretion, perhaps because it produces too much vasoconstriction. It is an effective secretory stimulant for the sympathetically innervated skin glands of the toad (Wastl, 1921).

The pancreatic and gastric secretion may also be stimulated by histamine and peptone, and by specialized "hormones," such as secretin. These are not antagonized by atropine, and presumably act on a "responsive" mechanism of the gland cell.

Similar chemical hormones probably affect the regulation of the secretions that are not under nervous control and are not responsive to pilocarpine and atropine; *i. e.*, the urine, bile, milk, the secretions of the oviduct (Riddle and King, 1921), the cerebrospinal fluid (Becht and Gunnar, 1921) and the whole series of "internal secretions."

Oral and pharyngeal mucus secretion is greatly increased by pilocarpine, arrested by atropine. *Epinephrine* has no effect or causes a slight increase (stimulation of the cervical sympathetic increases). *Morphine* increases the mucus during nausea and tends to decrease it during narcosis (M. F. Montgomery, 1934, dog).

The **fluid secretion of the respiratory tract** is increased by parasympathetic stimulants (E. M. Boyd and Lapp, 1946).

Salivary secretion is increased by *pilocarpine* and *reflexly* by acids and ether. It is arrested by *atropine* (also by *morphine*, acting centrally). The response to *sympathetic* stimulation varies in different animals. In dogs, it provokes a flow of thick, mucilaginous saliva from the submaxillary and none from the parotid gland; in cats, it gives a profuse mucilaginous flow from the submaxillary and a scanty, thick secretion from the parotid. Histologic data indicate that the demilune cells of cat's submaxillary gland are innervated by the orthosympathetic, the mucus cell exclusively by the parasympathetic (Rawlinson, 1936). *The quantitative antagonism of atropine and pilocarpine on salivary secretion* was investigated by Cushny, 1915, on dogs with salivary fistula. The ratio remained the same (about 1 part of atropine to 9.5 of pilocarpine) whether the two drugs were injected simultaneously or some time apart, and it remained unaltered whatever total dose was injected.

Gastric Secretion.—The peptic cells, which secrete the ferments, the parietal cells, which secrete acid, and the mucus cells may function independently, but all are excited by *parasympathetic stimulation* through the vagus, *pilocarpine* or *choline* and its esters. The increase concerns chiefly the enzymes and mucus (Vineberg and Babkin, 1931). The fluid is not greatly increased by choline in the empty stomach, but the flow in response to test meals is markedly increased (MacIntosh and Krueger, 1938). *Atropine* abolishes the secretory response to parasympathetic stimulation and to a meal, but only partly the response to histamine (J. Gray, 1937). *Histamine*, which is used as a test of achlorhydria, increases the flow, the acid and the inorganic constituents, but not the enzymes or mucus (Vineberg and Babkin, 1931). It stimulates only the parietal cells. The *Brunner glands of the duodenum*, which probably secrete chiefly mucin, are stimulated by acetylcholine, and by a hormone. *Mucus secretion of the colon and cecum* is stimulated by local irritation with mustard oil or acids, not by histamine, peptone or acetylcholine (Florey and Webb, 1931).

The **pancreatic juice** is controlled chiefly by secretin; but it is increased by pilocarpine and by vagus stimulation and is inhibited by sympathetic stimulation. The insulin output is probably regulated directly by the blood sugar level.

Prostatic secretion responds to drugs somewhat like sweat and submaxillary saliva. It is increased by pilocarpine, acetylcholine, epinephrine and nicotine. Histamine and yohimbine have no effect. Atropine and ergotamine antagonize pilocarpine (Farrell and Lyman, 1937).

Milk Secretion.—This is started and regulated by the sex hormones. Takahashi, 1927, reported that it is increased in goats by both pilocarpine and epinephrine, but the response is uncertain.

◆

ATROPINE

Atropine and other closely related alkaloids (hyoscyamine, scopolamine, etc.) produce a variety of peripheral and central effects: (1) complete paralysis of the peripheral distribution of the parasympathetic (craniosacral autonomic) nerves (oculomotor, secretory, bronchial musculature, cardiac and intestinal vagus, uterus, etc.); (2) consequently, antagonism to pilocarpine, choline and its esters, physostigmine, muscarine, etc.; (3) excitation and then paralysis of certain cerebral and medullary centers; (4) slight peripheral sensory paralysis, on local application; (5) slight stimulation and, in large doses, subsequent depression of smooth and cardiac muscle and other cells.

Mechanism of Parasympathetic Paralysis.—Atropine antagonizes acetylcholine, and since this stimulates after nerve degeneration, the action of atropine appears to be on the receptive mechanism. It does not prevent the formation of acetylcholine on nerve stimulation, but prevents it from acting on the cell. Atropine paralyzes also a few augmentory and inhibitory sympathetic nerves (uterus and sweat glands; Cushny, 1910).

The *dosage of atropine required to paralyze parasympathetic response* varies widely for different organs; for instance, V. E. Henderson, 1923, reports the following as necessary to block response to electric stimulation of the nerves (mg. per Kg.): salivary secretion (chorda), 0.025 to 0.15; cardiac vagus, 0.07 to 0.7; pyloric sphincter, small intestines, chorda dilator, to 5 mg.; urinary bladder, more than 20 mg. Very much smaller doses prevent stimulation by pilocarpine.

Occurrence.—Atropine occurs in a number of plants (*Belladonna, Stramonium, Hyoscyamus, Scopola, Mandragora, Duboisia,* etc.) belonging to the order Solanaceae (the potato family). These also contain other alkaloids (hyoscyamine, scopolamine, etc.) closely related to atropine in structure and in action. The alkaloids, as first isolated, were mixtures; consequently, their properties appeared to vary with the origin, and these mixtures were given specific names (daturine, duboisine, etc.). The pretended difference between scopolamine and "hyoscine" is a survival of this tradition.

Historical.—The first indubitable notice of *belladonna* occurs in 1504, but it then came quickly into use for poisoning and cosmetic purposes. The name Atropos, which Linné gave to the plant, is from the oldest of the Three Fates, who cuts the thread of life. Belladonna comes from the Italian "handsome woman," as it was used to give luster to the eyes. On account of the slow course and the obscure symptoms, belladonna was a favorite with professional poisoners in the Middle Ages, and this abuse in regard to several species of Datura (Stramonium) has existed in India since remote ages. The name itself is Sanskrit (Dhatoora). Belladonna seems to have been first introduced into practice as an anodyne about 1860. *Hyoscyamus* was mentioned by Dioscorides in the first century and has been used continuously in folk medicine. It was introduced into practice by Stoerck in the middle of the eighteenth century. He also introduced *Stramonium. Mandragora* (Mandrake) was the subject of interesting medieval myths. The "herbarium" of Apuleius (eleventh century) cites its use externally for headache and insomnia and internally for mania.

Chemical Structure and Relations.—These alkaloids are ester-like combinations of certain bases with organic acids of the aromatic series. *Atropine* is the tropeic acid ester of a base, tropine, and is isomeric with *hyoscyamine;* hyoscyamine is levorotatory, while atropine is racemic. The esters of tropine are called *tropeines. Homatropine* is the mandelic ester of tropine; and other tropeines occur naturally or may be prepared synthetically. Tropine itself is related to ecgonine, the basic constituent of cocaine. The *osceines* are analogous esters of the base oscine. The tropeic acid ester constitutes the important alkaloid scopolamine or hyoscine. This also occurs in isomeric forms: *atroscine* (racemic, corresponding to atropine), and *scopolamine* proper (levorotatory, corresponding to hyoscyamine). Atropine and atroscine are the more stable products: alkalis and many other agents convert hyoscyamine into atropine, scopolamine and atroscine.

Belladonnine and *atropamine* are isomeric alkaloids (belladonnic acid tropeines), differing from atropine by the absence of a molecule of H_2O. They are present in the plants in small amount, and it is possible that they are formed only during the extraction.

Constitution and Action.—The relation between these was investigated by Cushny, 1920, using as criterion the antagonism of the pilocarpine salivation. The atropine effect is absent from tropine itself, but is produced by many of its compounds, especially those with the benzene nucleus. The *asymmetric carbon* is very important. The l-hyoscyamine is forty times more active than the d-hyoscyamine, but even this is more active than the nearest homologues that do not contain asymmetric carbon. This is not indispensable, however, for some activity exists in tropines without asymmetric carbon and without hydroxyls. The parasympathetic paralyzing potency is greatly diminished by *hydrolysis* into tropine and tropeic acid (Exler and Van Nieker, 1929). Both are involved in the action. The sulfuric ester of atropine is nearly devoid of peripheral actions, while the central effects, especially the respiratory stimulation, are preserved. Scopolamine-sulfuric ester does not share this respiratory action (Trendelenburg, 1913).

Other esters of tropine have been investigated by Rav, 1934. *Other esters of tropic acid* are all more or less paralyzant to parasympathetic stimulation, and antagonize intestinal stimulation by barium. The levo isomers are considerably more potent than the dextro, as is the case with atropine (Fromherz). *Apo-atropine* is formed along with atropine when hyoscyamine is treated with alkali. It acts directly on smooth muscle. It is five times more potent than atropine on the intestines, but acts weakly on the pupils and on salivation. It has a central excitant action. It is twenty times more toxic to mice than is atropine or hyoscyamine (H. Kreitmair and Wolfer, 1938; Sasa, 1939).

Distribution of Alkaloids.—*Belladonna and Stramonium* contain mainly atropine and hyoscyamine; one or the other alkaloid may predominate. The hyoscyamine is the most widely distributed of these alkaloids and is especially abundant in young parts of the plants, whereas older parts contain more atropine. It appears that the hyoscyamine is the original alkaloid, and is partly transformed into atropine in the plant itself and also during extractions. Stoll found that fresh belladonna leaves contain only l-hyoscyamine. The dried plant also contains small traces of scopolamine and atroscine, but the latter alkaloids are relatively more abundant in *Hyoscyamus* and *Scopola*, taking the principal part in the actions of these plants. The distribution and variation of the aklaloids in individual plants, as studied by Sievers, 1913 to 1915, suggest improving the alkaloidal content by selective breeding. *Discrepancies between the chemical and biological assays* of belladonna and stramonium are discussed by Watson, Heard and James, 1941.

Actions on the Eye.—Atropine dilates the pupil (mydriasis) and renders it insensitive to light. It also paralyzes accommodation (cycloplegia), the lens being adjusted for far vision. These actions are peripheral and consist in paralysis of the oculomotor endings. The intra-ocular tension in glaucoma is increased, the cycloplegia relaxing the muscle fibers which ordinarily draw open the lymphatic drainage canals of the ciliary zone. The atropine mydriasis and cycloplegia are persistent; the mydriasis may last for several days. The ocular actions are produced in varying degree by all the atropinoid alkaloids. The atropine effects may be removed by drugs which stimulate the oculomotor reception (pilocarpine, physostigmine, choline esters, muscarine), and *vice versa.* The mydriatic effect of atropine is generally assisted by *reciprocal (central) stimulation of the sympathetic innervation,* so that the atropinized pupil contracts somewhat if the sympathetic innervation is severed. Atropine does not stimulate the sympathetic directly.

Localization of the Atropine Mydriasis.—Atropine dilates the pupil on local, as well as on systemic, application, The mydriasis remains confined to the eye, and even to that side of the eye to which it is applied. The dilatation is produced in the excised eye, and even in the isolated iris. The action must therefore be peripheral.

Direct Action on the Iris Muscle and Ciliary Ganglia.—The statement that the muscular fibers are not affected by atropine must be limited to moderate doses. High concentrations produce temporary miosis, attributed to direct stimulation of the muscle, followed by paralysis. Direct application of strong solutions to the ciliary ganglion also depresses this structure. The mydriatic effect on enucleated eyes of frogs is reported to be stronger for atropine sulfate than for the citrate or propionate (Régnier and Quevauviller, 1939). The *iris of birds* consists of striped muscle and is not dilated by atropine, but by curare.

Cycloplegia.—The ciliary muscles, situated at the junction of the choroid and the cornea, consist of radial and circular fibers, the former predominating. The contraction in both planes narrows the ring of attachment of the suspensory ligament of the lens, thereby relaxing the tension on this ligament, thus permitting the anterior surface of the lens to become more convex, *i. e.*, to accommodate for near vision. The ciliary muscles are innervated by the oculomotor, and are under more or less tone. Their paralysis by atropine fixes the lens for far vision; and their spasm by pilocarpine or physostigmine, for near vision. The derivatives of atropine are all cycloplegics. The sympathetic mydriatics, cocaine and some synthetic bases, epinephrine and ephedrine have little effect on accommodation. They may reduce its range, but do not change the static tonus of the ciliary muscle (Hartgraves and Kronfeld, 1931).

Changes in Intra-Ocular Tension.—All mydriatics tend to increase intra-ocular tension in glaucoma, although not in the same degree, Conversely, the tension is lowered by miotics. Neither has much effect on the normal intra-ocular tension (Luebs, 1913; Myashita, 1913).

Mechanism of the Change in Tension.—It is believed that the rise of pressure in mydriasis is produced mainly by lessened filtration of the aqueous humor into the venous sinuses of the channels of Fontana and canal of Schlemm. These lie in the angle of attachment of the iris and would be compressed by the relaxation of the ciliary muscle and by the crowding back of the iris. Miosis would have the opposite effect (especially in glaucoma; in the normal eye miotics lower the pressure very little). The intra-ocular tension is also influenced by the blood pressure in the vessels of the iris (Leber), and would be lowered whenever these are ischemic through fall of the general blood pressure (relatively little influence; Kochmann and Roemer, 1914), or through local vasoconstriction. The vasoconstricting cocaine, therefore, generally lowers intra-ocular tension, although it produces mydriasis; and it is claimed that atropine also tends to lower the pressure in the *normal* eye. Exceptionally, however, glaucoma attacks have been reported after cocaine, phenacaine, and even after epinephrine (Gifford, 1916).

Glaucoma.—The phenomena of this serious eye disease depend mainly upon excessive intra-ocular tension presumably due to blocked drainage (Schoenberg, 1913). It is therefore treated by miotics (see physostigmine), and contraindicates the employment of mydriatics. If their use is indispensable, cocaine and ephedrine should be chosen; and if cycloplegia is necessary, the briefly acting homatropine would be preferred to atropine.

Clinical Application of Atropine to the Eye.—Atropine is utilized mainly for paralyzing the ciliary muscle to facilitate ophthalmoscopic examination; and in the treatment of iritis. For *diagnostic work*, the persistent cycloplegia is often objectionable, but in other cases the enforced rest of the eye may be desirable. The less persistent homatropine may be substituted. This is less liable to provoke glaucoma, but in that disease it should also be used as dilute as possible (1 or 2 per cent), and followed by physostigmine, 0.2 per cent, a drop three times daily until the pupil and accommodation have returned to normal (Gifford, 1916). In *iritis*, atropine mydriasis is used to secure rest, to prevent adhesions of the iris to the lens, or break them if already formed, and to effect assumed favorable changes in the circulation of the iris. The more prolonged action of atropine causes it to be preferred for this purpose.

Administration to Eye.—The atropine is applied locally, by dropping an aqueous solution of the sulfate, or an oily solution of the free alkaloid, on the cornea; or by placing impregnated gelatin discs (*Lamellae Atropinae* B.P., $\frac{1}{5000}$ grain) in the conjunctival sac. Watery solutions tend to flow into the lacrimal duct, thereby lessening the local action, and tending to systemic poisoning. To avoid this, a single drop of 1 per cent solution should be applied at a time, and the lacrimal sac should be compressed with the finger. For continued use, in iritis, greater dilutions may be employed, down to $\frac{1}{10}$ per cent (even 1:100,000 is somewhat effective).

Duration of Action of Atropine.—With a single drop of 1 per cent atropine solution, the mydriasis reaches its maximum in about twenty-five minutes, the cycloplegia in about two hours. The cycloplegia disappears in two or three days (seven to nine days if the application has been continuous); the mydriasis endures even longer, ten to twelve days. The persistence of the action is due to the slow exchange of the intra-ocular fluids. The duration increases with the dosage, and on intravenous injection (Koppanyi and Lieberson, 1930).

Side Actions.—Besides the increase of tension, atropine causes photophobia (because of the irresponsive pupil), and micropia, from the loss of accommodation. In sensitive individuals, it produces some conjunctivitis, and rarely edema of the eyelids. If it is used carelessly, it may give rise to systemic poisoning, headache, dryness of the mouth, palpitation, etc. Chronic poisoning may occur in this way (Tyrrell, 1906). If atropine causes local irritation, scopolamine should be substituted, since this may be used in one-fifth the concentration.

Substitutes for atropine fall into two classes: (1) Those which produce mydriasis without cycloplegia (eucatropine or euphthalmine; ephedrine); and (2) those which produce both mydriasis and cycloplegia (atropine, hyoscyamine, scopolamine, eumydrine and homatropine—in the order of the persistence of the cycloplegia). Hyoscyamine is effective in about one-half the concentration, scopolamine in one-fifth the concentration, of atropine.

Quantitative measurements of the relative efficiency of mydriatics and miotics, alone and combined, are given by Joachimoglu, 1915.

The following table shows the strength of solutions

Drug	Percentage used	Mydriasis		Cycloplegia	
		Action complete, hours	Recovery complete, days	Paralysis complete, hours	Recovery complete, days
Atropine	1	$\frac{1}{2}$	5 to 7	2	3 to 4
Scopolamine	$\frac{1}{5}$	$\frac{1}{2}$	5	1	3
Eumydrine	1 to 5	$\frac{1}{2}$	2	1	2
Homatropine	2	$\frac{1}{2}$	1 to $\frac{1}{2}$	1	1
Eucatropine	5 to 10	1	1		

usually employed for ophthalmoscopic examinations, and the ordinary duration of their actions.

***Homatropine Hydrobromide,** U.S.P., the mandelic ester of tropine. Freely sol. in water (1:6), sol. in alc. (1:40). Instilled as 1 to 2 per cent solution. Dose, 0.5 to 1 mg., $\frac{1}{120}$ to $\frac{1}{60}$ grain. Its systemic actions are similar to those of atropine, probably somewhat less toxic. Coma with recovery occurred after the hypodermic injection of 40 mg. Homatropine affects the parasympathetic, for instance the vagus, much less than atropine; or rather, requires five to ten times as high a dosage to paralyze (Zulik, 1915). Homatropine also dilates the conjunctival vessels and on injection lowers blood pressure. Macht, 1922, attributed the actions of homatropine to the *mandelic acid* part of the ester, rather than to the tropine.

Eumydrine (Methylatropine Nitrate). Readily sol. in water. It agrees closely with atropine in systemic actions and may be substituted for it, in the same dosage; in eye, $\frac{1}{2}$ per cent. Its toxicity is about one-fiftieth and its mydriatic strength one-tenth that of atropine. Cushny, 1920, found it one and one-half times more active than atropine in the salivary pilocarpine antagonism. Continued use may lead to some tolerance.

Eucatropine Hydrochloride, U.S.P. (*Euphthalmine*), is a mandelic ester of a base similar to beta-eucaine. It is useful for ophthalmic examinations: Instillation of two or three drops of a 2 per cent solution produces wide dilatation of the pupil within half an hour. It does not produce anesthesia, irritation or cycloplegia. It does not raise intra-ocular pressure in normal individuals, but it may precipitate glaucoma attacks in patients disposed to these. The mydriasis disappears more rapidly than with homatropine. The systemic effects resemble those of atropine. It is readily soluble in water and may be used to 10 per cent.

Use as "Antispasmodic."—The atropine-containing drugs, belladonna, hyoscyamine and stramonium, have long been used against spasm of smooth muscle, ranging from asthma to the various "colics." They are highly successful in the few cases where the spasm is due to parasympathetic stimulation; their efficiency against other forms of stimulation is limited.

Several derivatives of atropine have been introduced as antispasmodics, with the claimed advantage of less side actions on other functions: *Novatropine* (*Novatrin*), N.N.R., the methylbromide of homatropine, is used especially against gastro-intestinal spasm and hyperchlohydria. It is less potent and less toxic than atropine. It is marketed in tablets of 2.5 mg. ($\frac{1}{24}$ grain). Dosage, one or two tablets three times daily before meals. *Syntropan,* N.N.R., the phosphate of the tropic acid ester of diethylaminodimethyl propanol, is used as antispasmodic, especially against intestinal colic and dysmenorrhea. Compared with atropine, it produces greater decrease of gastric and intestinal tonus and less dryness, mydriasis and tachycardia (B. B. Clark, Shires *et al.*, 1939). It is marketed in tablets of 50 mg. ($_{6}$ grain) and in 1 cc. ampuls of 10 mg. Dose, 50 mg. orally and 10 mg. hypodermically, three or four times per day.

The structural formulas and relations of synthetic "antispasmodic" chemicals are tabulated by R. R. Buetner, 1945.

Bronchial Muscles and Glands.—Atropine paralyzes the innervation of these structures, and thereby dilates and dries the bronchial tubes. The dilatation is obtained in excised rings of bronchial musculature (Trendelenburg, 1912), and is therefore peripheral. It is effective not only against parasympathetic stimulation (mecholyl, etc.) but also against muscular stimulants (histamine, barium) and anaphylactic spasm (Barlow and Beams, 1932; Sollmann and Gilbert, 1937).

Therapeutic Use against Asthma.—Bronchial asthma involves bronchial spasm, against which atropine should be useful; but it generally also involves acute edema of the mucosa and chronic catarrhal infiltration. The efficiency of atropine is therefore much more limited than in experimental spasms, although it sometimes gives striking relief. Atropine has been largely displaced by the generally more effective epinephrine, but it may be employed as adjuvant. Atropine ($\frac{1}{2}$ to 1 mg., $\frac{1}{120}$ to $\frac{1}{60}$ grain) or the drugs containing it may be administered by any channel.

Inhalation is most effective since it brings the drug directly to the site of its action. *Asthma powders* consist of atropine-containing drugs, mixed with sufficient saltpeter to insure their combustion; *e. g.*, Powdered Stramonium, 3 Gm.; Lobelia, 1; Anise, 2; Potas. Nitrate, 2. This dose is burned on a plate and the smoke inhaled. Stramonium cigarettes are also used; the smoke of 1 to 1.25 Gm. of stramonium contains 0.3 to 0.5 mg. of atropine (Guenther, 1911).

Biliary and Renal Colic.—Atropine paralyzes the innervation of the smooth muscle of the bile ducts and ureters, and therefore relaxes the painful and obstructive spasm which results from the passage of calculi through these tubes. The vagus paralysis is useful by preventing the dangerous cardiac reflex which sometimes occurs. The atropine, 1 mg., $\frac{1}{60}$ grain, is given hypodermically, usually combined with morphine, 15 mg., $\frac{1}{4}$ grain.

Gallbladder.—This may be relaxed (Lieb and McWhorter, 1915); but not by ordinary therapeutic doses (Macht, 1917).

Excised Ureter.—Small doses of atropine may stimulate the tone and peristaltic movements. Stronger solutions (1:10,000) inhibit them, as also the stimulant effects of pilocarpine, physostigmine and choline (Macht, 1916). G. B. Roth, 1917, however, found nicotine, pilocarpine and atropine practically ineffective. Levo hyoscyamine stimulates the contractions and slightly raises the tonus; large doses depress. The dextro inhibits from the start, without stimulation (Macht, 1918).

Urinary Bladder and Incontinence of Urine.—Atropine is employed to relieve incontinence of the urine, due to overaction of the bladder muscle; and retention of urine from overactivity of the vesical sphincter. A. Jacobi advises for children $\frac{1}{2}$ grain of Belladonna Extract at night, increasing if necessary, to flush the cheeks. The actions of atropine on the bladder were investigated by Edmunds and Roth, 1920. It produces primary contraction, then relaxation. It antidotes pilocarpine and physostigmine, but not electric stimulation of the erigentes (confirmed by Henderson, 1922).

Urine Flow.—Cow, 1912 and 1913, finds that atropine has no effect if the urine is collected directly from the pelvis of the kidney, but that it merely modifies the flow through the ureter by lessening its tonus. The suppression of sweat and other secretions might temporarily increase the output of urine.

Uterus.—Clinical doses of scopolamine have little if any effect on the parturient uterus (Dodek, 1932). Larger experimental doses of atropine relax and arrest its nongravid peristaltic movements (Ludwig and Lenz, 1923). It antagonizes pilocarpine, physostigmine and also anaphylactic stimulation, but is not as effective against pituitary extract (Stoland and Sherwood, 1923). *Atropine in dysmenorrhea* was advocated by Novak, 1915, especially in the spasmodic, colic type. The side actions interfere with its use (Litzenberg, 1919). G. Lehmann, 1943, obtained no effect from syntropan and other tropic acid derivatives on excised human uterine muscle, and concludes that any relief of dysmenorrheic pain is probably not due to uterine relaxation.

Intestines.—Atropine relaxes intestinal spasm due to parasympathetic stimulation, but is not very potent against other intestinal stimulation. It has little effect on normal peristalsis, but tends to lower the tonus and slow the propulsion of the intestinal contents. Atropine, 1 mg. ($\frac{1}{60}$ grain), or belladonna extract (15 mg., $\frac{1}{4}$ grain) or tincture (0.5 cc., 8 minims) is sometimes administered in lead and other intestinal *colics*, but they are generally ineffective, as these do not often involve parasympathetic stimulation. They have also been added to *irritant cathartics*, especially aloin, to diminish "griping," but well controlled clinical comparisons indicate that they are inefficient for this purpose.

In unanesthetized dogs with permanent intestinal fistulas of the *small intestines*, moderate doses of atropine caused pronounced and prolonged delay in the propulsion of a soft bolus (Quigley, Highstone and Ivy, 1934). Pressure records show decrease of tonus, without decrease of the amplitude of the rhythmic contractions with moderate doses; but large doses also decreased these. There is mutual antagonism with morphine (C. M. Gruber *et al.*, 1930). The atropine inhibition occurs also after division of the extrinsic intestinal nerves; it may be presumed that it renders the intestinal muscle unresponsive to acetylcholine produced in the muscle independently of extrinsic innervation (Youmans *et al.*, 1943). *Excised intestine of rabbits* is relaxed by atropine. Pilocarpine and other parasympathetic stimulants are antagonized by doses that have no effect on normal intestines (Magnus). If the segment has been extensively soaked in saline solution atropine may produce stimulation instead of depression. This is attributed to loss of parasympathetic tone by the removal of the choline present in the walls of fresh intestine (LeHeux, 1920). *Extreme doses of atropine* (so large that they cannot be brought into action by systemic application, but only locally and in the excised intestine) paralyze successively the ganglion cells, the endings and the muscle, destroying the response to the muscular poisons such as barium. The *optical isomers* of atropine act quantitatively alike on excised intestine (Liljestrand, 1919). The quantitative relation between atropine and pilocarpine has been investigated by van Lidth de Jeude, 1918. *Syntropan* requires fifty times the concentration of atropine to antagonize acetylcholine in excised intestines of dogs. It also antagonizes barium and histamine in a more favorable ratio (B. B. Clark and Shires, 1938).

The natural *colon motility* of dogs is inhibited by atropine (0.03 to 0.05 mg. per Kg.). It prevents the morphine increase of propulsive motility, but not the increase of tonus and nonpropulsive motility (Adler and Ivy, 1940).

Frog's intestine is relaxed by atropine, 1:10,000, especially if the tonus was high. Atropine is somewhat effective against contraction by barium, 1:40,000, and additive to the relaxing effect which pilocarpine has on frog's intestine (G. B. Roth).

Gastric Functions.—Ordinary oral clinical doses of atropine or belladonna have practically no effect on the secretory or motor functions of the stomach. Large doses, especially hypodermic, tend to reduce the volume of gastric secretion, and probably the mucus, but the concentration of the acid may be increased. Pylorospasm and cardiospasm are sometimes relieved if due to vagus stimulation, but not if they are of sympathetic, emotional or ulcerative origin. The minimal effective dose (1 mg., $\frac{1}{60}$ grain, before meals) produces decided side effects, dryness and mydriasis (review, Bastedo, 1936).

Motility of Normal Human Stomach.—Tetelbaum, 1928, reported that pyloric peristalsis is arrested by 0.3 to 0.5 mg. of atropine in the empty stomach, and by 1 mg. after food; Kellermann, 1929, found the emptying time prolonged; but Keefer and Bloomfield, 1926, observed no definite effects on gastric motility after 2 mg. of atropine (with oral administration of 50 cc. of 7 per cent alcohol). Veach, 1937, reports inhibition of gastric motility by intravenous injection of therapeutic doses of atropine and mutual antagonism with the spastic action of morphine. In *cardiospasm* atropine may cause sudden relaxation or it may be ineffective (Barclay, 1915; fluoroscope). It is often used in hyperchlorhydria, especially in acute conditions with severe pain and vomiting (A. Schmidt, 1914). Large doses are employed against *infantile pylorospasm*, 0.05 to 0.15 mg. three to four times a day (Stolte). This produces flushing, but no dangerous effects; it has been given daily to six-week-old infants, for weeks (Ochsenius, 1916). Atropine also inhibits the gastric hypertonicity induced by *insulin hypoglycemia* (Wilder and Schlutz, 1931; dogs) but has little effect on the cardiospasm of vagotomized dogs (G. Lehmann and Knoefel, 1942). *Excised stomach* is relaxed by atropine, and pilocarpine is antagonized (M. Smith, 1918).

Gastric secretion is decreased by moderate therapeutic doses of atropine (Chiari, 1915; Crohn, 1918). Clinically, the decrease involves chiefly the volume, then the acid, and with larger doses also the enzymes (Kellermann, 1929).

With the *histamine test*, atropine decreases markedly the volume of the secretion and the concentration and total output of pepsin, with comparatively slight inhibition of the secretion of acid, so that the concentration of acid rises (Polland, 1930). *With the alcohol test* (50 cc. of 7 per cent alcohol by mouth), atropine (2 mg.) also diminishes the acid secretion less than the volume (Keefer and Bloomfield, 1926). *In dogs*, intramuscular injection of atropine (0.0125 mg. per Kg.) completely inhibits secretion in response to food. Smaller dosage, 0.003 mg. per Kg., diminishes the volume and the peptic activity. The acid concentration is not affected until a dosage is reached that diminishes the volume by 50 to 80 per cent. There is a mutual antagonism toward histamine and gastrin, extending to nearly fatal doses of atropine. With large doses, the atropine and gastrin appear to act directly on the gland cells; smaller doses probably act on some other site (Keeton *et al.*, 1920). *Homatropine* has about a tenth the potency of atropine on gastric secretion (Tennenbaum, 1930).

Antiemetic Action.—Atropine sulfate (1 mg.) or scopolamine hydrobromide (0.5 mg.) (see Index) are probably the most effective agents in *preventing seasickness*, in perhaps half of those who would otherwise succumb. The dosage may be repeated in eight hours.

Eggleston, 1916, found that small doses of atropine (0.01 mg. per Kg.) prevent the emetic action of pilocarpine and nicotine, but not of apomorphine, morphine, ouabain or emetine. It also abolishes the emetic action of magnesium sulfate and diminishes that of intravenous potassium arsenite (Hatcher and French, 1932). The fact that the antiemetic dose is smaller than is required against the peripheral actions of pilocarpine suggests that atropine depresses an emetic center. Hatcher and Weiss, 1923, attribute the antiemetic action to paralysis or blocking of certain afferent paths to the emetic centers, while other paths remain open. S. Wolf, 1943, claims that addition of physostigmine increases the effectiveness of atropine against seasickness, by maintaining the normal gastric tonus and motility which are inhibited in nausea. Others failed to confirm the additional benefit of physostigmine.

Pancreatic Juice.—Atropine suppresses the increase of pancreatic secretion which ordinarily follows stimulation of the vagus or the administration of pilocarpine or choline. Large doses provoke a pancreatic flow in the dog (Modrakowski, 1906); the mechanism of this peculiar action is not understood. Atropine has no direct effect on the flow provoked by secretin (Chiari, 1915), but since it diminishes the secretion of acid in the stomach, it probably lessens the production of secretin indirectly and hence interferes with the physiologic pancreatic secretion. The pancreatic stimulants which are antagonized by atropine yield active juice, whereas those not affected by atropine require the addition of erepsin (Camus and Gley, 1905). Atropine prevents the pancreatic secretory response to vagus stimulation and to fats in acute experiments; but in permanent fistula experiments Savich, 1919, found it ineffective.

Saliva.—The secretion of saliva is suppressed by atropine. This is an unpleasant side effect in the therapeutic use of the drug, but small doses (0.5 mg.) may be employed to allay excessive ptyalism.

The submaxillary gland furnishes a classical object for *localizing the action of atropine*. This suppresses the secretory response to chorda-tympanic stimulation, even when this is applied at the hilus of the gland, *i. e.*, to the postganglionic fibers. The paralysis must therefore be peripheral to these. The cells still respond to sympathetic stimulation, so that the paralysis must be in an intermediary receptive mechanism. This argument, however, involves the assumption that the chorda tympani and the sympathetic act upon the same cells in the salivary gland, which is doubtful (Gaskell, 1916). Large doses of atropine inhibit the response to sympathetic stimulation (Cannon and Cattell, 1916).

In man, Ewing, 1911, found that 0.5 to 1 mg., by mouth, caused marked decrease in the volume of saliva secreted. The percentage of ptyalin fell markedly, but recovered long before the volume or solids had returned to normal.

Vasodilator fibers of the chorda tympani nerve are not affected, so that stimulation of the atropinized nerve still dilates the vessels and produces an increased venous outflow from the gland. (The effects of atropine and pilocarpine on the submaxillary circulation are discussed by Henderson and Loewi, 1905.)

Antagonism.—Atropine completely suppresses nicotine salivation (since this stimulates the ganglion cells); it is mutually antagonistic with pilocarpine, etc., but the atropine action, as usual, tends to be the stronger. The quantitative relations were studied by Cushny, 1915. Atropine is said to suppress *mercurial salivation*, but not the "paralytic secretion" which sets in when the divided nerve degenerates.

Paradoxic Reflex Secretion in Chronic Poisoning.—Abundant reflex secretion of saliva occurs in cats and dogs after repeated injections of atropine and continues for months if the injections are continued. The chorda nerve may or may not be excitable. The sympathetic is excitable (Arima, 1918).

Suppression of mucous secretion may be employed in the hypersecretion of coryza, bronchorrhea, or ether anesthesia. Minimal doses of atropine are used to "abort" incipient colds (0.5 mg., $\frac{1}{120}$ grain or less, in a glass of water, sipped slowly in the course of an hour; Kohnstamm, 1906). The cutaneous vasodilatation may play a part in this abortive action.

Suppression of sweat (anhidrotic action) is one of the earliest actions, and can be secured with small doses (0.3 to 1 mg., $\frac{1}{200}$ to $\frac{1}{60}$ grain, of atropine hypodermically). It is the most effective means of suppressing the nightsweats of phthisis, but the relief is only symptomatic, and scarcely justifies the inconveniences. Atropine decreases the *insensible perspiration* in infants. The decrease averages nearly a fourth, and may be a factor in atropine fever (I. Howe, 1934).

Other Anhidrotics.—Nightsweats may also be suppressed by *scopolamine* or eumydrine. *Agaric acid* arrests sweating by a peripheral action of the sweat glands, but is uncertain. *Camphoric acid* has been employed, but it does not act upon the sweat glands. If it has any effect (which is doubtful) it must be indirect, through improvement of the respiration. *Local measures* are often preferred, especially for local hyperhydrosis: sponging with cold lotions containing alcohol, dilute acids, tannin, salicylic acid, formaldehyde, etc. *Dusting powders* are likewise useful (talcum with 5 per cent of salicylic acid or 10 per cent of boric acid).

Glands that do not have a parasympathetic secretory innervation are not affected directly by atropine. This includes the *kidney*, the *liver* and *all endocrine glands.*

Lacteal Secretion.—Ott and Scott, 1912, confirm Roehrig that this is somewhat diminished by atropine.

Oviduct Secretion of Birds.—Atropine has practically no effect on the secretion of albumen or of shell material (Riddle and Ring, 1921).

The **epinephrine output** is not materially influenced, in cats, by atropine or pilocarpine (G. N. Stewart and Rogoff, 1920).

The **blood sugar level** is somewhat lowered by atropine in normally fed or fasting rabbits and raised by pilocarpine and physostigmine (S. Lang, 1931; Hrubetz, 1936); doses of atropine which produce excitement may thereby raise the blood sugar level (Pitini, 1908; McGuigan, 1916; Lang, 1931). *The mechanism of the hypoglycemic action* of atropine is not clear. It is not due to paralysis of hepatic glycosecretory nerves, for atropine does not diminish the glycemic response to the splanchnic stimulation (Macleod, 1906). It does suppress epinephrine hyperglycemia in decerebrate rabbits (Forster and Chalmers, 1933), and piqûre hyperglycemia in fasting rabbits, but not if the liver is rich in glycogen (Macleod, 1934). It diminishes other glycosurias materially, but not chloroform glycemia, which is probably asphyxial (E. L. Ross, 1919, 1920). It has been asserted that atropine increases the tolerance for carbohydrates in diabetes, but this needs confirmation (Mosenthal, 1912). It has no effect on insulin hypoglycemia in depancreatized dogs (S. Lang, 1933).

Temperature.—Atropine suppresses perspiration, and thus causes a rise of *temperature* with *moderate doses*, notwithstanding the cutaneous vasodilatation. Animals that do not have sweat glands (dog) do not show this rise. *Larger doses* produce a fall of temperature from lessened heat production, the result of the general depression. The final convulsions may again cause a rise.

Gaseous metabolism is increased by therapeutic doses (1 mg.) in man (Higgins and Means, 1915). In dogs, the intravenous administration of atropine diminished the respiratory metabolism and the CO_2 of the blood. This effect is mutually antagonized by pilocarpine (Klemen, 1918).

Uric Acid.—Atropine prevents the increase of uric acid that normally follows the ingestion of food; presumably by preventing the secretion of the digestive juices (Mendel and Stehle, 1914). It also prevents the cinchophen increase (Abl, 1913).

Hepatic Actions and Coagulability of Blood.—The *secretion of bile* is sometimes slightly diminished by atropine. The lymph flow may be either increased or unchanged (Yanagawa, 1916). The injection of large doses of atropine into the portal vein lowers the *coagulability of blood*, first that of the hepatic vein. This effect is not produced by injection into the jugular vein, or by addition of atropine to shed blood, but is due to an action on the liver. The anticoagulant substance is also produced by the perfusion of atropinized blood through an excised liver (Doyon, 1910).

The **leukocytes** are not changed by ordinary doses. Toxic doses, especially when often repeated, diminish the eosinophils. The action is probably indirect (Herrick, 1914). The emigration of leukocytes in exposed mesentery is not inhibited by atropine or scopolamine (Ikeda, 1916).

Yeast fermentation is stimulated by small quantities, inhibited by large doses (Somoggi, 1916).

Circulation.—*Single therapeutic doses* of atropine do not usually affect the pulse rate materially, but *ordinary experimental doses* greatly increase the heart rate by paralyzing the vagus endings. Atropine *abolishes cardiac inhibition by all drugs* which act through the vagus mechanism, whether they stimulate this reflexly (ammonia or chloroform inhalation); centrally (picrotoxin or veratrum), or peripherally in the ganglia (nicotine), or in the endings (pilocarpine, cholines, muscarine). The blood pressure rises moderately, mainly through the quickened rate, but partly through central vasomotor stimulation. If the blood pressure has been abnormally lowered by excessive vagus stimulation, the atropine rise appears correspondingly greater. The cutaneous vessels are actively dilated. *Toxic doses* paralyze the vasomotor center and eventually also the arterial and cardiac muscle, so that the blood pressure falls profoundly.

Changes of Heart Rate.—Atropine stimulates the vagus center in common with the other medullary centers. It may therefore cause a slight *primary slowing*, which is soon overcome by the peripheral paralysis. This vagus paralysis results in *quickened heart rate* in all animals in which the vagus is tonically active (in man, the cat, dog, etc.). In completely atropinized dogs and cats the rate is about 140 to 240 per minute. The vagus tone being small in rabbits and frogs, these animals show little or no quickening; but in them the vagus is also paralyzed, for its stimulation does not slow the heart.

Electrocardiogram.—In dogs, small doses of atropine usually produce auriculo-ventricular block. With larger doses this is followed by increased sinus rate. At the same time it abolishes any existing blocks, sinus arrhythmias or ectopic beats (as with digitalis). In this last respect, atropine is more efficient than nitrite. The A-V conduction is usually slowed by small and quickened by large doses. The P wave at first tends to negative, then to more positive (Halsey, 1917). In *intact animals*, atropine increases the auricular, but decreases the ventricular, efficiency (Wiggers, 1916).

Therapeutic Use of Vagus Action.—The paralysis of the vagus endings indicates atropine (1 to 2 mg., $\frac{1}{60}$ to $\frac{1}{30}$ grain, hypodermically, repeated as needed) in conditions of excessive vagus stimulation, such as cerebral pressure; the reflex vagus inhibition of colic, of angina, of chloroform anesthesia; operations about the vagus trunks, etc. Atropine also abolishes such cardiac irregularities as are due to heightened vagus excitability (pulsus respiratorius), and it may be used to diagnose whether a cardiac slowing is due to vagus stimulation. In fact, however, response to atropine (or amyl nitrite) merely shows that the heart is still under vagus tone—not that the bradycardia was of vagus origin (Fredericq, 1916). It has been found clinically effective in sino-atrial block (N. W. Brown, 1919; 0.5 to 1 mg.). It has no effect in complete heart block (van Egmond, 1913).

Atropine on Normal Human Heart Rate.—The hypodermic dose of 0.5 mg. produces either no effect or slowing, to about 69, attributable to central vagus stimulation. With 1 mg., this slowing is complicated by a tendency to irregularity. With 2 mg., the slowing is transient, and is followed by quickening. This dosage is the minimum that can be relied upon to depress the vagus (Platz, 1923). The vagus tone is greatest in middle life, between twenty and thirty years, less in old age (after fifty years), and least in infancy; the response of the heart rate to atropine varies accordingly.

Both *sexes* react practically alike, but there are considerable individual variations. These have no constant relation to the rate before the injection (J. H. Crawford, 1923). Paskind, 1921, reports that the slowing by small doses is practically absent in the *Negro race* (twenty cases); but their normal rate averages about ten beats lower than in the white race, so that the vagus center is probably already in a somewhat higher tone and therefore less susceptible to further increase. The later accelerator effects are the same in both races.

Atrio-ventricular rhythm may occur in man from doses of 1 mg. It sets in within eight to ten minutes, soon reaches a maximum, and then disappears. Wilson, 1915, assumes that atropine releases the A-V tissue from vagus control somewhat before it releases the sinus.

Atropine Test for Typhoid Fever; "Vagotonia" and "Sympathicotonia."—In fever, when the vagus control is weak, atropine (2 mg.) does not produce much further quickening. This was suggested as a test for typhoid fever (F. A. Marris, 1916), but it may be absent in this disease and is often present in other fevers, exophthalmic goiter, etc. (J. H. Crawford, 1923). The sensitiveness to pilocarpine and especially to epinephrine is also often altered in typhoid fever (Matsua and Murakami, 1918), but again is not characteristic. Eppinger and Hess, 1909, suggested that the response to these drugs would reveal disturbances in the equilibrium of the sympathetic and parasympathetic innervation; but when disturbances exist, they often involve both systems.

Response in Cardiac Diseases.—In chronic heart disease, in which the sino-auricular node is in control, the response to atropine is diminished; auricular fibrillation shows increased response (J. H. Crawford, 1923). Removal of nodal rhythm by atropine (milligram doses) has been reported (L. F. Bishop, 1921).

Atropine on Voluntary Tachycardia.—N. B. Taylor, 1922, reports a student who could voluntarily increase his heart rate from 70 to 125 along with other manifestations of sympathetic stimulation (glycosuria, vasoconstriction, mydriasis). After 2 mg. of atropine, which raised the heart rate to 90, the rise by volition was only to 115.

Atropine Response in "Effort Syndrome" with Irritable Heart.—The pulse rate responds with the normal incipient slowing, followed by an increase which is generally greater than normal, *i. e.*, six to thirty per minute. The respiratory quotient is slightly lowered. The basal metabolism remains unaffected (Sturgis *et al.*, 1919).

Influence of Heart Rate on the Output of the Heart.—Atropine, 1 mg., hypodermically in man, increases the minute output of the heart in about three-fourths of the subjects, but not as much as the rate (Suarez *et al.*, 1943). When the rate exceeds 80 per minute, it tends to lessen the amplitude of the excursions, for a faster rate does not permit time for the complete diastolic filling of the heart.

Results of Vagus Stimulation after Atropine.—In dogs, when the atropine action has gone just so far that *stimulation* of the *divided vagus trunk* causes no perceptible slowing, this still produces a slight fall of blood pressure; larger doses abolish this response also, so that the inotropic properties of the vagus terminations seem to be somewhat more resistant than the chronotropic. When the *intact vagus* is stimulated in atropinized mammals, the blood pressure may fall or rise by stimulation of the afferent vasodilator or constrictor fibers which run in the vagus. In atropinized *frogs*, the inotropic as well as the chronotropic functions of the vagus are paralyzed (Ransom, 1917). The refractory phase is lengthened (Junkmann, 1925). Stimulation of the vagus trunk quickens the heart, since this carries the accelerator fibers, which are not affected by atropine.

The *dosage* required to paralyze the vagus was studied by Pilcher and Sollmann, 1914. It varies somewhat in different animals, even of the same species, and even for the two vagi of the same animals; the left vagus is more susceptible. Low blood pressure increases the susceptibility. In every respect, the susceptibility to atropine is inverse to the natural excitability of the vagi. In the dog, about 0.01 mg. per kilogram lessens the response to vagus stimulation perceptibly; and about two or four times this dose abolishes the response completely. When the paralysis is incomplete, a slight further slowing may be secured by strengthening the stimulus; but with the larger dosage even the strongest stimulus remains ineffective. *The duration of the paralysis* varies with the dose and with the species. It lasts only a few minutes in rabbits (Rossbach, 1879), longer in goiterous rabbits (Fleischmann, 1911). In dogs and cats, a partial effect persists for hours (Pilcher and Sollmann).

Atropine after Double Vagotomy.—If both vagi of an animal be divided, there is usually no regeneration apparent, even after long periods; nevertheless, the fast rate gradually returns to normal, but atropine at this stage causes marked quickening (F. T. Rogers, 1920).

Perfusion of Turtle's Medulla.—Atropine, 0.02 per cent, has practically no effect on the heart rate or rhythm (Bush, 1919).

Action on Cardiac Muscle.—Atropine has slight direct effects on the *cardiac muscle*, but these are insignificant in the systemic administration. They may be observed in the isolated heart and on the nerve-free heart of the embryonal chick. Small doses stimulate the muscle, causing an increased tonus, greater excursions and some slowing. Turtle heart perfused with 1:25,000 shows only some depression of conductivity (Wedd and Blair, 1945). In the auricles of *terrapin*, atropine is said to increase the tonus, without affecting the periodic tonus waves (Gruber and Markel, 1918). An exhausted frog's heart may be made to beat again. Large doses diminish the tonus and may slow or quicken the rate.

In the *excised mammalian heart* (Langendorff method) atropine provokes rhythmic contractions of the apex after the base is clamped. This requires larger doses than are needed for paralyzing the vagus. These large doses may also restore the beat when it has been arrested by muscular poisons (Luchsinger, 1881).

In the isolated heart of snails, atropine produces slowing with increased amplitude (Boyer and Hazard, 1927).

Cutaneous Circulation and Skin Eruptions.—Atropine produces intense *scarlet or crimson flushing of the skin*, particularly of the face and chest, occurring as extensive erythematous spots, or as a continuous *erythema* which has sometimes been mistaken for scarlatina. This effect is much greater in some patients than in others; it may occur with therapeutic doses. It is due to active dilatation of the cutaneous vessels (vasodilator stimulation), with increased general blood pressure. The hyperemia may be so intense as to lead to desquamation.

The **vasomotor center** is moderately stimulated, but not sufficiently to raise the blood pressure when ordinary doses are injected after dividing the vagi (Sollmann and Pilcher, 1910).

Peripheral Action on Blood Vessels.—Large doses of atropine prevent the dilator effect of cholines (Hunt, 1918). They also antagonize the constrictor action of epinephrine, but not of pituitary (Regniers, 1926).

The coronary arteries are constricted by atropine in dogs (Katz and Lindner, 1939). Atropine has no effect on the normal *pulmonary vessels*, but removes the constriction of pilocarpine or histamine (Berezin, 1914). *Cerebral vessels* are dilated (Berezin, 1916).

Respiration.—Therapeutic doses (1 mg. hypodermically in man) stimulate respiration, increasing somewhat the rate and minute volume, and sometimes the depth of the respiration. The excitability of the respiratory center is not increased directly, for the alveolar CO_2 tension is unchanged. The stimulation is therefore indirect, due partly to increased CO_2 production (increased gaseous metabolism), partly to increased "dead space" in the lungs by bronchial dilation (Higgins and Means, 1915). Toxic doses produce late depression of the center (Binz, 1896), which is the usual cause of death in atropine poisoning.

Therapeutic Uses of Respiratory Stimulation.—The mechanism of this respiratory action in man would render its usefulness doubtful. On the basis of the animal experiments (which, however, involve larger doses) it has been used against poisoning by morphine, and as a preliminary to anesthesia, or even as a restorative in anesthetic fatalities (Webster, 1908). It is also often used in whooping cough, but is of doubtful efficiency (child of one year, 5 mg., $\frac{1}{12}$ grain, of Extr. Belladonna, or 8 to 10 drops of Tr. Bellad. three times daily, doubling the dose in a week if tolerance is acquired; A. Jacobi, 1907).

Respiration in Animal Experiments.—The results have been contradictory. Heinz, 1890, found no appreciable change in the respiratory volume of rabbits; Wood and Cerna, 1892, increased rate and minute volume in dogs. According to most observers atropine *counteracts respiratory depression* from chloral (Husemann, 1877) or morphine (Voegtlin and Wiggers, 1918); but others found that it augments the morphine depression (Orlowski, 1897). Atropine was ineffective against depression of the respiration by cerebral compression (Loevenhart *et al.*, 1918). Hanzlik, 1923, found that 1 mg. (hypodermically) per Kg. of rabbit (without anesthesia) depressed the respiration. With morphinized rabbits, Meissner, 1923, recorded increase of depth without change of rate, from the intravenous injection of 1 to 10 mg. of atropine. With *larger doses*, the psychic excitement and muscular activity increase the respiration indirectly. *Toxic doses* depress respiration, producing slowing, Cheyne-Stokes type, and finally cessation. Artificial respiration may enable an animal to survive six times the fatal dose.

Effects on Psychic Functions.—Therapeutic doses of atropine have no perceptible effects on psychic functions. Overdoses produce symptoms superficially resembling those of alcoholic inebriation. Exaltation and stimulation are more prominent, passing from mere restlessness to hallucinations and delirium, and even mania; and the effects are much more lasting. Similar symptoms can be seen in animals. With toxic doses the stimulation passes into coma, convulsions and asphyxia.

Atropine Alkaloids on the Cerebral Functions of Rats.—Judging by behavior in the circular maze, atropine, scopolamine, homatropine and their derivatives alike produce stimulation in small doses and depression with large doses, but differ materially in the absolute dosage. The action is associated with the tropine and oscine (scopoline) nucleus, and appears to be potentiated by the tropic acid, which is itself inactive. The levo-compounds are more active than the racemic (Macht, 1923). The *convulsions* are not entirely asphyxial, for they are not abolished by artificial respiration. The *vision* is disturbed more than can be explained by loss of accommodation. The *motor areas* in dogs are stated by some observers to be more excitable, but others deny this. *Homatropine* was reported by Issekutz, 1927, as having a fiftieth of the potency of atropine, for central effects. In *frogs*, atropine first increases the reflexes; this is followed by general paralysis and this again by late tetanus.

Atropine and Novatropine in Insulin Hypoglycemia.—J. P. Quigley, 1937, reported that moderate doses of atropine (0.6 to 1.8 mg.) or novatropine (2.5 to 3.5 mg.) counteract promptly the acute symptoms of moderate hypoglycemia induced in normal man by 12 to 20 units of insulin, but about half an hour later many of the subjects developed pronounced mental disturbances, chiefly amnesia, confusion, automatism and speech disturbance, different from the normal effects of either atropine or insulin. They disappeared on administration of carbohydrate.

Atropine against Postencephalitic Parkinson's Syndrome.—Atropine and scopolamine are used against muscle rigidities, especially those following encephalitis (Roemer), often with considerable relief of the muscular stiffness, disturbances of speech and writing, the tics and salivation, improvement of the restlessness and depression, but with little improvement of the psychoses and tremor.

Large doses are usually necessary, beginning with 0.75 mg. and increasing gradually to 15 or even 20 mg. of atropine per day. Scopolamine is more effective against the tremor and rigidity. *Amphetamine* controls the rigidity but not the tremor. *Epinephrine* increases both tremor and rigidity. *All the actions are central,* scopolamine probably depressing the cortex, amphetamine stimulating the basal ganglia (Loman, Myerson and Myerson, 1942). The response to atropine and scopolamine is only symptomatic and the administration must therefore be continued. The side actions are not sufficiently serious to preclude this use and mostly disappear with continued employment. Anorexia, diarrhea and emaciation may persist. Caution should be used in cardiovascular diseases (Marinesco and Facon, 1936). The action is probably on the proprioceptive reflex. Other reflexes are normal in atropinized decerebrate cats (L. Davis and Pollack, 1930).

The "*Bulgarian treatment*" with a white wine extract of Bulgarian belladonna root, introduced by Ivan Raeff, 1926, was claimed to give better results with a smaller equivalent of alkaloids (Fabing and Zeligs, 1941; Price and Merrit, 1941). Similar claims were made for artificial mixtures of hyoscyamine, atropine and scopolamine (Vollmer, 1940). It may be doubted whether this superiority is critically established.

Striped Muscle.—Large doses (greater than could be used in living mammals) block the response to nerve stimulation, similar to curare (Haffner, 1918). Smaller doses (but greater than suffice to paralyze parasympathetic responses) antagonize physostigmine twitchings (E. Frank and Nothmann, 1921), acetylcholine contracture (Riesser and Neuschloss, 1921), nicotine, veratrine, Tiegel and potassium tonus, but not chloroform, caffeine or thiocyanate contracture.

Anodyne Action.—Belladonna liniment or plaster is applied topically for the relief of pain, especially neuralgic and rheumatic. Belladonna suppositories (extract, 0.1 Gm., 1½ grains) are also used in painful hemorrhoids. The rationale is not clear, as atropine is not a local anesthetic.

Dosimetric Tabulation.—The following (adapted from Schmiedeberg) shows the usual progressive effects of therapeutic and toxic doses: 0.5 mg., slowing of pulse and slight dryness of throat; 0.5 to 1 mg., dryness in mouth, often with thirst; 2 mg., pupil dilated, not quite immobile, and increase of pulse rate; 3 to 5 mg., headache, dysphagia, alteration of voice, muscular weakness, restlessness; 7 mg., considerable dilatation of pupils, disturbance of vision; 8 mg., excitement and muscular incoordination more marked; 10 mg., apathy, hallucinations or delirium, unconsciousness.

Atropine Poisoning.—Atropine is readily absorbed, somewhat even from the intact skin, so that toxic symptoms have been observed after the use of belladonna plasters (Doland, 1906). They occur rather commonly in ophthalmic use, through the lacrimal ducts. Where the plants grow wild, the seeds of stramonium ("Jimson weed") and the berries of belladonna are often eaten by children.

Course.—The symptoms set in promptly, but usually run a long course, lasting five to fifteen hours, or even several days in fatal cases. The first to be noticed are those arising from *dryness of the mouth and throat:* difficulty of deglutition and articulation, great thirst, a sense of burning and constriction in the throat. On the eyes, the dilatation of the *pupils,* impaired vision, absence of reaction of light will be noticed. There is often *nausea* and sometimes vomiting. *Excitement,* passing into delirium, is a prominent feature. The delirium may be pleasing, with spectral illusions; or anxious or furious. The onset of the *paralytic symptoms* is ushered in by giddiness, numbness of the limbs and staggering gait, and passes into drowsiness and stupor. The *pulse* is quick (to 170) and small. The respiration is stertorous, fast or slowed. The face is flushed scarlet. In *fatal cases* death is preceded by coldness of the extremities, rapid and intermittent pulse and deep coma. Convulsions are rare. Glycosuria is sometimes seen and may be attributed to the asphyxia. *Postmortem* findings are those of asphyxia. The minority (about 12 per cent) end fatally. Recovery has occurred after 7½ grains (488 mg.) of atropine, although the stomach was not evacuated till one and one-half hours later (Comrol, 1933). The usual *fatal dose* of atropine is probably 0.1 Gm. or more for adults; 0.01 Gm. for children. Therapeutically, children bear proportionately larger doses than adults, and this holds also for young animals.

Recovery starts within two days, the respiration, pulse and pupils returning gradually to normal. Sometimes violent delirious symptoms may last for days, and it has happened that patients have been consigned to the insane asylum on a mistaken diagnosis. Physic "slowness," disturbance of vision and some other symptoms may persist for weeks.

The *treatment of atropine poisoning* is usually effective, and the prolonged course gives time for interference. It comprises the chemical neutralization, prompt removal and meeting the symptoms. The delirium is best treated by the ice cap, the general symptoms by pilocarpine (10 mg., ⅙ grain hypodermically, repeated until the mouth is moist). Morphine (10 mg.) is indicated in the early stages, but not after depression has set in. The latter is combated by medullary stimulants (coffee, etc.). Artificial respiration should be kept up if necessary. The effects on the eye may be abolished by the local application of physostigmine.

Chronic atropine poisoning has been reported, especially from ophthalmic use (Tyrrell, 1906). With continued administration, as against Parkinsonian symptoms, the dosage must be increased progressively, indicating some degree of acquired tolerance. This applies also to the toxic dose, but not to the effects on the vagus or oculomotor (Cloetta, 1911).

Excretion.—The greater part of the atropine disappears rapidly from the blood (Cloetta, 1908). It is excreted mostly unchanged, entirely by the urine, mainly within thirty-six hours (in man, a fourth to a third of the amount administered, within fourteen hours; P. Pulewka, 1932). The application of a drop of the urine to the eye of a cat is a convenient test for poisoning.

Mydriasis occurs with a single drop of 1:150,000 solution, equivalent to 0.000245 mg. of atropine. Of scopolamine, the minimal mydriatic dose is 0.00001855 mg. (Joachimoglu, 1915). The human pupil is about equally sensitive (Metzner, 1912). The antagonism against choline esters on rat duodenum reveals 0.1 gamma of atropine (J. Lévy and Michel, 1938). An adaptation of the chemical Vitali test is sensitive to 10–50 gamma (Morin, 1936). Atropine resists *putrefaction* for a long time and may be found in the cadaver even months after burial. Confusion with putrefactive bases must be guarded against.

The excretion is not complete, more or less of the atropine being destroyed in the body. A part is excreted as tropine and as another base (Fickewirth and Heffter, 1912). Hydrolysis of atropine at the tropic acid: tropine linkage destroys the pharmacologic action (Macht, 1922). The variations in this destruction and in the rapidity of excretion may partly explain the racial and individual idiosyncrasies and acquired tolerance; but the different sensitivity of various animals does not correlate with the ability of their tissues to inactivate atropine; for instance, rats do not inactivate atropine, but are one of the least sensitive species (A. J. Clark, 1912).

Racial and Acquired Tolerance.—Rodents and marsupials are very tolerant, as also, to a less extent, the goat, dog, birds and some other animals. (The dosage for different animals was determined by Wilberg, 1914.) The immunity is not complete. It is perhaps greatest in rabbits, and can be increased by habituation, owing mainly to *destruction of the atropine* by the serum and organs. The atropine appears to be promptly bound by the plasma protein and then gradually hydrolyzed by esterase (Beutner, 1943).

The liver plays a large part in this destruction, and suspensions of liver cells also have this effect (Fleischmann, 1913). The serum of man, dogs and rats generally lacks this quality, which varies considerably in degree in different rabbits. Kako, 1926, claimed that the destruction of atropine by rabbit's blood is decreased after thyroidectomy, and Ikoness and Kusnetzowa, 1927, claimed this for dogs and stated that the activity is restored by reimplantation of thyroid. They also claim that the serum of hyperthyroid patients destroys atropine more actively than normal serum, and the reverse for hypothyroid patients.

The detoxication by rabbit's serum is due chiefly to the rapid destruction of the levoisomer, which is also demonstrable *in vitro* (von Oettingen and Marshall, 1934). However, rabbit's serum also binds other alkaloids, especially pilocarpine, so that they become undialyzable (Beutner, 1923). Homatropine and scopolamine are also destroyed by serum. Frogs, like rabbits, tolerate large doses of atropine, through rapid destruction in the liver (v. Oettingen, 1918). The *hydrolysis of homatropine and atropine* was studied by Bernheim and Bernheim, 1938, in various tissues of different animals. Homatropine and the levoisomers are always hydrolyzed more rapidly. The *esterase* is similar to that which attacks ethyl mandelate. It is inhibited by physostigmine. It is present in the liver of guinea pigs and frogs, and in the blood of about a fourth of the rabbits. It is absent from human blood and from that of all other animals which have been studied (Jeanne Lévy and Michel, 1938; Gliock and Glaubach, 1941).

Atropine Tolerance of Infants.—Infants and young unweaned animals often appear to tolerate relatively large doses of atropine. The mechanism is not clear, but it it not due to destruction of the levo-atropine by serum, as it is with rabbits. The urinary excretion of atropine is high, but it is doubtful whether this is an adequate explanation (J. D. Pilcher, 1934).

Cause of Habituation; Excretion in Animals.—Cloetta, 1911, found that nonhabituated rabbits excrete 15 to 20 per cent of the atropine, the excretion being completed in two or three days. (Fickewirth and Heffter find that the total excretion of all bases is about 50 per cent of the administered quantity.) After immunization, the excretion is completed in one day; and as little or none can be found in the tissues, it appears that the rapidity of destruction and excretion has been increased. The destructive power of the serum, however, is not raised (Fleischmann). Normal cats excrete little of the atropine; but by habituation, the excretion is markedly raised, while the capacity for destruction is not increased. With these, therefore, the tolerance is due mainly to the acquired speed of excretion. Dogs excrete about one-third of the atropine within two days (Wiechowski, 1900). Heckel, 1875, found that rabbits and guinea pigs not only throve for weeks on an exclusive diet of atropine-containing plants (Schroff, 1852), but that this exclusive diet could be continued for several generations. A further degree of immunity was thus acquired, so that the mydriatic effect was smaller and the fatal dose (hypodermically) higher. The flesh of these animals contained relatively little atropine, although the meat of ordinary rabbits poisoned with atropine is toxic to other animals and man (Lewin, 1894).

PREPARATIONS.—***Atropine Sulfate**, U.S.P., is a white, odorless, crystalline powder, freely sol. in water or alc. It is incompatible with alkalis, tannic acid and mercuric salts. Watery solutions of the free alkaloid are hydrolyzed rapidly even at room temperature (P. Hardy, 1922), but atropine sulfate solutions may be boiled for half an hour without decomposition (G. Kühl, 1925). Sterilized solutions in ampuls preserve their full activity at least four weeks (Joachimoglu, 1915). Dose, 0.25 to 1 mg., $\frac{1}{240}$ to $\frac{1}{60}$ grain. Commercial atropine is usually contaminated with varying quantities of hyoscyamine (Liljestrand, 1919). *Atropine Sulfate Tablets*, U.S.P.; usual sizes 0.3, 0.4, 0.5, 0.6 and 1.2 mg. ($\frac{1}{200}$, $\frac{1}{150}$ $\frac{1}{100}$ and $\frac{1}{50}$ grain).—*Atropine* alkaloid, U.S.P., is slightly sol. in water, freely in alc. and in oils.

Belladonna Leaf, U.S.P., the dried leaves and tops of Atropa Belladonna, with not less than 0.3 per cent of alkaloids, is the source of ***Belladonna Extract**, U.S.P., which contains 1.25 per cent of alkaloids (dose, 15 to 30 mg., $\frac{1}{4}$ to $\frac{1}{2}$ grain), and the 10 per cent *Tincture*, U.S.P., representing 0.03 per cent of alkaloids (dose, 0.3 to 1 cc., 5 to 15 minims). There appears little justification for the external use of belladonna in the form of *Belladonna Ointment*, U.S.P., and *Belladonna Plaster*.

Hyoscyamus, U.S.P. (Henbane), the dried leaves and tops of Hyoscyamus niger, contains chiefly hyoscyamine with some atropine and scopolamine. The *Tincture*, U.S.P., represents 10 per cent of the drug, about 0.004 per cent of alkaloids. Dose, 2 cc., 30 minims. The *Extract*, U.S.P., contains about 0.15 per cent of alkaloids. Dose, 0.05 Gm., $\frac{3}{4}$ grain.

Stramonium, U.S.P. (Jimson Weed, Jamestown Weed), the dried leaves and flowering or fruiting parts, with branches, of Datura Stramonium, represents at least 0.25 per cent of alkaloid, chiefly hyoscyamine with some atropine and scopolamine. Against asthma, 10 to 20 grains of the dried leaf, smoked in a pipe; hemorrhoids, fissures and painful ulcers, 10 per cent ointment. *Stramonium Extract*, U.S.P., contains about 1 per cent of alkaloid. Average dose, 20 mg., $\frac{1}{3}$ grain. *Stramonium*

Tincture, U.S.P., contains about 0.025 per cent of alkaloids. Average dose, 0.75 cc., 12 minims. The B.P. Tincture represents 20 per cent of the drug. *Stramonium seeds* are sometimes eaten by children and cause serious poisoning.

◆

HYOSCYAMINE

This is the levo-isomer of the racemic atropine. Cushny, 1903, compared these two alkaloids and the dextro-isomer. He found that the peripheral actions on the iris, cardiac vagus, and glands are twelve to eighteen times as strong with the l-isomer (ordinary hyoscyamine) than with the d-, and about twice as strong as with atropine. Hyoscyamine has some advantage when the peripheral effects are desired, especially in ophthalmic work. Internally, it has no advantage. All the isomers act practically alike on the central nervous system of mammals. The d- has a greater stimulant effect on the spinal cord of frogs. On the intestine, the isomers act quantitatively alike (Liljestrand, 1919).

◆

AGARIC ACID

Agaric acid and the impure mixture *agaricin* are derived from a fungus of the larch tree. It is a white, odorless and tasteless crystalline powder, but slightly soluble in cold water and alcohol. Agaricin was introduced against the night sweats of phthisis by Young, 1882. The effect appears only after some hours (if at all) and then lasts for about twenty-four hours. It is a local irritant and cannot be given hypodermically. Large doses produce vomiting, diarrhea and death through central paralysis (Hofmeister, 1888). It is advisable to start the dosage with 0.5 mg. and increase as needed, but not to exceed 30 mg. per single dose or 100 mg. per day. Clinical opinions differ as to its value. The mechanism of its action has not been satisfactorily explained. Hofmeister claimed that it prevents the sweating response of the cat's paw to sciatic stimulation or heat, indicating that its action is peripheral. It does not arrest the saliva or tears. McCartney, 1917, finds that it has a digitalis action and that it stimulates smooth muscle. Bergstrom, 1928, reports that low concentrations increase the excitability of excised intestines and of the vagus endings of frog heart, that larger doses depress parasympathetic endings and that still larger doses depress smooth muscle directly.

◆

SCOPOLAMINE (HYOSCINE)

The U.S.P. specifies the levorotatory scopolamine. Commercial samples were often rather impure mixtures of two isomeric alkaloids (tropeic esters of oscine or scopine; Willstätter and Berner, 1923, a base closely related to tropine): scopolamine proper (levorotatory) and atroscine (optically inactive). They occur in the various atropine-containing plants, but are now prepared mainly from scopola. The *peripheral actions* of scopolamine agree qualitatively with those of atropine, but there are quantitative differences; for instance, the actions on the oculomotor and secretions are stronger, while the vagus action is relatively weak. The *central actions* differ more profoundly, scopolamine being mainly sedative in all doses, while moderate doses of atropine are excitant. There are great individual variations, however, in the response to scopolamine, and in its toxicity, even with the purest samples, although the uncertain composition of the commercial samples probably played a part.

It was formerly stated that there are specific differences in the effects according to the origin of the alkaloids, and that "hyoscine" derived from hyoscyamus is therapeutically superior to the "scopolamine" of scopola. No such difference exists if the alkaloids are pure; for these are identical, whatever their source (E. Schmidt, 1894).

Apoatropine (also called belladonnine or atropamine) was demonstrated in a commercial sample by Kobert, 1905, and has been held responsible for the occasional toxic effects, but this is improbable. It is a rare impurity (Kionka, 1908), and its presence is easily shown, by reduction (brown color), on adding a few drops of permanganate solution (Kessel, 1906). It exists preformed in the plants and may be derived chemically from atropine by the abstraction of one molecule of water. In rabbits it produces rise of blood pressure, paralysis of cardiac vagus endings, convulsions by central excitation and death with relatively small doses by paralysis of respiration. The oculomotor and secretory endings are not paralyzed. It is more potent than atropine on the intestines, acting directly on the muscle and not on the parasympathetic endings. It is more active by mouth than hypodermically, being destroyed by tissue enzymes as well as by the plasma (Kreitmair and Wolfes, 1938).

Deterioration of scopolamine solutions has been suggested as a cause for toxic reactions, but according to the seemingly more reliable experiments of Kionka, 1908, Willstätter and Hug, 1912, and Beck, 1914, the solutions keep unchanged indefinitely, at least in sealed ampuls. H. Bolten, 1917, described abnormal effects in six patients from a solution that had been kept for several months in a "sterile" bottle (not ampul).

Rabbits' serum destroys the levo-isomer more rapidly than the dextro-, while the rate of destruction is equal in egg white. This holds true also for the hyoscyamine isomers and is therefore due to the tropic acid radical (von Oettingen and Marshall, 1933).

Pharmacologic differences between scopolamine and atroscine are important in the peripheral actions, but not in the more important central effects. Cushny and Peebles, 1905, found that the levo- and rotatory-alkaloids act alike on the central nervous system in mammals, and on the motor endings; but that the levo-alkaloid (scopolamine) is twice as active on the salivary and vagus endings as is the racemic atroscine. This has been confirmed, also for the pupil, by Hug, 1912. Smith, 1915, found the fatal dose the same for mice. Cushny, 1921, states that eleven hyoscine isomers are possible, since both tropeinic acid and oscine are asymmetric. He quotes instances showing that the optical rotation may be involved in some of the actions, and not in others of the same substance.

Psychic Actions.—In man, doses of 1 to 3 mg. ($\frac{1}{60}$ to $\frac{1}{20}$ grain) generally produce, within ten or fifteen minutes, fatigue, drowsiness and a natural dreamless sleep, lasting several hours. The response, however, is variable. In some the sleep is preceded by hallucinations, which may be rather pleasant with small doses, but become violent if the dosage is increased. Animals are also affected differently by scopolamine (Kochmann, 1913).

Dogs react similarly to man: small doses produce sleep and hallucinations; larger doses cause more marked hallucinations and restlessness, ataxia and often emesis. The excitability of the motor areas is said to be lowered (Sohrt, 1886; Ramm, 1893). With white *rats* Barlow, 1932, found small doses (to 13 mg. per Kg.) slightly sedative and analgetic, but never hypnotic. Between 65 and 130 mg. per Kg., it was purely excitant. *Rabbits* react by a mixture of depression and stimulation (Liljestrand *et al.*, 1919). *Frogs* show central abolition of reflexes (Wood, 1883), preceded by more extensive spreading of the reflexes (Kochmann).

Site of the Narcotic Action.—Scopolamine is more potent in rabbits after removal of the cerebral hemispheres, so that it acts apparently, at least partly, on the sleep centers of the midbrain (Mehes, 1929).

Therapeutic Use of Sedative and Hypnotic Action.—Scopolamine is employed especially in acute maniacal excitement, delirium tremens and tetanus. It has *advantages* over morphine, in that it quiets the reflexes and avoids addiction; and over chloral, in that it does not usually depress the medulla. However, it produces the unpleasant *side effects* of mydriasis, cycloplegia and excessive dryness; sometimes muscular tremors and occasionally serious delirium (the latter is said to be promptly controlled by small doses of morphine). The therapeutic dose lies much below the ordinary fatal dose; but small doses (0.2 to 0.75 mg., $\frac{1}{300}$ to $\frac{1}{75}$ grain) have produced serious poisoning, with cardiac and respiratory collapse. On the other hand, $\frac{1}{10}$ and even $\frac{3}{4}$ grain (6.5 and 50 mg.) have been taken without ill effects. Insane patients generally seem to be tolerant, so that the effective doses (1 to 3 mg., $\frac{1}{60}$ to $\frac{1}{20}$ grain) may be given; with ordinary individuals it is not safe to exceed 0.5 mg. ($\frac{1}{120}$ grain), repeating this smaller dose every six to eight hours, if necessary; and it would be safer to use this dosage also for the insane. Smaller doses (0.2 mg., $\frac{1}{300}$ grain) may be used to enhance the hypnotic effect of morphine. The use in *drug addictions* has been discussed under "Morphine."

Prevention of Motion Sickness.—Scopolamine hydrobromide, 0.6 mg. by mouth half an hour or an hour before the trip, protects the majority of susceptible persons against *seasickness* and *airflight sickness* with negligible side effects. It may safely be repeated in eight hours, but beyond this only under medical supervision.

In well controlled trials on experimental sea trips, H. E. Holling, 1944, found the following ratios of susceptible individuals protected: Scopolamine, 0.6 mg., 50 to 75 per cent (the percentage was no better with 1.2 mg.); atropine, 1 mg., 40 per cent; homatropine, 2 mg., 25 per cent. No protection was obtained with barbiturates, with diphenyl hydantoin sodium, 0.2 Gm., and with methedrin, 8 mg. The only *side effect* of scopolamine was dryness of the mouth. There was no drowsiness, no eye symptoms, no impairment of physical performance, but little effect on adjustment to heat. Similar successful trials of scopolamine against *airsickness* are reported by J. L. Lilienthal, 1945. The U. S. Army experimented with a mixture of scopolamine hydrobromide, 0.2 mg., atropine sulfate, 0.15 mg., sodium amytal, 60 mg. Serious and fatal barbiturate poisoning occurred from unauthorized overdosage (Foucar *et al.*, 1946).

"Swing sickness," which appears analogous to seasickness, is prevented in about half the susceptible individuals by the following: scopolamine hydrobromide, 0.5 or 0.75 mg.; atropine sulfate or l-hyoscyamine hydrobromide, 1 mg. Homatropine is less effective; demerol and pavatrine are of doubtful value; barbiturate, amphetamine, thiamine and pyridoxine appear ineffective. Amytal does not add materially to the potency of atropine or scopolamine. Neostigmine decreases the effectiveness of scopolamine, but does not abolish it (P. K. Smith, 1946).

Parkinson's Disease.—Rather large doses of scopolamine (0.8 mg., $\frac{1}{75}$ grain, four to five times per day) often produce some improvement in the tremor and rigidity, and are rather more effective than atropine or hyoscyamine. The action, as with these, is probably central.

Respiration and Circulation.—Therapeutic doses ordinarily do not cause any important effects (Kochmann, 1903). The respiration is practically unchanged. The pulse may be unchanged or considerably slowed (central vagus stimulation). The blood pressure shows no change, or with somewhat larger doses a moderate rise (stimulation of vasomotor center). Toxic doses depress the respiration, the heart and the blood pressure. With fatal doses, the respiration stops before the heart.

The Eye.—The effects of scopolamine correspond qualitatively with those of atropine. They are produced more quickly and by doses only one-fifth or one-tenth as large (Joachimoglu, 1915), but are not quite as lasting. The intra-ocular pressure is less affected (Bollet and Curtil, 1911). It is less irritant than atropine, and patients who do not tolerate atropine can often take scopolamine. It is used like atropine (iritis, etc., 0.1 per cent; cycloplegia, 0.2 per cent).

The secretion of saliva, sweat, mucus, etc., is paralyzed by therapeutic doses of scopolamine, more actively than by atropine.

The effects on the intestine correspond to those of atropine. The *excised uterus* is stimulated (Kehrer, 1907; Barbour and Copenhaver, 1915). *Isomers on Excised Ureters.*—The levo- stimulates the contractions and slightly raises the tone. Very large doses depress. The dextro- inhibits without stimulation. The racemic is also inhibitory (Macht, 1918). *Potassium tonus* is antagonized by scopolamine in the isolated intestine, not in striped muscle (Blumenfeldt and Köhler, 1928).

Scopolamine-Morphine Synergism.—The two alkaloids produce additive narcosis. It is questionable whether there is actual potentiation (Madelung, 1900; Buergi, 1910; Kochmann, 1913; Mehes, 1929) or simple summation of the effects (M. I. Smith, 1915; Storm van Leeuwen and van der Made, 1919). The improvement probably consists in diminution of side effects, such as the deliriant tendency of scopolamine, rather than in intensification of the narcotic action. (*Bromide* also renders scopolamine more hypnotic for rabbits and cats; Mehes, 1929.)

Buergi claimed that a dosage of scopolamine which has no effect when given alone to rabbits (0.1 to 1 mg. per Kg., by mouth or hypodermically) produces narcosis when used with two-thirds of the dose of morphine required to produce narcosis when given alone. Similar "potentiation" was described for a mixture of $\frac{1}{80}$ of the minimal effective dose of morphine with $\frac{1}{2}$ of the minimal effective dose of urethane, or $\frac{2}{5}$ morphine with $\frac{1}{25}$ urethane. Electroencephalograms, which show little change with 1 mg. of scopolamine clinically, react with typical sedation when 10 to 20 mg. of morphine are added (H. Berger, 1934).

Preanesthetic Sedation.—Scopolamine hydrobromide, 0.6 mg., $\frac{1}{100}$ grain, may be injected with morphine sulfate, 15 mg., $\frac{1}{4}$ grain, partly to intensify the sedative action, and partly to diminish mucus and postoperative nausea and emesis similarly to atropine (Waters *et al.*, 1938). Many anesthetists advise against this, as its variable action makes the course of anesthesia more uncertain and therefore more risky. It also tends to add to the respiratory depression of morphine and may cause marked fall of blood pressure (A. Mayor, 1908). It is especially dangerous with chloroform (W. Straub, 1913).

Scopolamine alone is not narcotic (for rabbits or mice), even in large doses; nor does it diminish the concentration of ether or chloroform required for light anesthesia; but it does permit a deep anesthesia with relatively lower concentrations. It also deepens the morphine narcosis. The two alkaloids used together produce a deeper anesthesia with a given concentration of inhalation anesthetic (Ludewig, 1913). With rats, Barlow, 1932, obtained intensification of nitrous oxide-oxygen anesthesia by scopolamine alone. It decreased the effectiveness of morphine premedication and intensified the respiratory depression.

Scopolamine-Morphine Anesthesia.—The combination of adequate doses of the two alkaloids results in a deep narcosis that may permit of major surgical operations (Scheiderlin, 1900). The advantages of exclusive scopolamine-morphine anesthesia, as compared with ether or gas, are rather minor, while the disadvantages are serious (Hatcher, J.A.M.A., 1910, *54:* 446). The combination increases not only the narcotic action, but also the depression of respiration and circulation, and this in irregular degree. The susceptibility varies so much that the surgical anesthesia is often incomplete and must be supplemented by ether; and on the other hand, serious accidents and fatalities are alarmingly frequent. The anesthesia cannot be modified to suit the needs of the moment. Delirium, sometimes serious, is not uncommon. In obstetrics, deep scopolamine-morphine anesthesia is especially dangerous to the child, owing to the great susceptibility to morphine. In nonfatal cases, the child may show somnolence and deficient respiration for days after delivery (Jung, 1914).

Scopolamine-Morphine Amnesia, "Twilight Sleep."—Moderate doses of morphine with rather heavy doses of scopolamine produce narcotic amnesia, a drowsy condition in which consciousness is blunted but not abolished, so that the patient can follow orders. Pain also is felt but blunted. The narcotic stupor lasts from six to ten hours; and when the patient fully wakens, there is no memory of the intervening events and experiences, in successful cases. This seminarcosis, introduced by Gauss, 1906 and 1907, as "*Dämmerschlaf,*" is used in obstetrics "to deprive labor of its terrors." It requires careful management, but those who have experience and skill in its use obtain good results in most cases. Under favorable conditions it probably reduces the maternal and fetal mortality, and diminishes perineal injury, especially for primiparae. It does not interfere with uterine contractions, but if the narcosis is deep it may abolish the abdominal contractions and thus delay delivery. The chief drawback is the variability of the response; it fails not infrequently, and some patients become delirious or maniacal. Toxemia and cardiac dilatation require special caution. Morphine must not be administered within three hours of the end of the second stage, for it delays the breathing of the child.

Doses for Twilight Sleep.—The minutely defined technic involves exclusion of noise, light and all excitant factors—apparently the cooperation of suggestion is essential. The drugs are not started until regular pains occur, perhaps every four to five minutes and lasting half a minute. The first injection is of 8 to 15 mg. of morphine and 0.45 mg. of scopolamine hydrobromide. The morphine must not be repeated. The scopolamine, however, is repeated; first in three-quarters of an hour with 0.45 mg., then every one and one-half hours with 0.3 mg., until amnesia (loss of memory) is sufficiently advanced. This is tested every half hour.

Effects on Uterus.—Morphine and scopolamine amnesia has no constant or marked effect on the uterine contractions clinically (Dodek, 1932), or on anesthetized animals (Barbour, 1915) The alkaloids slightly increase the tone of the excised uterus, without synergism or antagonism (Barbour and Copenhaver, 1915).

Scopolamine during parturition also appears to add amnesic potency to intravenous pentobarbital injection (P. P. Volpitto, 1946).

The toxic effects of scopolamine are similar to those of atropine: dry mouth (xerostomia), vertigo and ataxia, marked mydriasis and disturbed accommodation; mental confusion, loss of memory, muttering, somnolence, deep sleep, stupor, coma; or, exceptionally, delirium and maniacal excitement (McCowan *et al.*, 1926). There is often a Babinsky reflex. The symptoms differ from those of atropine generally by the greater hebetude and by the absence of the scarlatinal rash and pulse acceleration, and usually of the restlessness. The *treatment* consists in alkaloidal antidotes. Central stimulation by ephedrine has been shown to be of some value in cats (Kreitmair, 1926).

***Scopolamine Hydrobromide,** U.S.P. (*Hyoscine Hydrobromide*, B.P.), is the levorotatory isomer obtained from various Solanaceous plants. It occurs as colorless crystals, freely sol. in water (1:1.5) and alc. Dose, 0.3 to 0.6 mg., $\frac{1}{200}$ to $\frac{1}{100}$ grain.

◆

PILOCARPINE

Pilocarpine, the principal alkaloid of jaborandi leaves (Pilocarpus), stimulates the parasympathetic receptor mechanism, increases secretions, augments the gastro-intestinal movements, constricts the pupils, etc. It also increases the response of all autonomic ganglia to natural or test stimuli (Bacq and Simonart, 1938; Marrazzi, 1939) and thereby increases the output of epinephrine and quickens the heart rate in mammals. It has no effect on striated muscle. The central effects of pilocarpine are unimportant. The peripheral effects are easily inhibited by atropine. Conversely, pilocarpine removes the depressant effects of small doses of atropine, but is ineffective against large doses. Pilocarpine is used as miotic and as diaphoretic; in the latter respect it surpasses all other drugs. Pulmonary disease enjoins caution in its use, since the increase of mucus and the action on the circulation may result in dangerous *pulmonary edema.*

Other Jaborandi Alkaloids.—Pilocarpus contains two other alkaloids, isopilocarpine and pilocarpidine. These differ chiefly in the strength of their action, pilocarpine being the strongest and pilocarpidine the weakest. It was formerly believed that pilocarpus contains another alkaloid, jaborine, with atropine actions. This view was shown to be erroneous (Marshall, 1904).

Arecoline, the alkaloid of Areca or Betel nut, is closely related to pilocarpine in its actions (Marmé, 1889; Leepin, 1891). It stimulates peristalsis (Paetz, 1910) and produces marked bronchial constriction by peripheral action, but is overcome by atropine or epinephrine (D. E. Jackson, 1914).

Glands.—Pilocarpine increases the secretion of saliva, sweat, tears, mucus, of the gastric, pancreatic and possibly of the intestinal juice and of the milk, not of the urine or bile. A gallon of water may be removed by these secretions, after a single injection.

Microscopic Changes during Pancreatic Secretion.—As described by E. Ries, 1935 (from fixed preparations), the proenzyme granules of the pancreatic cells are formed from "lipochondria," which contain fat and take basic vital stains. After pilocarpine, or feeding, these proenzyme granules are discharged, and the lipochondria form daughter granules, which increase, are transformed into proenzyme granules and discharged. The nucleus of the cell does not undergo any changes in the process.

Smooth muscle is contracted practically everywhere, in the eye, bronchi, uterus, ureter, bladder, spleen, stomach and especially in the intestines, resulting in diarrhea and colic. The blood vessels are not contracted.

Paradoxical Effects.—In several situations, and under special conditions, the effects of pilocarpine correspond to stimulation of the sympathetic. This has been attributed to increased output of epinephrine, but acceleration occurs also in the excised heart and excised intestine.

Suprarenal Stimulation.—Dale and Laidlaw, 1912, describe evidences of oculomotor stimulation even if the cervical ganglia have been excised, but not if the suprarenal has been removed. They ascribe this to stimulation of the suprarenals, *i. e.*, increased production of epinephrine. There is a similar condition as regards the uterus. Jackson, 1913, accepts the same explanation for a dilator effect on bronchial muscle. However, Stewart and Rogoff, 1916, showed that pilocarpine does not increase the output of epinephrine.

Direct application of pilocarpine to the hypothalamic centers (by injection into the lateral ventricles of human patients) produces effects analogous to those of intravenous injection: quickened pulse, sensation of heat, abundant salivation, emesis (Cushing, 1931). In rabbits it also causes mydriasis, exophthalmos, hyperthermia and gastric ulcers (R. Light *et al.*, 1932). Apparently pilocarpine acts locally on the parasympathetic centers of this region.

Eye Effects.—Topical application of pilocarpine produces miosis and spasm of accommodation, by peripheral stimulation of the oculomotor.

In rats and guinea pigs, pilocarpine dilates the pupil (J. A. Waddell, 1926; Koppanyi). The miosis begins in fifteen minutes (independently of the concentration), reaches its maximum in thirty to fifty minutes and disappears in twenty to twenty-four hours. The spasm of accommodation also begins in fifteen minutes, and lasts about two and a half hours. The intra-ocular tension is first raised, followed by more persistent fall. Pilocarpine nitrate in $\frac{1}{4}$ to 4 per cent solution is applied as a milder substitute for physostigmine in glaucoma, corneal ulcer, etc.

Diaphoretic Action.—To produce this effect, pilocarpine should be injected hypodermically (5 mg., $\frac{1}{12}$ grain), the patient being kept warm. This dose may be repeated in half an hour if necessary. Several liters of sweat may be excreted. The diaphoretic action is used in *nephritis,* to relieve the kidneys and to remove edema. This dosage usually produces salivation, sweating and nausea, often vomiting and singultus; exceptionally, slowing of the pulse; sometimes considerable general depression, and with larger doses serious collapse, especially in children.

Pilocarpine causes sweating after degeneration of the nerves, though less than on the sound side (Langley and Anderson, 1904). It is completely antagonized by atropine and diminished by epinephrine—the latter perhaps through vasocontriction. In paralyses of the cortical psychomotor region, the corresponding parts of the skin are reported to perspire especially strongly in response to pilocarpine (Bikeles and Gerstmann, 1915). *Acceleration of the blood current* through the glands occurs as a secondary effect of their increased action. A common effect of pilocarpine, a *hyperemia of the skin* (resulting in an increase of its temperature), may possibly be due to the greater activity of the sweat glands. The increased circulation of the skin is said to augment the *growth of hair* and to darken its color. The statement may be doubted.

Other Diaphoretics (Sudorifics or Hidrotics).—The secretion of sweat may be increased (1) by stimulating the secretory structures, (*a*) peripherally (pilocarpine, furmethide, acetylcholine) or (*b*) the sweating center (camphor, ammonium acetate); or (2) by increasing the cutaneous circulation, (*a*) locally (mustard; external heat) or (*b*) through the vasomotor center (internal heat; alcohol, salicylates, acetanilide, nauseants etc.): Children sweat more, old people less easily, than adults. Among animals, horses sweat most profusely; pigs and beef, not readily; dogs, rabbits and sheep, not at all; cats only on the paws.

Indications for Diaphoretics.—The sudorific measures specially adapted to the different indications are as follows:

For the Absorption of Edemas and Exudates.—A powerful action is needed: pilocarpine combined with external heat (hot baths or packs).

To Relieve Inflamed and Overtaxed Kidneys.—The large amount of fluid and excrementitious material removed by a thorough sweating secures functional rest to the kidneys and lowers blood pressure. Here, also, pilocarpine and hot baths are preferred.

Ordinary sweat (Hoelscher, 1904) contains 0.22 to 0.81 per cent of ash, and 0.043 to 0.084 per cent of *nitrogen,* mainly in the form of urea (0.285 per cent of NaCl and 0.21 per cent of urea; Kovesi). The daily cutaneous excretion of nitrogen is from 0.3 to 1.8 Gm. (Benedict, 1905; Schwenkenbacher and Spitta, 1907). Even during rest, the sweat averages 0.07 Gm. of nitrogen per day. This is considerably increased, in proportion to muscular labor, to 0.22 Gm. of nitrogen per hour (F. C. Benedict, 1905). The proportions of *Cl, Na and K* in human sweat vary considerably for different individuals. The *lactic acid* concentration is much higher than in the blood. The reaction is ordinarily acid to *p*H 4.4 (A. G. R. Whitehouse, 1935). The *p*H of pilocarpine sweat ranges from below 5.4 to 7.6, being less acid than that from light-baths (4.5 to 6.5; A. Marchionini, 1929). The acidity of sweat appears to be due to substances given off by the epidermis; normal sweat from the glands has the slight alkalinity of blood plasma (Whitehouse).

The sweat excreted under the influence of pilocarpine contains in normal individuals 0.051 to 0.085 per cent of nitrogen, and 0.26 to 0.31 per cent of ash. Three liters of sweat—a not unusual quantity after pilocarpine—would therefore remove about 2.5 Gm. of nitrogen. In nephritis, the nitrogen content may be much higher, to 0.288 per cent, so that the 3 liters could remove 8 Gm. of nitrogen. The abnormally great depression of the freezing point of the blood of uremic patients may be reduced to normal by diaphoresis (Bendix, 1904). The freezing point of the blood of normal animals is not affected. Alimentary glycosuria could also be prevented by free diaphoresis, the excess of sugar being excreted by the skin. However, Austin and Miller, 1914, could find no evidence that sweat baths materially diminish the nitrogen retention in nephritis.

For the removal of poisons, especially in chronic intoxication by the metals, the efficiency is doubtful. Hot baths and drinks would be used.

To reestablish disturbed circulation in the skin, and thereby to influence the circulation of internal organs, determines their use in colds, rheumatism, etc.; in cold skin from whatever cause; in inflammations of the lungs, pleura, etc. Relatively mild diaphoretics suffice for this purpose: external heat; hot drinks (tea, lemonade or alcohol); Sweet Spirits of Nitre; Dover's powder; salicylate, etc.

The increased vascularity of the skin is used to hasten the outbreak of *febrile exanthemata, to promote the absorption of salves, etc.*, and in certain *diseases of the skin* where its nutrition is defective. In *ophthalmology*, diaphoresis has been reported useful in congestive and exudative lesions of the uveal tract, in retinal detachment and in toxic blindness; it is useless in atrophic and cicatricial lesions.

Pilocarpine Salivation.—The *sialagogue* action is employed (10 mg., $\frac{1}{6}$ grain, by mouth, three or four times a day) against poisons which suppress this secretion (atropine, meat poisons, etc.). The increased secretion of *mucus* may be used in a dry cough. This also results in loosening croupous membranes. The increase in biliary mucus is said to facilitate the passage of *gallstones*. Its utility is doubtful.

In man, 5 to 10 mg. of pilocarpine, by mouth, increase the volume of saliva considerably. The percentage of inorganic solids is unchanged; that of organic solids shows an insignificant increase. The proportion of ptyalin is markedly diminished, but its total quantity is considerably increased (Ewing, 1911). In dogs, hypodermic injection of 0.5 mg. per Kg. raises the chloride concentration of the saliva and lowers it in the blood, increases the metabolism of the salivary glands and decreases the sedimentation rate of the erythrocytes (Vladesco and Nichita, 1939). The composition of pilocarpine saliva is not changed by the injection of sodium phosphates, sulfate or carbonate, or of glucose, unless toxic doses are given (Asher, 1908). The submaxillary gland, when *perfused* with Locke's solution, can be provoked to secretion by pilocarpine, but not by chorda stimulation (Demoor, 1912).

Gastric Secretion.—Pilocarpine increases the volume and the enzymes of the gastric juice (Chiari, 1913), clinically as well as in animals, even when histamine is ineffective (Blakely and Wilkinson, 1933). Mucin is increased but little, if at all (F. Hollander, 1944). Reports as to acidity are contradictory. The effects have a relatively long latent period and long duration (Hollander and Stein, 1943).

It is usually stated that the *acidity* is markedly decreased even to total anacidity (Blakely and Wilkinson, 1933). It is more potent if injected into the lateral ventricles. It is antagonized by atropine, but only with difficulty by histamine (Ferguson and Smith, 1934). On the other hand, Hollander, 1944, claims increased secretion of gastric acid.

Gastric Motility.—Pilocarpine quickens the peristalsis of the prepylorus and increases the tonus of the pylorus (Schroeder, 1933). The stomach generally begins to empty earlier, but its complete evacuation is delayed (Herrin, 1936). The effects are antagonized by atropine.

Acute hemorrhagic erosions of the gastric and duodenal mucosa occur in rabbits after repeated doses of pilocarpine (five injections of 25 mg. at intervals of twenty-five minutes), also after histamine (five injections of 7.5 mg.). They have not been observed after physostigmine and choline. They differ from clinical gastric and duodenal ulcers in that they do not become chronic. They are probably due to mechanical injury of the thin gastric wall of rabbits by the violent muscular contractions induced by the drugs, especially when it is filled with coarse food. They are not easily produced in the cat and rat and are somewhat different in guinea pigs (Underhill and Freiheit, 1928).

The pilocarpine nausea and emesis arise reflexly from the parasympathetic disturbance, especially of the heart, and presumably also the gastric movements. They are antagonized by atropine and do not occur on direct application of atropine to the medullary vomiting center (Kwit and Hatcher, 1933).

Pancreatic Secretion.—Lannoy, 1905, claimed that this is not increased if the pylorus is ligated. He therefore believed that the ordinary increase is indirect, due to the increased secretion of acid in the stomach, and therefore increased production of secretin. However, Camas and Gley, 1913, find that it is effective even when the small intestine has been removed, so that it must act directly on the pancreas.

Succus Entericus.—Kubikowski, 1927, reported that this is increased, the fluid more than the enzymes, by pilocarpine, physostigmine and choline.

Milk Secretion.—Earlier investigators claimed some increase (Roehrig; Ott and Scott, 1912), but Hays and Thomas, 1920, found the response inconstant and within the range of accidental variation. Other reputed lactagogues were also ineffective.

Bile and Lymph Flow.—Janagaw, 1916, claims that these are increased.

Cerebrospinal fluid is increased by the respiratory embarrassment (Dixon and Halliburton, 1913).

Oviduct Secretions.—Pilocarpine has practically no effect on the albumen or shell production in birds (Riddle and Wing, 1921).

Development of Ova.—Sollmann, 1904, described the phenomena of antagonism to atropine.

Yeast Fermentation.—Somogyi, 1916, claimed that this is inhibited by small concentrations, but stimulated by larger doses.

Intestinal motility is stimulated by pilocarpine, in man and most animals. Moderate doses speed the propulsion, but the effects are erratic and not very marked (soft bolus, permanent loop of jejunum, dog; Quigley *et al.*, 1934). Large doses cause violent peristalsis and colic.

Paradoxical Relaxation.—Excised intestine of *frogs* is generally relaxed by pilocarpine. This antagonizes barium contraction and is additive with atropine relaxation (G. B. Roth). With excised intestines of *rabbits*, pilocarpine and arecoline contract if applied separately, but relax if used together (Busquet, 1933).

Other Smooth Muscle.—Pilocarpine generally stimulates the *bronchioles*, *uterus* and *urinary bladder*, as discussed under Autonomic Actions (see Index). It stimulates the gallbladder (Lieb and McWhorter, 1915).

Contraction of the spleen (Palitz and Morse, 1936) results in increase of blood cells (Bornstein and Vogel, 1921) and leukocytes, the latter being aided by the contraction of the smooth muscle of the lymph glands (Harvey, 1906).

Circulation.—The effect of clinical doses is not important. With doses of 7.5 to 10 mg., Blomberg and Ronnel, 1930, report pulse acceleration of 13 to 17 per minute, and 4 to 7 mm. rise of blood pressure. Intense nausea and vomiting may modify these effects. The *cardiac acceleration* is contrary to what would be expected from parasympathetic stimulation, but it is the usual result with mammals (not with frogs). It has been attributed to increased epinephrine output, but it occurs also in the excised heart.

Excised Mammalian Heart (Hedbom-Langendorff).—The effects are similar to those in the frog heart, but the stage of vagus stimulation is short: the rate is suddenly slowed; this lasts a short time, then there is marked quickening with increased tonus. If the auriculoventricular bundle is divided, pilocarpine or muscarine does not produce inhibition (Cullis and Tribe, 1913); nor do they inhibit isolated ventricular strips (Leetham, 1913). Their action must therefore be on the auricular vagus terminations. Large doses paralyze the muscle. The *frog heart* responds with vagus stimulation; *i. e.*, slowing and weakening, and diastolic standstill (Harnack and H. Meyer, 1880). The slowed rate decreases the oxygen consumption (David, 1930). Atropine prevents both the chronotropic and inotropic effects; both are also antagonized by epinephrine and by caffeine; digitaloids antagonize the weakenings, but not the slowing (F. Ransom, 1917). The slowing occurs after nicotine (Galsboeck, 1911) and is therefore probably postganglionic. The vagus excitability is increased. Combinations with muscarine give additive effects; physostigmine does not (Loewi, 1912). The sympathetic innervation is not affected (Barlow, 1936). High concentrations paralyze the cardiac muscle. Small doses of chloral, by depressing the cardiac muscle, delay the escape from *vagus* inhibition, whether by pilocarpine, muscarine or electric stimulation (Loewi, 1912). Pilocarpine arrests the contractions of *terrapin's heart*, but does not affect the auricular tonus waves (Gruber, 1920).

The blood pressure of dogs falls by vasodilatation, after intravenous injection of 0.1 mg. per Kg. With larger doses this is followed by considerable rise, which is increased by nicotine, decreased by cocaine, and abolished by atropine and by pentobarbital (Koppanyi, 1939). Nelson and Keiper, 1923, observed that with small doses, the organ volume may increase after the fall of blood pressure. *Perfused blood vessels* are dilated (frogs; Froelich and Pick, 1913). Berezin, 1914, claims constriction of the lung vessels.

Pilocarpine (1:1000) has a true *curarizing action* in frogs, but not in cats. The nerve-muscle block is not antagonized by atropine (G. Coppée, 1943).

The urine output is ordinarily not affected directly (MacCallum, 1905); but the great loss of fluid by other channels usually diminishes the water and chloride output by the kidneys (Asher, 1905; Cow, 1912). Repeated injections of large doses produce glycosuria and diuresis, which Waterman, 1911, attributes to increased renal permeability.

Metabolism.—Pilocarpine somewhat increases CO_2 production and tends to raise the temperature, even in curarized animals, by stimulation of the glands and unstriped muscle. The increase is antagonized by atropine (Keleman, 1918). Mendel and Stehle, 1915, claim that pilocarpine and other stimulants of digestive glands increase the excretion of uric acid.

Blood Sugar Level.—Rather large doses of pilocarpine cause moderate hyperglycemia in normal animals (Hrubetz, 1937). Doses which are not effective alone increase the hyperglycemic response to epinephrine (Belak and Klamartsik, 1930). The hyperglycemia is antagonized by both insulin and atropine (Framaviglia, 1930). It is more marked after excision of the pancreas (Appelrot, 1935). It is attributed to discharge of epinephrine, for it does not occur after excision of the adrenal glands; indeed, pilocarpine then lowers the blood sugar level (Viale and Napoleoni, 1928).

Central Nervous System.—Except for direct injection into the lateral ventricles, the central actions of pilocarpine are weak and appear late, so that they are overshadowed by the peripheral actions. The effects are mainly *depressing*. *Vasomotor paralysis* is a rather early and prominent symptom; it leads to *dyspnea*. Later, the *respiratory center* is also depressed. The *motor centers*, especially those of the cord, show some stimulation (increased reflexes, tremors, convulsions) and later paralysis.

Fate and Excretion.—A large part is excreted unchanged, but in combination, by the urine (Curci). The activity of pilocarpine is destroyed by digestion with liver emulsions or serum; but active pilocarpine can be extracted from such mixtures by acidified alcohol. The inactivation is therefore probably an adsorption phenomenon. The "bound" alkaloid does not dialyze (Beutner, 1923) and is not precipitated by iodine (Jendrassik, 1923). The inactivating substance is not cholesterol or lecithin. Its quantity varies for the serum of different animals, the disintoxication occurring most readily in the serum of rabbits and least readily in dogs; with cat or ox serum intermediate (Storm van Leeuwen, 1918). Similar combinations apparently occur between rabbits' serum and other alkaloids; for instance, atropine, strychnine, procaine and cocaine (Beutner, 1923).

Symptoms of Poisoning.—The symptoms, which apply also to muscarine, begin with greatly increased secretion of saliva, sweat and tears; then nausea, profuse vomiting and painful diarrhea; pupillary contraction and spasm of accommodation; pulse variable in rate, tense and arrhythmic; palpitation; dyspnea with rales; sometimes confusion of ideas, vertigo, tremors and feeble convulsions. Death occurs either by paralysis of the heart or edema of the lungs. *Untoward effects* from the alimentary canal are seen most frequently if the drug is given by mouth, but occur also on hypodermic administration. They consist in prolonged and depressing nausea and vomiting, sometimes leading to collapse. The disturbance of accommodation causes misty vision. A burning sensation in the urethra, with sudden and irresistible desire to urinate, is often noticed. Atropine is a physiologic *antidote.* The general *treatment* of alkaloidal poisoning would be employed.

***Pilocarpine Nitrate**, U.S.P., is freely sol. in water (1:4). Dose, 3 to 12 mg., $\frac{1}{20}$ to $\frac{1}{5}$ grain. The *hydrochloride* is highly deliquescent and therefore undesirable.

◆

PHYSOSTIGMINE AND NEOSTIGMINE (PROSTIGMINE)

Physostigmine (also called *eserine,* from the native African name of the plant), an alkaloid of physostigma or "calabar bean," has been synthesized (by P. L. Julian and Pikl, 1935). It has a cholinergic action, chiefly by inhibiting the esterase that converts acetylcholine into the much less active choline. Its effects, therefore, correspond to those of parasympathetic stimulation, and it is a potent antagonist of atropine. Its powerful miotic action is employed in glaucoma, the stimulation of the intestines in intestinal paresis. Glandular stimulation is much less marked than with pilocarpine. It causes fascicular twitchings of striped muscle and is mutually antagonistic with curare. It is used in the treatment of myasthenia gravis. It is quite toxic by depression of the central nervous system, including paralysis of the respiration. It is employed as the salicylate. Solutions deteriorate on standing, turn brown and become more irritant. The characteristic sensitization to parasympathetic stimulation by inhibition of acetylcholine esterase is also produced by a considerable series of aromatic amine urethane derivatives (A. C. White and Stedman, 1931; N. W. Karr, 1942). The most important is *neostigmine* (*prostigmine*). Its somewhat lower toxicity is advantageous for systemic administration in myasthenia. Its intestinal potency is about equal to that of physostigmine; its miotic action is somewhat less.

Synergism of Smooth Muscle.—Fuehner, 1918, demonstrated on the ganglion-free smooth muscle of the *leech* body the remarkable potentiation by physostigmine of the stimulant action of acetylcholine (over 1,000,000 times) and to somewhat less degree of barium, while choline and pilocarpine are not potentiated at all by physostigmine. Guanidine acts like physostigmine, but is somewhat weaker.

Autonomic Antagonisms.—The inhibition of the augmentory actions by atropine is less complete for physostigmine than for acetylcholine, so that there is still some question whether physostigmine acts solely on the choline esterase (A. S. Dale and Narayana, 1935; Kahane and Levy, 1937). Physostigmine neutralizes the atropine action on the parasympathetic innervation of smooth muscle in practically all organs, but not the secretory paralysis of glands. It antagonizes the augmentor actions of epinephrine on the uterus, heart and blood vessels, but not the depressant action on intestines or on guinea pig uterus. It does not antagonize barium or posterior pituitary stimulations (K. Granberg, 1926).

Actions on the Eye.—Physostigmine causes constriction of the pupils (discovered by Fraser of Edinburgh, 1863), spasm of accommodation (near vision), twitching of the eyelid and lowering of the intra-ocular pressure. The intra-ocular actions are due to increased excitability of the oculomotor receptive mechanism. The effects of physostigmine can be removed by the application of atropine, and *vice versa;* but this requires much larger doses than does a normal eye. The localization was discussed in the general description of autonomic reactions.

The action on the pupil appears somewhat earlier and lasts somewhat longer than that on accommodation; on local application of a 1 per cent solution the *miosis* begins within ten minutes, reaches its maximum in thirty to fifty minutes, stays maximal for three or four hours and then disappears gradually in three or four days. The physostigmine contraction is greater than can be produced by strong light, although the physostigmine pupil contracts further even to weak light. With the maximal contraction, the pupil is generally irregular in shape. Physostigmine is much more effective in counteracting the mydriasis of cocaine than of atropine. *The spasm of accommodation* begins in about twenty minutes and passes off in about two and one-half hours, leaving the excitability somewhat increased. Through the contraction of the ciliary muscle, the lens becomes more spherical and objects appear enlarged and more distant. *The excised iris sphincter of mammals* is constricted by dilutions of 1:30,000, the intensity varying with the concentration. With 1:50,000, it dilates (D. R. Joseph, 1917). In the normal eye, physostigmine produces a slight fall (3 to 8 mm.) of *intra-ocular tension*, lasting some twelve hours (Luebs, 1913). The fall is more marked in glaucoma (Bollet and Curtil, 1911).

Permeability.—After intravenous injection of trypan red, this appears in the aqueous humor much more abundantly when the eye is inflamed or when physostigmine is applied. It is not influenced by atropine (P. A. Lewis, 1916). The potency of *local anesthetics* on rabbit's conjunctiva is diminished by neostigmine (Le Bow and Slaughter, 1945).

Therapeutic Use of Oculomotor Actions.—Physostigmine may be used to counteract effects of atropine, to break up adhesions of the iris and lens (in alternation with atropine); in the treatment of peripheral corneal ulcer; and to lower the intra-ocular pressure in *glaucoma.* The continued use of physostigmine or pilocarpine produces amelioration of the glaucoma symptoms, often more than iridectomy; but they are not curative (Posey, 1914). Witmer, 1921, states that strong solution (2 drops of 1 per cent) may provoke an acute attack of glaucoma in patients subject to the disease; while $\frac{1}{10}$ per cent solution tends to relieve attacks. Even this concentration may produce conjunctivitis if its use is long continued. Its action in *ulcer* is perhaps explained by contraction of the iris vessels.

Application.—Physostigmine is used locally, in 0.1 to 1 per cent solution of the salicylate (in glaucoma, generally 0.1 per cent, two to six times a day). Solutions of 0.5 per cent and higher sometimes cause considerable irritation and pain.

Intestines.—Therapeutic doses of physostigmine increase gastric and intestinal peristalsis. Toxic doses produce spastic contraction. The action is utilized in intestinal paresis (postoperative ileus, etc.): 2 mg. ($\frac{1}{30}$ grain) hypodermically (larger doses would be dangerous). Cannon and Murphy, 1907, showed that it has a marked effect, lasting, however, only a few hours. Acetylcholine has been added to increase the action (McCrae).

Colon movements, recorded from human colostomized patients by a balloon technic, are stimulated by 1 mg. of physostigmine, and more potently by neostigmine. The latter is markedly potentiated by pituitrin and by ergot (H. F. Adler and Atkinson, 1941).

In experimental *paralytic ileus* produced in dogs by intestinal obstruction, A. Ochsner, Gage and Cutting, 1930, found physostigmine the only substance that consistently raised the intestinal tone and motility (neostigmine was not tried). Pituitary, choline, acetylcholine and hypertonic sodium chloride solutions were ineffective. With excised rabbits' intestines, physostigmine produces large rise of tonus by parasympathetic stimulation, abolished by atropine. Larger doses paralyze the parasympathetic ganglia, and still larger doses the muscle (Heathcote, 1932). J. L. Law, 1940, reports considerable success from treating *megacolon* in children with parasympathetic stimulants.

Neostigmine against postoperative intestinal paresis is at least as effective as physostigmine, and somewhat less toxic. One cc. of 0.5:1000 solution is injected hypodermically on the day after the operation, and repeated in four to five hours if necessary. Its action is assisted by an enema. It is used similarly with *postoperative paresis of the bladder.* It generally produces fecal and urinary evacuation in about half an hour. It has relatively little action on the pupil, and in therapeutic doses on the circulation. Harger and Wilkey, 1938, advise prophylactic injection of 0.25 mg. at the time of operation, repeated every four to six hours, or every two hours if necessary.

Gastric movements in man are usually inhibited by *neostigmine*, but it increases them after atropine (Veach, Lauer and James, 1938). The volume and acidity of the *gastric juice* are increased (Necheles *et al.*, 1938).

Pharmacology of Neostigmine.—This was synthesized by Stedman, 1931, and investigated pharmacologically by Aeschlimann and Reinert, 1931, and clinically by Weigandt, 1931, and Carmichael *et al.*, 1934. It is less active than physostigmine on the eye and less depressant to the heart and blood pressure (0.1 mg. per Kg. had practically no effect); but 0.02 mg. per Kg., by vein, stimulates peristalsis, and 1:7,500,000 contracts the isolated intestine of rabbits. Its toxicity by hypodermic injection in rabbits is about four times greater than that of physostigmine. Aiazzi-Mancini, 1934, found that 1:100,000 increases the movement and tonus of the excised intestines of rats, antagonizes the epinephrine paresis and is inhibited by atropine. In *rabbits* it produces transient vasoconstriction, stimulation of the vagus and paralysis of the respiration. On *leech muscle* it is synergistic with acetylcholine and with barium.

Striped Muscle.—Physostigmine and neostigmine produce fascicular contractions and tonic contracture. Several distinct actions are involved:

(1) *Fascicular twitchings* of peripheral origin, *not* antagonized by atropine, increased by blocking the nerve with procaine, not abolished by section of the motor nerve (Harnack and Witkowski, 1876), but disappearing on degeneration of the nerve (Magnus, 1908; Langley and Kato, 1915). The action is, therefore, on the receptive mechanism. It is mutually antagonistic with curare (Pal and Rothberger) and with magnesium (Meltzer and Auer, 1906; Joseph and

Meltzer, 1909). Similar twitchings are produced by guanidine, barium, nicotine and by electric nerve stimulation in certain stages of fatigue (Langley, 1916; Langley and Kato, 1920). (2) *Tonus* in frogs, by peripheral action, through sensitization to acetylcholine, and antagonized by atropine. (3) *Tonus* in fowl, by direct muscular action, not prevented by atropine or by nerve degeneration (Edmonds and Roth, 1908). (4) *Coarser contractions of the muscles;* nystagmus and rhythmic movements of the nictitating membrane of cats. These are of central origin and are abolished by atropine. (5) *Increased work capacity* with diminished lactic acid production, in athletes as well as in excised frog muscle (E. Milla, 1939). (6) Large doses of physostigmine weaken the response of muscle in cats, both to direct and to indirect stimulation (F. W. Maurer, 1939).

In *warm kept frogs*, physostigmine and neostigmine produce no change in the main response to stimulation, except in after-tension after the shock (S. L. Cowan, 1940).

Direct Muscular Action.—When choline esterase has been inactivated by "DFP," skeletal muscles respond to arterial injections of neostigmine as they do to acetylcholine, suggesting that neostigmine acts directly on muscle, in addition to its inactivation of the esterase. Its chemical structure is also related to the choline esters; the latter, conversely, inhibit choline esterase (W. F. Riker *et al.*, 1946).

Motor nerves exposed directly to physostigmine or neostigmine show practically no change in action current, but lower stimulation-frequency suffices for contraction (S. L. Cowan, 1940).

In *myasthenia gravis*, neostigmine and physostigmine produce marked but transient improvement of muscular tonus (Mary B. Walker, 1934, 1935). The effect is noticeable in five minutes after hypodermic injection of 1.5 to 2.5 mg., becomes optimal in an hour and fades in six to eight hours. For continued treatment, 0.5 mg. of neostigmine may be administered hypodermically, or 15 mg. by mouth, beginning with three times daily. Viets, 1944, states the average daily maintenance dose as 163.5 mg. One patient took 375 mg. (25 tablets) daily for more than two years, without untoward effect. No tolerance is acquired. Ephedrine, potassium chloride, or guanidine is sometimes added. Neostigmine does not improve the muscle tonus in other neurologic conditions, so that it has some diagnostic as well as therapeutic value (A. M. Harvey and Whitehall, 1937; Gammon and Scheie, 1937). The effects agree with those of acetylcholine, and Dr. Walker introduced physostigmine on the assumption that myasthenia involves acetylcholine deficiency.

Intra-arterial injection of neostigmine into the brachial artery of *normal subjects* produces local paresis and fascicular twitchings. *In myasthenia* patients it causes almost immediate increase of grip strength, lasting three to five hours. Even high concentrations do not produce fascicular twitchings as in normal subjects. Intra-arterial injection of *acetylcholine* also produces transitory weakness in *normal* subjects. In *myasthenia* patients it causes sustained contracture of the injected muscle. *Epinephrine* increases the motor power, but much less than does neostigmine. *Ephedrine* by mouth results in moderate increase of muscle power (A. M. Harvey *et al.*, 1941). Destruction of choline-acetylase by intra-arterial injection of "*DFP*," (1.5 mg. in 3 cc. of saline into brachial artery) is similar to that effected by neostigmine, but the improvement of local strength is noticeable for eight to ten days (A. M. Harvey *et al.*, 1946).

These facts would suggest that myasthenia involves excess of choline acetylase, but this is not so The choline esterase content of muscle (M. S. Jones and Stadie, 1939) and of blood (A. Wilson and Stoner, 1944) is normal, but is lowered when physostigmine or neostigmine is administered (A. T. Milhorat, 1941). The serum and cerebrospinal fluid are less effective than normally in promoting acetylcholine synthesis *in vitro* (Torda and Wolff, 1944).

An alternative assumption is that myasthenia involves some curare-like factor that impedes the transmission of acetylcholine stimulation to the muscle, and that can be overcome by increasing the acetylcholine concentration, directly or by blocking the acetylase. Clinical observations suggest that this curaroid factor comes from *hypoplastic thymus*, for half of the myasthenia patients have demonstrable abnormalities of the thymus, and excision of this gland often results in prompt cure (Blalock, McGehee *et al.*, 1941; A. M. Harvey *et al.*, 1942).

Relief of "Muscle Spasm."—Neostigmine decreases the proprioceptive hyperirritability and incoordination of *poliomyelitis*, and partially relaxes the muscle spasm, relieving the pain and facilitating the use and training of the muscles. It was reported to give similar relief in rheumatoid *arthritis*, fibrositis and bursitis, in spastic hemiplegia and post-trauma disability, even if this has persisted for years. The action is not antagonized by atropine and is assumed to be directly on synapses in the spinal cord (Kabat and Knapp, 1943; H. Brainerd *et al.*, 1945; M. J. Fox and Spankus, 1945; A. Cohen, Trommer and Goldman, 1946). The results in rheumatoid arthritis have been disappointing, and over half the patients had alarming reactions (P. S. Hench, 1946; V. G. Baldoni *et al.*, 1946). Intrathecal injection of neostigmine in man produces loss of muscle tonus (M. Kremer, 1942).

Deafness is sometimes benefited by neostigmine (C. T. Davis and Rommel, 1939). The mechanism is not clear, and others have found no significant improvement in fairly extensive series of patients (Ersner *et al.*, 1941).

Bronchial Stimulation and Pulmonary Circulation.—Physostigmine contracts bronchial and tracheal muscle, with asthma-like dyspnea. It is claimed that the alveoli themselves are contracted, in contrast to histamine (J. Yamada, 1930), but this is difficult to conceive. Perfusion of physostigmine through the pulmonary circulation causes constriction of the pulmonary vessels as well as of the bronchi (A. S. Dale and Nasayana, 1935).

Systemic Circulation.—In man, therapeutic doses of physostigmine or neostigmine (0.5 mg. hypodermically) produce marked rise of skin temperature, lasting two to six hours, owing to arterial vasodilatation (Perlow, 1939). Toxic doses of physostigmine cause serious dizziness and faintness, without significant change in the heart rate (Robinson, 1915). The experimental data are somewhat complex (Heathcote, 1932). In general, *small doses* of physostigmine slow the heart rate in frog, rabbit and cat. They increase the T wave of the electrocardiogram (F. R. Miller *et al.*, 1940). *Moderate doses* potentiate vagus and acetylcholine stimulation (Verlot, 1936), and prolong but do not increase the acetylcholine fall of blood pressure (E. Zinnitz, 1936). The cardio-inhibiting carotid reflex is strongly sensitized (Van der Linden, 1932). *Large doses* paralyze the vagus ganglia or center. *Very large doses* produce systolic arrest by direct action of the cardiac muscle.

Sensitization to Choline and Acetylcholine.—Preliminary injection of physostigmine greatly intensifies and prolongs the effects of choline and acetylcholine on the circulation, both the vagal phase (slow heart and fall of blood pressure) and the sympathetic phase (quickened heart and rise of pressure; Viale and Martini, 1931). Small doses potentiate and large doses antagonize the pressor action of nicotine (F. W. Maurer, 1939).

The *blood pressure* tends to rise by strong vasoconstriction, partly through sensitization of the carotid sinus vasomotor reflex (Vercanteren, 1932), but chiefly by peripheral action mainly on the intestinal vessels (Dixon, 1903). It occurs on perfusion of the limbs of frog and cat and of the ear and kidney of rabbit. It is not prevented by atropine or ergotamine (T. Kunika, 1927). The action is, therefore, directly on the arterial muscle.

Neostigmine quickens the excised frog heart, but produces peripheral vagus slowing in dogs. It increases the blood pressure of cats, also after atropine, perhaps by increasing epinephrine output. In dog heart-lung preparations it slows the heart, decreases the total output and the coronary flow, with variable effects on the blood pressure (Mendez and Ravin, 1941). It has been reported useful against peripheral *vasospasm*, 7.5 to 15 mg. by mouth three times daily (Perlow, 1940).

Polycythemia; Contraction of the Spleen.—Physostigmine produces acute and considerable increase of the red cells and also of the total volume of the circulating blood (maximum in an hour, return to normal in two or three hours) (Nelson and Edmunds, 1923). This does not occur if the spleen has been excised, so that it is due to contraction of the splenic musculature (P. Testoni, 1930). The increased blood volume also contributes to the rise of blood pressure. The *coagulation time of the blood* is shortened by physostigmine, in dogs and rabbits (S. Marras, 1934).

Blood Sugar Level.—In rats, physostigmine produces marked rise of blood sugar. Atropine prevents this effect (Preobrazkenski, 1934; M. C. Hrubetz, 1937).

Epinephrine output is increased by physostigmine, in contrast to pilocarpine. The stimulation is central, for it does not occur after section of the nerves (Stewart and Rogoff, 1920).

Glandular Secretions.—Physostigmine stimulates the same glands as pilocarpine (except mammary; Ott and Scott, 1912); but the increase of secretion is much less marked, being counteracted by the vasoconstriction. Like other intestinal stimulants, physostigmine increases the elimination of *uric acid* (Abl, 1913).

Sweat.—Physostigmine provokes sweating of cat's paw. This is decreased or arrested by section of the nerves, so that the action is perhaps partly central (Langley and Kato, 1915).

Menstruation.—Neostigmine, 0.25 mg. intramuscularly, or 0.5 mg. of the methylsulfate, on three successive days almost invariably induces menstruation without untoward results in amenorrhea when this is not due to pregnancy, endocrine deficiency or gross pelvic disease. It is useful in treating temporary functional amenorrhea; but as a diagnostic sign of pregnancy it is unreliable, misleading, and sometimes causes abortion (Soskin, Wachtel and Hechter, 1940; A. Winter, 1940; Winkelstein, 1942).

Central Effects.—The action on the central nervous system is first tetanizing (Heubner, 1905), then rapidly paralyzing, *beginning*, at least in man, in the *lower portions*, so that *consciousness is preserved* to the end. The *respiration* is at first increased, due largely to stimulation of the afferent endings of the vagi, for the quickening is much less after the vagi have been cut. There are also other evidences of stimulation—excitement, etc.—but these have been considered *secondary to respiratory paralysis*, the central actions of the alkaloid being mainly depressing. It inhibits the knee jerk and depresses other spinal reflexes (Merlis and Lawson, 1939). Dyspnea is a marked symptom, due to paralysis of the respiratory center and spasm of the bronchial muscles (Harnack and Witkowski, 1876). The depressant action of physostigmine has led to its therapeutic trial in epilepsy, chorea, tetanus, etc., without much success. Neostigmine and acetylcholine depress spinal reflexes and inhibit strychnine convulsions, but physostigmine has the opposite effect (Schweitzer and Wright, 1937). In dogs, physostigmine decreases the minimal convulsive and lethal dose of *metrazol* and increases the intensity and duration of the convulsions. Pilocarpine does not have this effect (Gutierrez-Noriega, 1945). Neostigmine inhibits respiration. This may be preceded or followed by stimulation, the latter more marked in decerebrate animals (A. Schweitzer and Wright, 1938).

Neostigmine-Morphine Synergism.—Dr. Slaughter *et al.*, 1940, 1946, report that neostigmine doubles the analgetic potency of morphine clinically (0.5 mg. of the methylsulfate, hypodermically) and in cats. It produces a similar increase of analgesia with dilaudid and codeine, but not with monoacetyl morphine. H. L. Andrews, 1942, failed to confirm the potentiation, and the matter is in dispute.

Physostigmine Poisoning.—The *symptoms* are restlessness, weakness, nausea, vomiting, sometimes purging; epigastric pain; rarely miosis; salivation, lacrimation and sweating; palpitation with slowed pulse; dyspnea; muscular twitchings; convulsions; collapse. Death occurs by asphyxia, through depression of the respiratory center and by bronchial spasm (Schweitzer and Wright, 1938), with the reflexes preserved to the end. The fatal dose is not known. The location of the *emetic action* has not been definitely determined, because of the difficulty of fixing the emetic dose (Eggleston and Hatcher, 1915). *The treat-*

ment of physostigmine poisoning consists in evacuation, stimulants and atropine ($\frac{1}{2}$ to 1 mg.). Frazer found that small doses of atropine saved animals from three times the fatal dose of physostigmine, but that larger doses are synergistic; curare and magnesium are effective in the laboratory, but are dangerous for man.

Fate.—Physostigmine is not destroyed by frog's liver (Clark, 1912).

Neostigmine Poisoning.—Although 30 mg. by mouth do not produce untoward effects (Everts, 1935), even when repeated three times daily, 45 mg. by mouth cause toxic symptoms, identical with those of physostigmine. They may be quite severe. Goodman and Bruckner, 1937, report vagal bradycardia and salivation; then, three hours after the administration, sudden onset of collapse, great intestinal hyperactivity of a peculiar variety, fibrillary twitching of skeletal muscles, and miosis. Improvement began in an hour (atropine had been given). Consciousness was not disturbed. The minor toxic effects which sometimes occur in the clinical use are promptly relieved by atropine, 0.65 mg. ($\frac{1}{100}$ grain) under the tongue (Perlow).

Eseridine, another alkaloid of physostigma, acts similarly to physostigmine, but is only about a tenth as active (R. S. A. Heathcote, 1932).

PREPARATIONS.—***Physostigmine Salicylate,** U.S.P. (Eserine Salicylate), is soluble in water (1:75) and in alc. Dose, 0.6 to 2 mg., $\frac{1}{100}$ to $\frac{1}{30}$ grain. Watery solutions of Physostigmine salts (not the dry salts) oxidize under the influence of light, air and the alkali of glass vessels, acquiring a pink color (due to "rubreserine," Woelfflin, 1913). Such colored solutions should not be employed; Hallauer, 1899, states that they are more irritant. The decomposition products include rubreserine and eserine blue (with about a hundredth the potency of physostigmine on serum acetylcholine esterase), and the inactive eseroline and eserine brown (S. Ellis, Krayer and Plachte, 1944). The decomposition is retarded by the addition of a little boric acid.

***Neostigmine Bromide,** U.S.P., *Prostigmine bromide*, is a white, crystalline powder, freely sol. in water (1:1), relatively nonhygroscopic; used orally for the treatment of myasthenia gravis, as the *Neostigmine Bromide Tablets*, U.S.P., usually 15 mg., three times daily (the dosage may be doubled cautiously, if necessary).

Neostigmine Methylsulfate, U.S.P., sol. in water (1:10), is used hypodermically as the *Neostigmine Methylsulfate Injection*, U.S.P., in water for injection, usually available in ampuls of 0.25 mg. and 0.5 mg. in one cc. For prevention of *postoperative distension* 0.25 mg. is injected every four to six hours, beginning twenty-four hours before the operation; for treatment of this condition, 0.5 to 1 mg.; for myasthenia gravis, 0.5 mg.

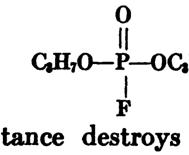
DI-ISOPROPYL FLUOROPHOSPHATE, "DFP,"



$$C_3H_7O-\overset{\overset{\displaystyle O}{\|}}{\underset{\underset{\displaystyle F}{|}}{P}}-OC_3H_7$$

This substance destroys choline esterase irreversibly, so that its administration decreases profoundly the choline acetylase activity of the blood plasma and muscle for several weeks after a single administration, although it returns eventually as new esterase is formed. It relieves the muscle weakness of myasthenia gravis less completely but more persistently than neostigmine (Comroe, Todd *et al.*, 1946). It relieves glaucoma more often than physostigmine (review, A. Gilman, 1946).

Sodium fluorophosphate also inhibits choline esterase, but alkyl groups which render it fat soluble, greatly increase its action.

Serum choline esterase is especially susceptible to DFP, so that it may be destroyed by doses which leave that of other tissues practically intact. Synaptic transmission and the functions of muscle and nerve tissues are not inhibited until a dosage is reached which destroys nearly 80 per cent of their choline esterase. Conduction in the nerve fibers themselves is not affected by complete destruction of their choline esterase (Crescitelli, Koelle and Gilman).

The regeneration of choline esterase of serum requires a few weeks; several months are necessary for the brain and muscle.

Injected into the brachial artery, 1.5 mg. of DFP in 3 cc. of saline, produce the same effects as acetylcholine or neostigmine: diffuse sweating of the forearm and hand, numerous spontaneous fasciculations, pronounced motor weakness. A single nerve stimulus gives the normal voltage of muscle potential, but the response becomes repetitive. The effects reach their height in thirty to forty minutes and are still detectable after 120 hours.

DFP inhibits the action-potential for direct stimulation of curarized skeletal muscle (R. Couteaux *et al.*, 1946).

The effects in *myasthenia gravis* patients are the same as with neostigmine: striking localized increase of muscular strength, perceptible for eight to ten days; no fascicular twitchings. The improvement of motor power does not occur if neostigmine was injected just prior to the DFP (A. M. Harvey, Jones *et al.*, 1946).

Continued administration of therapeutic doses does not result in significant damage. *High doses* produce nicotinic fibrillation, transient muscarinic signs (bronchial constriction, salivation, diarrhea), persistent urinary incontinence, hindleg paralysis; cardiospasm with extreme esophageal distention, leading to death by starvation (G. B. Koelle and Gilman, 1946).

Physostigmine protects choline acetylase from inactivation by DFP *in vivo*, and gives considerable protection against the toxic effects of DFP, provided that this is administered in advance. Physostigmine with atropine saves from thirty times the LD_{50}. If the DFP, however, is injected first, it sensitizes to physostigmine. The sensitization persists for months after the choline acetylase has returned to normal. DFP also sensitizes to future administration of DFP (R. Koster, 1946).

Conjunctival instillation of 0.1 to 0.2 per cent DFP in normal men produces miosis lasting six to twenty-seven days, and decreased intraocular tension for four to eight days, without local irritation. It overcomes and outlasts the cycloplegic action of atropine and homatropine. In *glaucoma* it is more often effective than physostigmine and pilocarpine, and needs less frequent application. *Undesirable effects* are visual blurring, brow and eyeache, spasm of accommodation and pericorneal congestion (Leopold and Comroe, 1946).

◆

CHOLINE AND CHOLINE ESTERS

Acetylcholine is important as the parasympathetic neurohormone. It is rapidly hydrolyzed by the choline esterase of the blood and tissues into the much less active *choline*, trimethyl-oxyethyl-ammonium hydroxide,  $(CH_3)_3N\langle^{CH_2CH_2OH}_{OH}$. This occurs as a constituent of lecithin probably in all animal and vegetable tissues. It is doubtful whether it exists free in the living tissues, in detectable quantity. Choline and its derivatives have *three distinct actions* (Dale, 1914) which vary independently in relative degree in the different derivatives: (1) parasympathetic stimulation ("*muscarinic action*"), which lowers blood pressure of nonatropinized cats; (2) "*nicotinic action*," which stimulates autonomic ganglia and many myoneural functions, including skeletal muscle, in small concentrations; and depresses them in high concentrations (Rosenblueth and Simeone, 1938). It raises the blood pressure of atropinized cats, and also produces contracture of denervated gastrocnemius of the cat; and (3) *epinephrine mobilization*, resulting in dilatation of denervated and atropinized iris. These actions are also produced by other *quaternary ammonium bases, arsonium* and other compounds of this general structural pattern (Reid Hunt and Renshaw, 1933). Numerous esters of choline have been prepared, and studied pharmacologically, especially by Reid Hunt and his associates. They may be discussed together, as their actions are qualitatively identical, but they differ greatly in potency, in the relative prominence of the three types of effects and in stability and, therefore, duration of action. Acetylcholine itself is unstable and its action brief. Its derivatives generally act by liberating acetylcholine (Renshaw *et al.*, 1938). Acetyl-beta-methylcholine (*methacholine*, "*mecholyl*") is stable enough for therapeutic use, intramuscularly as a brief but powerful parasympathetic stimulant, to slow the heart in tachycardia, to dilate the blood vessels in high blood pressure, and locally by electrophoresis for ulcers and arthritis; and more doubtfully for gastro-intestinal motor and secretory stimulation.

The *sensitivity to acetylcholine* is greatest for vasodilatation, then, successively, adrenal secretion, splenic contraction, respiratory acceleration. Cardiac inhibition requires relatively large doses (Tournade and Chardon, 1939). The most sensitive *test object* is physostigminized leech muscle, which detects 0.002 mg.; the Straub frog heart and the mouse intestine show 0.010 mg. (Gaddamer, 1936). Small intact earthworms are reported as sensitive as leech muscle (Gavrilesco and Ionesco, 1940).

Historical.—Choline was first isolated by Strecker, 1849, from bile; in 1862 he established its chemical constitution (G. A. Alles, 1934—reviewed). Acetylcholine was first prepared by von Baeyer in 1867. It was isolated from animal tissues by Dale and Dudley, 1929.

Distribution of Choline.—Choline and acetylcholine are the only forms which have been isolated from animal tissue and chemically identified. Choline may be assayed by conversion into acetylcholine and this by bio-assay, first suggested by Hunt and Taveau, 1906. Normal serum contains 2 to 20 mg. per liter (Hunt, 1915). About the same concentration exists in amniotic fluid; somewhat more in the urine and in cardiac and skeletal muscle; much less in cerebrospinal fluid and saliva. The proportion in the blood or cerebrospinal fluid has not been found increased in any pathologic conditions examined in man. No extra amount is liberated in anaphylaxis (S. Farber *et al.*, 1944). It has been reported increased by removal of the suprarenals, but the evidence is not decisive and does not prove a causative connection (Hunt, 1915). *Acetylcholine* is reported to occur regularly in the gastric juice of man and dog (E. Bloch and Necheles, 1938). It was demonstrated in ergot by Ewins, 1914.

Extraneous Sources of Choline.—Choline may be liberated from lecithin by putrefaction or autolysis. It therefore occurs in organ extracts, in many vegetables (Schulze and Trier, 1912) and in certain drugs (especially ergot). It may be formed in intestinal putrefaction, but it is readily destroyed by the intestinal bacteria and is less toxic than the analogous neurine and various amines which are also formed in putrefaction. Choline is but slightly toxic on hypodermic injection.

Fate.—Choline is largely destroyed in the body (v. Hoesslin, 1906). Its oral or hypodermic administration does not increase the amount in the urine, and intravenous injection does so but little (Guggenheim and Löffler, 1916), although it disappears rapidly from the blood stream (Hunt, 1915). After oral administration only 3 per cent of the choline can be recovered from the tissues; with intravenous, about 50 per cent, the greater proportion from the skin (Ellinger, 1914). It is not detroyed by blood *in vitro* (Wrede *et al.*, 1929). The destruction occurs largely in the liver, where the alcohol group is rapidly oxidized by an oxidase specific for choline (F. Bernheim and Webster, 1934). A part of the methyl is probably oxidized to formic acid, the remainder to CO_2 and water. No trimethylamine is formed (H. Fuchs, 1938). *The stability of acetylcholine* in aqueous solution was studied by Demole, 1930.

Acetylcholine esterases hydrolyze the ester in the tissues (Stedman *et al.*, 1932). Their concentration is especially high along the surface of the axons (Nachmansohn, 1941). Choline acetylase is inhibited by physostigmine, neostigmine and related substances, and to a less extent by a variety of other substances, including fluoride, antipyrine and other pyrazolones (E. A. Zeller, 1942). The physostigmine and neostigmine inhibition is a reversible balanced reaction, competing with acetylcholine for the surface of the enzyme (G. S. Eadie, 1942). Neostigmine is more effective than physostigmine (Babkin *et al.*, 1942). It is destroyed by "DFP" (see Index).

Choline Derivatives.—Hunt and Taveau, 1906 to 1911; Hunt, 1915; Ewins, 1914; Dale, 1914; and Simonart, 1932, investigated the relative toxicity and circulatory effects of a large series of choline derivatives. The substitution of OH in choline generally increases its activity, often greatly (Dale). The introduction of the acetyl radical increases the depressor effect 100,000 times, the toxicity only three times (Hunt). The correlation of the pharmacological actions with the physicochemical properties was attempted by von Oettingen and Bowman, 1933.

Choline antagonizes the acute toxicity of its triethyl analogue (A. S. Keston and Wortis, 1946).

Neurine, trimethyl vinyl ammonium hydroxide, may be formed from choline by bacteria. Its actions are similar to those of choline, but much stronger (Pal, 1911); it is far more toxic (Lohmann, 1911).

Betaine, trimethyl glycocoll anhydride, is nearly inactive by mouth; hypodermically, it acts similarly to choline. It is nontoxic (Velich, 1914); even 2.4 Gm. per kilogram by vein, in the rat, are harmless. It is excreted unchanged, and is therefore not a food (Andrlick, Velich and Stanek, 1902). The preparation and properties of its salts are described by Stolzenberg, 1914. It may be assayed by the response of striped, cardiac or smooth muscle, after conversion into its crotonic methyl ester (E. Strack and Fösterling, 1942). Betaine hydrochloride dissociates in solution, and has been utilized as a means of administering loosely bound hydrochloric acid. The dose, 0.5 Gm., corresponds to about 1.1 cc. of official Dilute Hydrochloric Acid.

Sulfonium Compounds.—The substitution of sulfur for the nitrogen of choline and betaine esters does not greatly alter their actions. In some cases there is considerable increase of the paralyzing nicotinic and curare actions. The addition of oxygen to the sulfur (sulfonyl compounds) greatly diminishes the potency (Hunt and Renshaw, 1932).

Acetyl-beta-methylcholine (Methacholine Chloride, Mecholyl) is closely related to acetylcholine. It produces practically no "nicotinic" action, *i. e.*, no stimulation of the sympathetic ganglia and no rise of blood pressure, but causes strong parasympathetic stimulation, *i. e.*, cardiac inhibition; peripheral vasodilatation involving most of the blood vessels, with fall of pressure; and stimulation of gastric and intestinal peristalsis.

Acetylcholine in small intravenous doses produces muscarinic effects (parasympathetic stimulation, antagonized by atropine). Nicotinic effects (rise of blood pressure after atropine) require much larger doses (Hunt and Taveau, 1911; Simonart, 1932). The effective dosage varies considerably in the same tissue; in frogs' heart, for instance, the minimal effective concentration ranges from 10−8 to 10−6 (Fuehner, 1923).

The *chief difference between mecholyl and acetylcholine* and most other choline esters is that the mecholyl hydrolyzes more slowly, in solution and in the tissues, and its action is therefore more lasting, although still brief: with intravenous injection, the effects on the heart and blood pressure last about a minute, those on the gastro-intestinal tract for ten to twenty minutes. The intensity of the actions is about the same with intravenous injection of equal doses of acetylcholine and mecholyl; but with hypodermic and oral administration, mecholyl is more effective.

Ethyl-beta-methylcholine acts similarly to the acetyl-beta-methyl choline. It is more stable, but somewhat less potent (J. Starr *et al.*, 1933).

Carbachol (*Doryl, Lentine*) is a relatively stable derivative, carbamylcholine chloride, with similar actions (Kreitmair, 1932; Dautreband, 1933; Velten, 1933). It is used locally in the eye for parasympathetic stimulation. Its intramuscular injection has caused fatalities (J.A.M.A., 1943, *123:* 1051).

Historical.—*Acetyl-beta-methylcholine* was first prepared by Taveau, 1909, and its pharmacology investigated by Hunt and Taveau, 1911, and subsequently by Simonart, 1932; Comroe and Starr, 1933; and others. Its clinical introduction is due chiefly to Starr and his associates, 1933. The earlier work entailed some confusion between the alpha and beta homologues, which was cleared by Major and Chite, 1932. Hunt and Renshaw, 1934, point out that their pharmacologic results of 1911 show that they had worked with the beta, since the alpha produces more pronounced nicotinic effects.

Response of Normal Human Subjects to Acetyl-beta-methylcholine.—The following phenomena are reported by J. Starr *et al.*, 1933, and Myerson *et al.*, 1937: Within a minute after the hypodermic injection of 20 or 30 mg. of mecholyl, the face, neck and chest become flushed. This is followed by generalized sweating, salivation, rhinorrhea, lacrimation, slight or moderate fall of blood pressure; increase of pulse rate lasting a few minutes and often followed by slowing, generally with transient sinus arrhythmia; rise of cerebrospinal blood pressure. The effects last several minutes. They can be prevented by atropine. One subject in the twenty studied by Starr developed a typical and rather alarming asthmatic attack; three others had a sensation of substernal constriction. *Oral administration* requires 50 to 100 times the hypodermic dosage to produce significant effects, and the symptoms are milder and develop more gradually. The *nasal mucous membrane* absorbs mecholyl rapidly, with the same phenomena, including a precipitate fall of blood pressure lasting three to sixteen minutes (Van Dellen *et al.*, 1937).

Response of Normal Human Subjects to Acetylcholine.—The phenomena reported by Carmichael and

Fraser, 1933, differ but slightly from those described for acetyl-beta-methylcholine: *Intravenous injection* of 10 to 30 mg. (in forty-six subjects) was followed in a few seconds by abrupt slowing of the heart, a sensation of obstructed breathing leading to increased rate and depth of respiration, a burning sensation in the throat and the desire to cough. These last only a few seconds and are followed by quickening of the heart above normal, flushing of the face and neck, a sensation of heat and sometimes palpitation. This second phase passes off more gradually, but the whole reaction is over in half a minute. The blood pressure falls as the pulse slows and rises a little above normal when the pulse quickens. The degree of response varies in different subjects. It can be intensified by the previous injection of physostigmine and abolished by atropine, not by epinephrine.

Continuous Intravenous Injection.—L. B. Ellis and Weiss, 1932, found (on seventeen normal human subjects) that acetylcholine has to be injected at the rate of 20 to 60 mg. per minute to maintain definite but minimal effects. The maximum tolerated rate was 90 to 140 mg. per minute. This therefore represents the rate of destruction. The larger doses caused nausea and emesis. The blood pressure was generally unaltered. The largest tolerated quantity injected amounted to 1 Gm. in ten minutes. Man appears to be more tolerant than animals. *Hypodermic injection* is much less effective, requiring about 200 times the dosage of intravenous injection, or of intramuscular mecholyl (L. Weiss and Ellis, 1934). *Intra-arterial injection* produced marked regional vasodilatation, lasting half an hour after injection, so that the destruction was much slower than with intravenous injection (Ellis and Weiss).

Toxic Dosage of Choline.—With ordinary slow venous injection, cats show no toxic effects after 15 mg. per Kg.; 30 mg. produce reversible arrest of respiration; 35 mg. per Kg. are fatal. As the choline is rapidly destroyed, 0.8 to 0.9 mg. per Kg. per minute (as 0.2 to 0.4 per cent) may be injected practically indefinitely (Arai, 1922). Neostigmine greatly increases the response to mecholyl, and may lead to dangerous cardiac collapse (Myerson, Rinkel *et al.*, 1937).

Cardiac Inhibition.—Choline and its esters weaken and slow the heart by vagus stimulation, central and peripheral (Hunt, 1915). Doses of acetylcholine too small to stimulate directly increase its sensitivity to electric stimulation. Large doses (0.2 to 10 mg. per Kg.) produce transitory stimulation, followed by marked and lasting decrease of response to electric stimulation (Barone, 1932). Intravenous injection of 0.25 to 2 mg. of mecholyl into dogs, 0.12 to 0.2 mg. in rabbits, causes auricular fibrillation or auriculoventricular block; also after section of the vagi (Iglauer *et al.*, 1941). The cardiac inhibition occurs in the *embryonic heart* only after the inhibitory nerve fibers have connected with the muscle (Armstrong, 1935), and does not occur even after physostigmine in the adult ventricle of fish, turtles and mammals, which is not directly innervated by the vagus (Garrey and Chastain, 1937). In the frog, segments from the different levels are inhibited about equally, so that all levels receive vagus innervation (Garrey and Bass, 1934). The site of the inhibitory action of acetylcholine appears to be on the *cell surface*, for its action on the frog heart is antagonized by *methylene blue*, which has been shown to act on the surface of the cells (R. P. Cook, 1926); and its action in the perfused frog ventricle is completed in a few seconds and can be removed by washing in a short time; nor is there any evidence of its accumulation by storage within the cells. The action is diminished by increase of Ca, K or OH in the Ringer fluid (A. J. Clark, 1927). The *oxygen consumption* is decreased by acetylcholine, even in the previously arrested frog and turtle heart (A. J. Clark, 1935). In dogs, also, small doses of acetylcholine decrease the oxygen consumption of the heart disproportionate to the reduction of the output (Gremels, 1936).

Other Cardiac Actions of Acetylcholine.—Vagus inhibition is ordinarily dominant; when this is prevented by atropine, the perfused heart of frogs (Barlow, 1928) and mammals shows stimulation of the sympathetic accelerator mechanism, which is abolished by ergotamine (R. J. S. McDowall, 1946). The perfusate relaxes rabbit intestine, indicating that acetylcholine liberates epinephrine in the heart (F. Hoffman *et al.*, 1945). Acetylcholine and atropine are mutual antagonists within a limited range, but higher concentrations of both give additive depression. Epinephrine in low concentrations counteracts the depression, but higher concentrations are also additive (Barlow, 1928). Continued *daily injections* of large doses of acetylcholine in rabbits lead to *focal necrosis of the myocardium* analogous to the degenerations in other organs (Henlein, 1939).

Anaphylactic Relations.—The guinea pig heart during anaphylactic shock liberates a cholinergic substance which inhibits the frog heart, probably in consequence of vagus stimulation. It is antagonized by atropine; but as it is not active on leech preparations, it is not acetylcholine (Went and Lissák, 1936). Sensitization of guinea pigs by protein injection causes their heart to respond to much greater dilutions of choline. This returns to normal with desensitization (Lissák and Went, 1936).

Cholines in Cardiac Therapy.—Vagus stimulation by choline was used by Boden and Wankell, 1928, with good results against paroxysmal tachycardia; to retard auricular flutter; in occasional dissociation of auricles and ventricles; and sometimes in auricular fibrillation. *Methacholine* (*mecholyl*) was introduced for the same field by Starr, 1933. In selected cases of paroxysmal tachycardia, which may have resisted other medication, the hypodermic injection of 30 mg. of mecholyl restores the normal rhythm, after a brief period of irregularity. For prophylaxis it is generally less efficient than quinidine. It is generally ineffective with other forms of tachycardia and with auricular fibrillation.

It is advisable to begin with small doses, 10 mg. of mecholyl hydrochloride hypodermically, increasing cautiously to 25 mg.; or 0.2 to 0.5 Gm. by mouth; both two or three times daily. Intravenous injection is dangerous and should not be used. If the effects are excessive, atropine may be administered (report, Council on Pharmacy and Chemistry, 1941, J.A.M.A., 117:*193*, 860; P. W. Morgan, 1943). Mecholyl is contraindicated in patients with bronchial asthma, coronary sclerosis, or with any severe illness.

Mecholyl may convert the auricular flutter into auricular fibrillation and thus slow the rate. The production of auricular fibrillation has been observed in several thyroid patients with previosuly normal hearts. It was of short duration (Nahum and Hoff, 1935). In patients in whom 0.1 mg. of *epinephrine*, intravenously, produced ventricular rhythms from numerous foci, this was prevented by the usual dosage of mecholyl (Nathanson, 1935). Hypodermic injection of 25 mg. of mecholyl into cats prevented ventricular fibrillation and death from electrocution which was fatal to control animals (Hoff and Nahum, 1935). Intracardiac injection of acetylcholine generally arrests electrically induced fibrillation of excised and perfused mammalian heart (R. Frölicher, 1945).

Blood Pressure Response to Choline and Its Esters.—The normal response is a considerable fall, due chiefly to a peripheral (parasympathetic) vasodilator action. In normal persons, 2.5 mg. of mecholyl hypodermically have little if any effect on blood pressure; in nearly all *hypertensive patients* this causes moderate to marked fall, generally with increase of pulse rate proportional to the fall of pressure (D. E. Engle and Binger, 1939). *In atropinized animals*, choline and acetylcholine produce a rise of pressure, a "nicotinic" action involving increased output of epinephrine; and probably stimulation of the vasomotor ganglia with larger doses. These nicotinic effects are slight with mecholyl.

Therapeutic applications of the vasodilator action have been tried against hypertension and in Raynaud's disease, without much success. H. Goldblatt, Kahn and Lewis, 1942, found it ineffective against experimental renal hypertension. It has been employed against vascular spasm from exposure to cold (0.05 to 0.1 Gm. by mouth). In obliterative arteriosclerosis, carbachol improved the rest-pain, but none of the other features (Saland *et al.*, 1945). In arthritis, mecholyl is carried to the joint by local *ion transfer*, moistening the positive pole with 0.2 to 0.5 per cent aqueous solution; but this has caused toxic systemic reactions, since the dosage is difficult to control. It is more useful in treating ulcers. The blood flow through the hand may be increased to more than five times the normal (H. Montgomery *et al.*, 1938). *Intra-arterial injection* of acetylcholine, 0.01 to 10 mg., or of mecholyl, 0.0001 to 3 mg., into the brachial artery of man produces marked vasodilatation of the arm and hand, without systemic effects (Myerson, Loman *et al.*, 1938). Cragg, 1936, reported encouraging results in tobacco amblyopia (more rapid improvement of vision) from the daily intramuscular injection of 15 mg. of acetylcholine. *Exophthalmos* may result mechanically from distention of the blood vessels of the orbit (C. E. Brunton, 1940).

Variability of Response.—Choline generally lowers blood pressure (Mott and Halliburton, 1897), but sometimes there is, instead, a rise of pressure. In cats, the rise generally follows the fall (Pal, 1911). The variable response does not depend upon impurities (Renshaw, Underhill and Mendel, 1912). The result is influenced by the dose, anesthetic, and other conditions (Abderhalden and Mueller, 1911). The fall predominates if the blood pressure has been high (Benelli, 1914); in protracted ether narcosis, and after some sorts of curare. It counteracts the epinephrine rise (Gautrelet, 1909). The *pressor effect* is more prominent in light anesthesia or after section of the medulla (Pal, 1911).

Mechanism of the Blood Pressure Fall.—Peripheral vasodilatation is the most important factor (Hunt, 1918). With acetylcholine there is intense dilatation of the vessels of most organs, including the skin; relatively feeble in the splanchnic area in comparison with the nitrite fall; doubtful in the kidneys; absent in the lungs. Larger doses are constrictor. This dilator effect is more powerful than that produced by any other method. It is diminished or prevented by atropine, but synergized by physostigmine. It does not involve any of the known vasodilator paths, sympathetic or parasympathetic, or the posterior roots. It is different both from epinephrine and nitrite dilatation, which are not antagonized by atropine (Dale and Richards, 1918).

Large doses of acetylcholine produce pulmonary edema and occasionally splenic edema, similarly to anaphylactic shock (R. Altschul and Laskin, 1946).

The *rise of blood pressure*, which occurs when the dilator receptive mechanism has been paralyzed by large doses of atropine, is due to increased output of epinephrine, exclusively so with small doses (Feldberg and Mintz, 1931); larger doses appear to stimulate the arterial muscle directly, for they raise the pressure after excision of the adrenal gland, and they constrict the vessels of atropinized excised or perfused organs (R. Hamet, 1934).

Special Vascular Beds.—The coronary blood flow is reported as first increased, then diminished, in rabbits, dogs and cats, by acetylcholine and mecholyl (Wedd, 1926). In the arrested dog heart, acetylcholine produced coronary dilatation (Katz and Londner, 1939). In the perfused cat heart, the coronary flow is diminished (Orczechowski, 1933). The *pulmonary arterioles* are slightly dilated by acetylcholine (Daley and von Euler, 1932, perfusion, dogs), the bronchiolar vessels are constricted (A. S. Dale and Narayana, 1935). Microscopic sections of pulmonary arteries are constricted by mecholyl (Gilbert, 1938). The *cerebral vessels* are dilated by acetylcholine, with rise of cerebrospinal pressure. The *portal vessels* are constricted by large doses of acetylcholine and unaffected by smaller ones (McMichael, 1933, cats). The *carotid artery* of rabbits is relaxed by mecholyl (Sollmann and Gilbert, 1937). The *spleen* is contracted by acetylcholine, clinically as well as in animals. This is prevented by atropine (Bouyoucos, 1932; Gotsev, 1936). The *lymph flow from the thoracic duct* is briefly increased by acetylcholine (Beznak, 1937). *Thio-esters of choline* produce rise of blood pressure, not abolished by atropine. The rise stimulates the carotid sinus to bradycardia and hyperpnea. The action is brief (W. F. Alexander *et al.*, 1938).

Gastro-Intestinal Tract.—Choline and its esters produce parasympathetic stimulation of the tonus and peristalsis of the stomach and intestines, similar to pilocarpine and physostigmine, but generally milder. They increase the secretions innervated by the parasympathetic, especially the saliva and the gastric acidity. Their therapeutic usefulness is questionable.

Submaxillary secretion is increased by acetylcholine even when the intravascular pressure is kept constant (by perfusion, in dogs). The action is therefore direct. The increase of acid secretion is much greater with fractional doses; a single large dose causes scanty secretion of low acidity; the pepsin concentration is high in both. The effects on pyloric and fundal pouches are described by G. W. Stavraky, 1943. Mecholyl is prevented by atropine. Small doses of pilocarpine increase the response, large doses are antagonistic. Acetylcholine is not effective if the gland has been exhausted by previous stimulation of the chorda tympani (Anochin, 1929).

Clinical Effects of Mecholyl on Digestive Tract.—In normal men, this increases the *gastric acidity*, but less than histamine, and with more systemic disturbance. It increases the *gastric motility* if the stomach is filled, but arrests the hunger contractions of the empty stomach. It increases peristalsis of the *small intestine*, but not constantly in the colon. It has been tried in *postoperative abdominal distention*, sometimes with symptomatic relief (W. O. Abbott), but its value is questionable. Patients with *atonic colon* are reported to respond to the hypodermic injection of 30 mg. of mecholyl with one or two imperative evacuations, within thirty minutes, and three or four within twenty-four hours (Myerson, Schube and Ritvo, 1937).

Acetylcholine on Gastric Acid Secretion.—Single intramuscular injections of 0.3 to 0.4 Gm. have little effect, but repeated doses give a moderate increase. Some hypochlorhydria patients, and rarely those with achlorhydria, were restored to normal acidity by a series of injections (Faroy and Deron, 1931). Necheles *et al.*, 1938, report increase of gastric secretion, volume, acidity and pepsin, in man and dogs. L. S. Goodman, 1938, reports that this is especially marked with another ester, "Doryl." Mecholyl and pilocarpine inhibit the secretion of acid. This occurs with smaller doses if the drugs are injected into the lateral ventricles of the brain. Atropine antagonizes the anacidity (Ferguson and Smith, 1935).

Choline on Peristalsis.—X-ray observations on cats after slow intravenous injection of 5 to 10 mg. per Kg. show that the increased peristalsis is of the normal type and not spasmodic. The stimulation persists for hours. The large intestines are relatively little affected (Le Heux, 1921). The contractions are antagonized by epinephrine as well as by atropine (Bernheim, 1933). Choline injection was found to remove the gastro-intestinal paralysis produced by prolonged chloroform anesthesia (von Kuhlewein, 1921), or by peritonitis through laparotomy and handling, or through the intraperitoneal injection of iodine (Arai, 1922). Adequate observations on animals other than cats are lacking. Magnus, 1925, proposed for *clinical use*, the intravenous injection of choline, 0.6 mg. per Kg. per minute, for seventeen minutes. However, the formation of decomposition products may greatly increase the toxicity, so that caution would be necessary. Properly prepared ampuls do not deteriorate. Weiland, 1912, showed that saline solutions in which intestines have been immersed extract a stimulant substance from the serous coat. Le Heux, 1918, identified this as choline and showed that its removal from the intestines decreased their excitability and their response to atropine. He assumed that choline serves as a normal "*peristaltic hormone;*" and that the cathartic action of the salts of organic acids is due to the synthesis of powerful choline esters (1921). *The gallbladder* is stimulated to contraction by mecholyl (J. Flexner *et al.*, 1938).

Sweat.—Mecholyl provokes profuse alkaline perspiration, which is arrested by atropine, increased by pilocarpine and by neostigmine, not materially affected by epinephrine. The action is peripheral (Myerson *et al.*, 1937). Acetylcholine, 1:1000, intradermally, causes local sweating, less in women than in men. This is weakened or abolished by sympathectomy (D. Kahn and Rothman, 1942).

Bronchioles.—Acetylcholine causes marked contraction in perfused lungs (A. S. Dale and Narayana, 1935), and mecholyl does so in lung sections (Sollmann and Gilbert, 1937). In intact and atropinized animals, acetylcholine dilates the bronchioles by mobilizing epinephrine from the adrenal glands (Melville, 1938).

Respiration.—Acetylcholine produces successively stimulation, inhibition and again stimulation. The stimulation is due to stimulation of the carotid sinus; the inhibition is exerted directly on the respiratory center (A. Schweitzer and Wright, 1938). Direct application to the fourth ventricle increases respiration, and physostigmine sensitizes to this action (Worzniak and Gesell, 1938).

Uterus.—Choline and its esters produce contractions (Starr, 1933).

Urinary Bladder.—Choline and acetylcholine cause prolonged tonus which is antagonized by epinephrine and by atropine. Good results have been reported in postoperative bladder atony (Marsalek, 1933).

Skeletal Muscle.—In *frogs*, dilute solutions (1:100,000) of acetylcholine decrease the height of contraction and prolong the relaxation, similarly to fatigue (W. R. Hess and Rehsteiner, 1926). Higher concentrations produce a contracture, which is antagonized by atropine, not by curare (Riesser and Neuschloss, 1921). It is not accompanied by increase of lactic acid, as are the contractures of quinine, ammonia or potassium (Zondek and Matakas, 1927). Acetylcholine contracture of toad muscle liberates potassium into K-free Ringer perfusion fluid (Cicardo and Moglia, 1940). *In mammalian muscle*, especially the diaphragm and ocular muscles, acetylcholine produces prompt and brief contraction, more marked after degeneration of the motor nerve (Heidenhain). The contracture is not due to parasympathetic stimulation and is not affected by atropine, but is abolished by curare more readily than is the response to nerve stimulation (G. L. Brown, Dale and Feldberg, 1936; Simonart and Simonart, 1935). Vertebrate skeletal muscle, leech muscle and the body wall muscle of earthworms and other annelids are relatively insensitive to acetylcholine alone, but the response is greatly potentiated by *physostigmine* and nicotine. Mammalian intestinal muscle is much more sensitive to acetylcholine and not greatly potentiated by physostigmine (K. S. Wu, 1939). Choline and acetylcholine have no effect on peripheral *nerve fibers*, even in 0.1 mg. concentration (Lorente de No, 1944).

Acetylcholine Content of Skeletal Muscle.—A substance with the actions of acetylcholine has been demonstrated in muscle extracts. Its amount is notably greater in muscles that normally have a "tonic" function and are normally more susceptible to acetylcholine tonus; for instance, the clasping muscles of the forearms of male frogs, and the extrinsic eye muscles in mammals. Decerebrate rigidity does not increase the acetylcholine content of muscles (F. Plattner, 1932). Choline esterase is 10,000 times more concentrated about the motor endings than in the nerve-free portions of toads' sartorius muscle (Feng and Ting, 1938).

The cerebral motor cortex is stimulated by direct application of 5 to 10 per cent acetylcholine solution, producing epileptic convulsions in dogs (Moustaché and Dias, 1941), and electric potential changes resembling grand mal seizures. These are sensitized by prostigmine, $\frac{1}{20}$ to 1 per cent, and abolished by dilantin (Merritt and Brenner, 1941). Central effects of acetylcholine, atropine and physostigmine have been studied with arterial injection into decerebrate cats, by Calma and Wright, 1944. Cats that have recovered from partial brain removal respond to intravenous acetylcholine by asymmetrical stimulations contralateral to the lesion. This is interpreted as sensitization of the residual parts of the neurones (G. W. Stavraky, 1943). Analogous phenomena result from intramuscular injection of mecholyl in human patients with central lesions (S. M. Fisher and Stavraky, 1944).

Nutritional Functions of Choline.—Choline is a growth factor concerned especially with the transport and deposition of fat and more indirectly with carbohydrate metabolism It is probably used in the formation of choline-phospholipids; it is a source of methyl in the synthesis of other metabolites, interrelated with methionine, homocysteine, betaine and creatine (reviews, W. H. Griffith, 1941; C. H. Best, 1941; McHenry and Patterson, 1944). This *lipotropic effect* is probably produced by stimulation of the phospholipid interchange between the liver and other tissues. Administration of choline to white rats and to depancreatized dogs rapidly lowers the *fat content of the livers*, even with diets rich in fat. It inhibits the deposition of fat into liver of rats poisoned by *phosphorus*, and hastens the removal of fat in the recovery period. It is effective in preventing the fatty liver changes of carbon tetrachloride poisoning of rats (H. M. Barrett, Best and Maclean, 1939), which deuterium tracer studies have shown to be due to withdrawal of fat from other tissue depots. Choline protects against phlorhizin fatty liver, but is not very effective against the fatty liver of *starvation*, which is also due to mobilization of tissue fat. Choline administration prevents the deposition of neutral fat, and to a less extent of cholesterol in the liver of animals fed with pure cholesterol. It protects against fatty liver from *thiamine*. It is partly effective against cholesterol, practically ineffective against *biotin*. *Lipocaic* is ineffective against cholesterol, effective against biotin; *inositol* is ineffective against thiamine, effective against cholesterol and biotin (Gavin, Patterson, and McHenry, 1943).

Conversely, *diets low in choline* result in the deposition of a large amount of neutral fats and a small increase of cholesterol esters in the liver (C. H. Best *et al.*, 1932, 1935, 1936). It may be induced in dogs, and prevented by supplementing the deficient diet with choline or dl-methionine (McKibbin *et al.*, 1944). Deuterium tracer studies on rats and mice show that the accumulation of fat in the liver is due to impaired transportation of fatty acids from the liver to the depots. Cystine and thiamine administration increase fatty acid synthesis (Stetten and Salcedo, 1944). Choline-deficient diet induces a unique *hepatic cirrhosis* in rats, especially if the protein income is low and cystine is added (Lowry, Daft *et al.*, 1941). This cirrhosis is different from any seen in man (R. D. Lillie, Ashburn *et al.*, 1942).

The lipotropic action of choline is probably due to its transformation into phospholipids of the lecithin type, which are a link in the transport of fat. This requires a *molecular structure* of the general configuration of choline and not merely the labile methyl group, but permits certain substitutions, tabulated by McHenry and Patterson, 1944, page 152. Arsenocholine also has marked lipotropic action (A. D. Welch and Landau, 1942). *Methionine* is lipotropic indirectly by supplying *labile methyl* group, for the synthesis of choline and creatine. Choline in turn may be used for the methylation of homocystine to methionine (Du Vigneau, Cohn *et al.*, 1941).

Dietary deficiency of choline or other substances with labile methyl groups produces in young rats, hemorrhagic degeneration of the kidney (W. H. Griffith and Wade, 1939), starting with congestion of the glomerular capillaries, followed by necrosis and calcifications of the cortical tubules (K. Christensen, 1942). *Other visceral changes* of choline deficiency include involution of the thymus; transformation of the lymph nodes in hemonodes; in severe cases, intra-ocular hemorrhage (Griffith and Mulford, 1941); perosis and growth failure in chicks and turkeys (Jukes and Welch, 1942). Addition of choline, methionine or homocystine to the diet of young rats counteracts the inhibition of growth from pyridine, detoxicating this by methylation (Stekol and Conway, 1941). More choline is required in diets rich in protein, especially cystine (Griffith and Wade, 1939).

On the other hand, *excessive administration of acetylcholine* also results gradually in focal necrosis of the myocardium, lungs and kidneys ascribed to ischemia from arteriolar spasm and elastic hyperplasia of the intima (Henlein, 1939).

Continued oral or hypodermic administration of large doses of choline or its esters for several months produces hyperchromic anemia, and multiple hemorrhages and neurone changes in the gray substance of the central nervous system. Administration of folic acid or of liver extract produces remission, with reticulocyte response, even if the choline is continued. Both remedial agents increase serum choline esterase (also in pernicious anemia). This may be a factor in their therapeutic action (J. E. Davis, 1946; Davis and Fletcher, 1946).

Choline administration retards the *deposition of cholesterol* in the liver (Hirnsworth, 1938). It does not, however, promote the regression of *atherosclerosis* induced by feeding cholesterol (A. Steiner, 1938). In *polycythemia*, induced in dogs by exposure to rarefied air, oral administration of choline tends to depress hematopoiesis and to return the cell count to normal (J. E. Davis, 1939). Long-continued excessive feeding of choline chloride produces hyperchromic anemia, amenable to liver extract or dried stomach (J. E. Davis, 1944), but the same dosage failed to have this effect in man (Cartwright and Wintrobe, 1945). In rats it lowers the growth rate (H. C. Hodge, 1945). It produces hyperchromic anemia in dogs (J. E. Davis, 1946). *Thermic shivering* of cooled dogs is temporarily suppressed by injecting acetylcholine, even after atropine (Tournade *et al.*, 1939). The *oxygen uptake* of fresh slices of liver or kidney of rats is increased by choline (Trowell, 1935). Werner and Lichtenberg, 1906, claim that choline injections in rabbits produce sterility or lessened *fertility* analogous to the effects of x-ray or thorium X. Werner and Asher, 1912, found similar blood and skin changes. Prolonged administration of acetylcholine is reported to cause *cancer* in mice, rats, dogs, guinea pigs and fowl (G. E. Hall and Franks, 1938).
